Attenuators These are devices used to attenuate the optical power, for example, in front of a receiver when the optical line is short and the power of the received signal is still too high for the detector, or when it is necessary to equalize the signals arriving from different optical lines. It exists both in tunable and fixed versions. The first ones allow adjustment of the attenuation value, however, the second ones have a fixed and predefined value. The fixed optical attenuators can be obtained by inserting a filter or stressing a fiber in a controlled and permanent way. The tunable attenuators are based on variable optical parameters as, for example, the distance or the lateral offset in an optical connection. They exist both as connect lengths of fiber (attenuated optical jumpers) or as compact components similar to a double connector (plug stile attenuator).

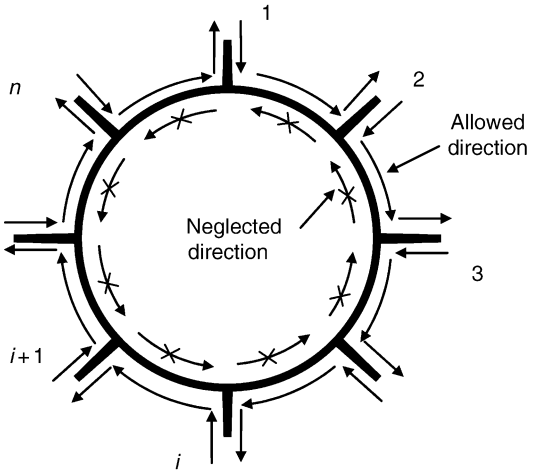

Figure 16 Principle scheme of an optical circulator.

Filters These are components with two ports employed to select or to filter some fixed wavelengths. They can be divided into the following categories:

- short-wave pass (only wavelengths lower than or equal to a specified value are passed);
- long-wave pass (only wavelengths greater than or equal to a specified value are passed);
- band-pass (only an optical window is allowed); and
- notch (only an optical window is inhibited).

It is also possible to have a combination of the above categories. The optical filtering can be obtained by inserting one or more filtering devices (as interferential films) into a fiber or creating a filter directly on the fiber by the FBG described above.

Isolators These are nonreciprocal two-port optical device in which the light flows in the forward direction, and not in the reverse one. The isolators are used to suppress

backward reflections along an optical fiber transmission line, while having minimum insertion loss in the forward direction. Fiber optic isolators are commonly used to avoid back reflections into laser diodes and optical amplifiers, which can make the laser and amplifiers oscillate unstably, and cause noise in the fiber optic transmission system.

Circulators These are passive components having three or more ports numbered sequentially $(1, 2, \ldots, n)$ through which optical power is transmitted nonreciprocally from port 1 to port 2,..., from port (i) to port $(i+1), \ldots$ and from port n to port 1 (Figure 16).

FIBER GRATINGS

Fiber gratings are periodic index variations inscribed into the core of an optical fiber, and are important devices for manipulating fiber guided light. Since their first fabrication in the late 1970s, fiber grating use and manufacture has increased significantly and they are now employed commercially as optical filters, reflectors and taps in telecommunications systems, and as strain and temperature sensors in various industries. We review optical fibers and the fundamentals of fiber grating characteristics as well as fabrication. Finally we consider several of the major industrial and scientific applications of fiber gratings.

Fiber Modes

A fiber grating couples light between the modes of an optical fiber, and therefore a knowledge of these modes is essential to understanding the characteristics of fiber gratings. In what follows, we emphasize single-mode fibers used near 1550 nm because these are very important in most practical applications that

use fiber gratings. A single-mode fiber can be viewed as a thin cylinder of silica with a central raised index region of small enough diameter so that only a single mode is guided through total internal reflection at the core boundary. The electric field (*E*-field) of the fundamental mode propagating in the core is described by a characteristic transverse *E*-field profile and a propagation constant k:

$$E = E(r, \varphi)\mathrm{e}^{-\mathrm{i}(\omega t - kz)} \qquad k = 2\pi n_{\mathrm{eff}}/\lambda \qquad [1]$$

Here r and φ are the radial and azimuthal directions, z is measured longitudinally along the fiber, ω is the radial frequency, and λ is the vacuum wavelength, and the *E*-field points in the same direction everywhere. As the second equation indicates, the fiber mode propagates in the fiber as though it has an effective refractive index n_{eff}.

The silica cladding acts to isolate the core mode from the outside, hence the core mode penetrates very little into the cladding. However, if the outer cladding surface allows total internal reflection, the cladding may also guide light. Such 'cladding modes' are also important in understanding fiber gratings, since the grating couples the core mode with the cladding modes. As shown in Figure 1, the cladding modes extend outside the core into the cladding region, and their effective index is therefore always less than that of the core mode. We also note that in the case when the outer coating of the fiber does not support total internal reflection, 'leaky' cladding modes result. In the limit that there is no reflection at the cladding boundary a continuum of 'radiation modes' results. Although these modes are not guided, they are exploited in a variety of applications and can be carefully tailored by a suitably designed fiber grating. Note that the radiation and cladding modes exist regardless of the presence of a grating; a grating simply couples power from the core mode to the cladding/radiation modes; the grating is typically only a small perturbation on the index profile of the waveguide and the corresponding mode fields.

Fiber Grating Theory

Fiber gratings are longitudinal periodic variations in the refractive index (or, more generally, the dielectric function) of the core and/or cladding of an optical fiber. The scattering from any grating may be understood simply by considering the scattering off each successive period and adding these contributions while taking the phase of the *E*-field into account. Figure 2 illustrates this analysis in the case of a fiber Bragg reflector. When the reflections from each period of the grating add constructively, a strong back-reflection results. This is known as Bragg reflection. The condition for Bragg reflection is given by:

$$\lambda_{\mathrm{Bragg}} 2n_{\mathrm{eff}} = \Lambda_{\mathrm{grating}} \qquad [2]$$

Here λ_{Bragg} is the vacuum wavelength of the light (equivalent to its frequency, $\omega = 2\pi c/\lambda$), n_{eff} is the effective index of the mode, and $\Lambda_{\mathrm{grating}}$ is the period of the grating refractive index modulations. This Bragg reflection is evident in a narrow dip in the

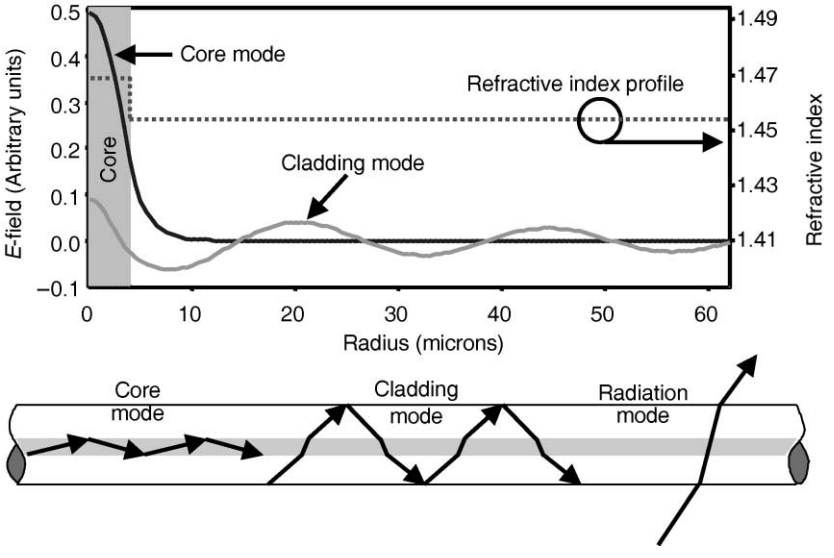

Figure 1 Fiber modes. Refractive index profile of a step index, single-mode fiber (dashed line). Radial profiles of mode *E*-fields of the fundamental (LP01) core mode, guided within the raised index region defined by the core, and one of the many higher-order cladding modes guided by the outer, air–silica interface. Also shown is a fiber indicating the ray paths for core, cladding, and radiation modes.

transmission spectrum of the grating (see Figure 3a). The ability of a fiber grating to selectively reflect the core light at one wavelength is one of its most important practical properties since it can be used as a narrowband filter or reflector. As a fiber component, the fiber grating has the advantage of compactness and provides in-line wavelength filtering.

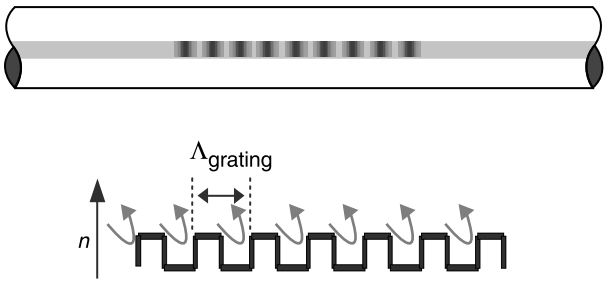

Figure 2 Bragg reflection. Each period of the grating reflects a small fraction of the incident light. When the period of the grating is adjusted so that these reflections add coherently, a strong Bragg reflection results and a narrow dip is observed in the transmission spectrum of the fiber (see Figure 3a). As shown in Figures 3 and 4, Bragg reflection can also occur into cladding modes.

The condition for Bragg reflection may be expressed more generally as a phase-matching condition. Phase matching refers to the condition when the phases of all the grating-scattered waves are the same and there is constructive interference. More specifically, this condition expresses the relationship between the spatial frequencies of the incident light, the scattered light, and the grating modulation, necessary for constructive interference in the scattered light. For a grating, the phase matching condition may be expressed in terms of the grating wavevector, $K_{grating} = 2\pi/\Lambda_{grating}$ and of the two mode propagation constants, $k_{incident}$ and $k_{scattered}$ (defined in eqn [1])

$$k_{incident} - K_{grating} = k_{scattered} \qquad [3]$$

Using phase matching, we can understand the various transmission spectra that result from fiber

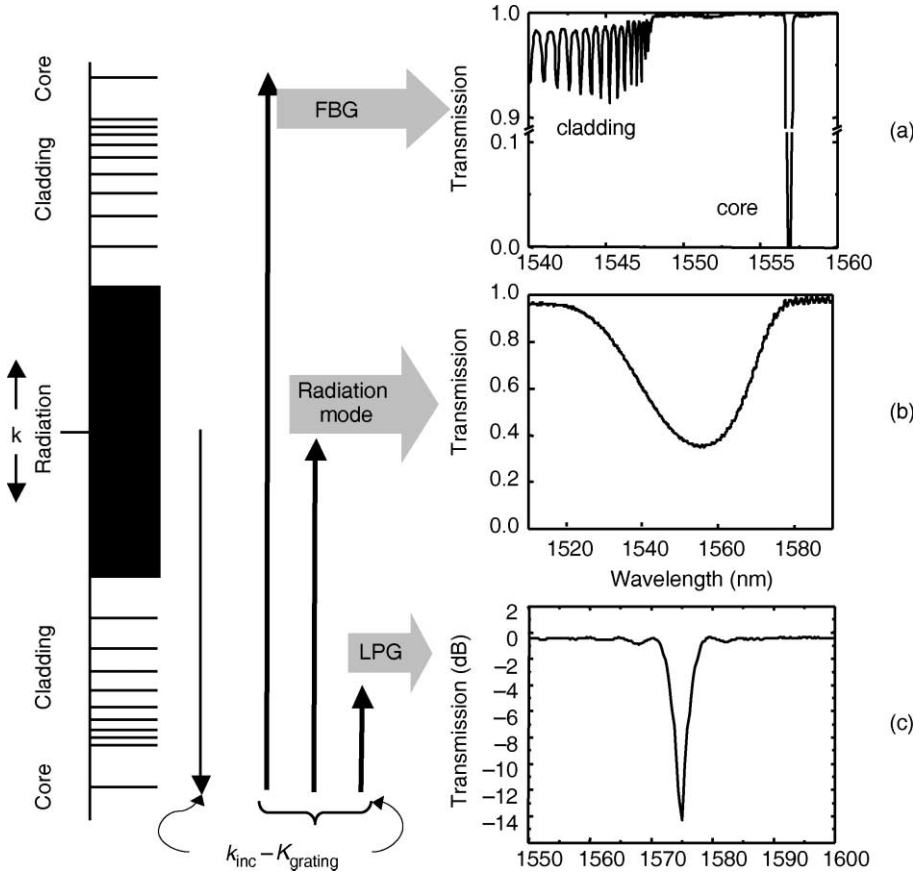

Figure 3 Phase matching. Fiber grating resonances occur when the phase matching condition is satisfied: $k_{inc} - K_{grating} = k_{scat}$. Propagation constants ($k = 2\pi n_{eff}/\lambda$) of the fiber modes are indicated as hash marks on the vertical line. The region indicates the regime of unguided radiation modes. The fiber grating is represented by its longitudinal spatial frequency (wavevector) $K_{grating} = 2\pi/\Lambda_{grating}$, where $\Lambda_{grating}$ is the period of the grating. Assuming an incident forward-going core mode, the grating wavevector then phase matches to (a) counter-propagating core and cladding modes (fiber Bragg grating, FBG), (b) continuum of radiation modes, or (c) a copropagating cladding mode (long-period grating, LPG).

gratings. Figure 3 shows the transmission characteristic observed for core guided light in a single-mode fiber containing three different types of gratings: Bragg reflector, radiation mode coupler, and copropagating mode coupler. Each grating has a different type of phase matching condition. Figure 3 also depicts the phase matching condition in eqn [3] graphically. The vertical line contains a mark representing the propagation constants, k, of modes of a single mode fiber (both positive and negative for the two propagation directions) and a solid black region representing the radiation mode continuum. Bragg reflection into backward-propagating core and cladding modes occurs for short grating periods ($K_{\text{grating}} \sim 2k_{\text{core}}$). Such gratings are known as fiber Bragg gratings (FBGs) and a typical transmission spectrum with a strong Bragg reflection and several cladding mode resonances is shown in Figure 3a (a typical Bragg reflection spectrum is shown in Figure 8 below; the FBG grating period was ~500 nm). Core-cladding mode reflection results in loss resonances for wavelengths shorter than the core–core Bragg reflection. When the grating period is very long (in general, $K_{\text{grating}} < k_{\text{core}}(n_{\text{cladding}} - 1)/n_{\text{cladding}}$; typically Λ_{grating} is ~1000 times that of an FBG), phase matching to copropagating cladding modes occurs. Such gratings are known as long-period gratings (LPGs). A typical LPG spectrum is shown in Figure 3c. The LPG resonance corresponds to coupling between the core mode and a single copropagating cladding mode. For wavevectors in between these two regimes, coupling to the continuum of radiation modes is possible. An example of such a grating spectrum is shown in Figure 3b. We note that fiber cladding modes can be either well guided (resulting in the sharp grating resonances of Figure 3a) or poorly guided (resulting in a broad continuum of Figure 3b) depending on the fiber surface. The radiation mode approximation is valid in the limit that the cladding mode is very poorly guided (i.e., has high loss) within the grating region.

While phase matching yields the resonance wavelengths of a fiber grating, the strengths of these resonances must be derived from a full solution of Maxwell's equations. The most common approximation used in these calculations is known as coupled mode theory (CMT). In CMT, the longitudinal refractive index variation is assumed to be a small perturbation to the waveguide modes, which results only in a change in the propagation constant of the modes but does not change the transverse dependence of the mode E-fields (see eqn [1]). CMT then assumes that the E-field amplitude of each mode varies slowly (compared to wavelength) along the grating. A pair of coupled equations relating the two mode amplitudes as a function of position along the grating can then be derived, and these allow for computation of the grating reflection and transmission. The coupling between two modes is determined by an overlap integral κ_{12} between the product of the E-fields of the two modes (E_1 and E_2) and the periodic refractive index variation:

$$\kappa_{12} \propto \int\int_{\text{Area}} E_1(r,\phi)E_2(r,\phi)\delta n(r,\phi)\,\mathrm{d}A \qquad [4]$$

where $\delta n(r,\phi)$ is derived from the refractive index modulation:

$$\delta n(r,\phi,z) = \delta n(r,\phi)\cos(K_{\text{grating}}z) \qquad [5]$$

This overlap integral is useful because it allows for a rough comparison of the strength of resonances for different modes without the need to obtain a full CMT solution. In the simple case of Bragg reflection of the core mode in a standard single-mode fiber (see Figure 1):

$$\kappa = \frac{\pi\delta n\eta}{\lambda}, \qquad [6]$$

where $\eta \approx 0.8$ is the overlap integral of the core mode intensity with the core.

To understand fiber grating spectra we first discuss a 'uniform' Bragg grating, of length L. Such a grating has uniform index modulation along its length and is shown in Figure 4a. Depending on the length and refractive index modulation of the grating, it may be classified as either weak or strong. The division between these two regimes may be understood by considering the light scattered by each successive period of the grating. The fraction of light scattered from each period can be approximated by $\delta n/2n$ using the Snell's law reflectance formula. The boundary between a strong and a weak grating occurs when the grating is either long enough or strong enough that the sum of the scattering from all periods is of order 1. This division may also be expressed in terms of κ and L: $\kappa L \sim 1$.

In the weak limit, the incident light propagates through the grating with very little scattering. In this case, both the LPG and FBG resonances have transmission spectra that are approximately related to the Fourier transform of the grating index profile. (For LPGs, this may not hold if modal dispersion is large; see the discussion below.) In the case of a uniform grating profile, this results in a $1 - \text{sinc}^2$ wavelength dependence of the transmission spectrum and a spectral width $\delta\lambda/\lambda \sim \Lambda_{\text{grating}}/L = 1/N_{\text{periods}}$ as shown in Figure 4a. An important feature of the uniform grating is the side lobes. The side lobes result from the sudden 'turn on' of the grating. In the FBG,

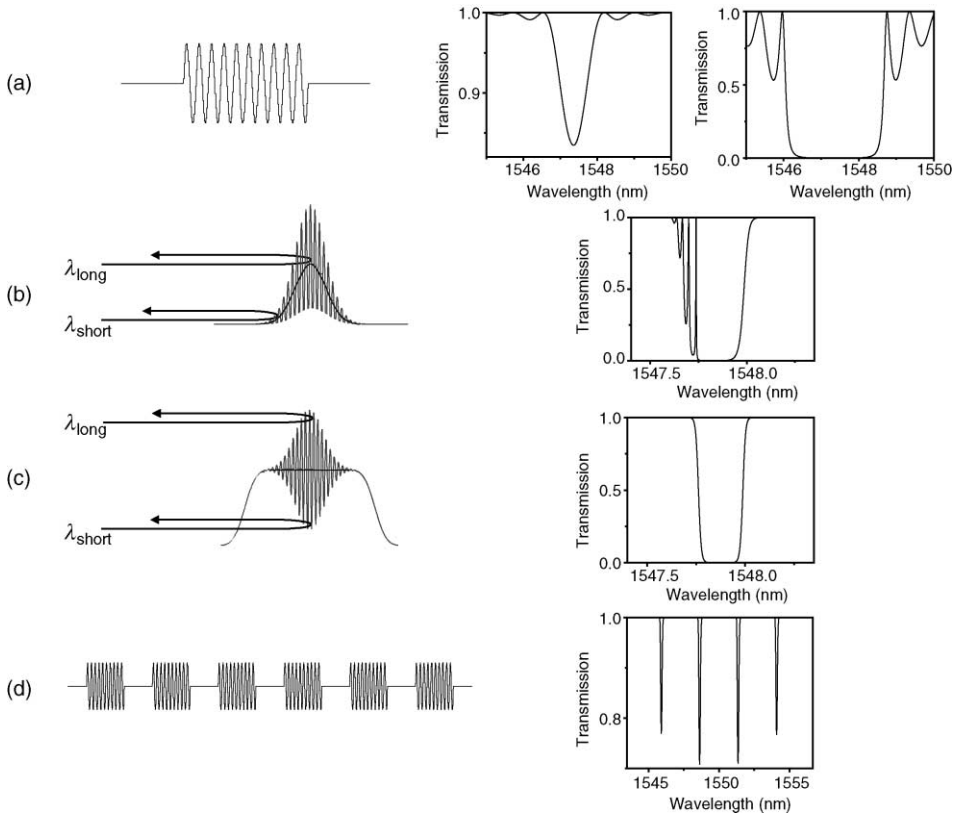

Figure 4 Fiber Bragg grating refractive index profiles and spectra. (a) A uniform profile with transmission spectra for both strong and weak index modulations. (b) An 'unapodized' Gaussian grating profile showing Fabry–Perot-like structure within the grating resonance. (c) A '100% dc apodized' Gaussian grating profile showing a symmetric transmission spectrum. (d) A superstructure grating exhibiting four resonance peaks.

they can be understood as resonances of the effective Fabry–Perot cavity defined by the sharp grating boundaries.

In the strong limit, a substantial fraction of light is scattered out of the incident mode, and the FBG and LPG transmission spectra become different. As shown in Figure 4a, the FBG spectrum widens to a width determined only by δn: $\delta\lambda/\lambda = \delta n/n$. The incident light penetrates only a short distance ($\sim \lambda/\delta n$) into the grating before being completely reflected. The strong LPG, on the other hand, becomes 'overcoupled' as the second mode is reconverted into the incident mode. The result is a higher transmission for the incident core mode (provided that the scattered mode propagates without loss).

While uniform gratings are easy to model and manufacture, most practical fiber gratings have a nonuniform profile. In a nonuniform grating profile, both the refractive index modulation amplitude, $\delta n_{AC}(z)$, and the average effective index value, $\delta n_{DC}(z)$, may vary along the fiber grating length:

$$\delta n(z) = \delta n_{DC}(z) + \delta n_{AC}(z)\cos(K_{grating}z) \qquad [7]$$

By controlling the ac and dc index change, a greatly improved filter may be fabricated. Figure 4b shows the index profile and the grating transmission spectrum of a fiber Bragg grating with an 'unapodized' Gaussian profile. Note that due to the smooth increase in modulation amplitude, the sidebands of the uniform grating have been eliminated. However, because the dc index (and hence Bragg condition) is not constant within the grating, sharp resonant structure is observed within the grating resonance. This structure can be understood as Fabry–Perot resonances in the cavity formed by the nonuniform Bragg condition within the grating. Figure 4c shows a grating with a '100% dc apodized' Gaussian profile. This grating has a constant dc refractive index within the grating and therefore the resonance is smooth and symmetric. Most useful bandpass filters require a profile close to 100% apodization. Although not shown in Figure 4, a smoothly varying index profile also eliminates the sidelobes in LPG resonances.

Other important types of nonuniform fiber gratings include chirped fiber gratings and superstructure fiber gratings. In a chirped fiber grating the grating period

slowly changes along the length of the grating. As discussed below, chirped fiber gratings may be used as chromatic dispersion compensators. They may also be used as broadband reflectors. LPGs may also be chirped to produce a broadband response. Superstructure gratings have oscillations in the period and/or amplitude of the refractive index modulations. The resulting grating can have several resonance peaks (see **Figure 4d**). The properties of nonuniform gratings may be computed using CMT and also understood intuitively using 'band-diagrams' and an effective index model of the fiber grating response.

Grating spectra showing radiation mode coupling are unlike FBGs or LPGs because there is no conversion of the radiation modes back to the incident core mode. The sharp resonances smooth out into a broad continuum. The grating transmission spectrum depends less on the refractive index profile of the grating than on the overlap of the core mode and grating with the radiation modes. Radiation mode coupling is greatly affected by tilting the grating planes with respect to the axis of the fiber. As discussed below, such tilted gratings may be designed as loss filters and optical fiber taps. Grating tilt has also been applied to decrease core mode back-reflection.

LPG resonances (and to some degree FBGs) may also exhibit strong dependence on the modal dispersion (or variation of the propagation constant, k, with wavelength). This wavelength dependence can dominate the wavelength dependence arising from CMT, making the resonance more or less narrow than predicted by CMT without modal dispersion. In an extreme case, very broadband LPG resonances (40 nm) may be produced between the core mode and a specially designed higher-order mode whose propagation constant varies such that it is resonant with the core mode over a large bandwidth.

Fiber Grating Fabrication

Photosensitivity

The key discovery leading to the study and practical application of fiber gratings was the phenomenon of UV-induced photosensitivity in the conventional germanosilicate optical fibers used in telecommunications systems. UV irradiation of the germanosilicate core region can produce refractive index changes in the range 0.01 to 0.0001. Such refractive index changes are large enough to produce useful filters and reflectors. The refractive index change is most efficiently produced by irradiation close to 242 nm or around 193 nm, where germanosilicate glass has strong absorptions. Numerous other dopants have been shown to be photosensitive at wavelengths ranging from 484 nm to 155 nm. These include P, Ce, Pb, Sn, N, Sn-Ge, Sb, and Ge-B. Other dopants, such as Al and F, show very little photosensitivity.

A second major discovery enabling practical manufacture of fiber gratings was the effect of 'hydrogen loading'. The fiber is placed in a pressurized hydrogen atmosphere until molecular hydrogen has diffused into the core region to a level of a few mole percent (a level similar to that of the photosensitive dopants). UV irradiation of the resulting fiber produces index changes an order of magnitude larger than in the unloaded fiber. Hydrogen loading allows gratings to be easily imprinted in conventional single-mode fibers, whose Ge content is too low to allow for strong gratings. The increase in photosensitivity is true for most photosensitive dopants. Index changes in excess of 10^{-2} have been produced with hydrogen loading. In order to avoid increased OH absorption in the telecommunications band (1520–1630 nm), deuterium (D_2) is normally used in place of hydrogen.

The origins of UV photosensitivity are not fully understood; however, at least two mechanisms are agreed to contribute to the index change. Firstly, as is evident from **Figure 5**, the UV absorption spectrum is modified during UV exposure. This bleaching corresponds to a change in refractive index in the infrared which may be computed using the Kramers–Kronig relations. In particular, the absorption band at

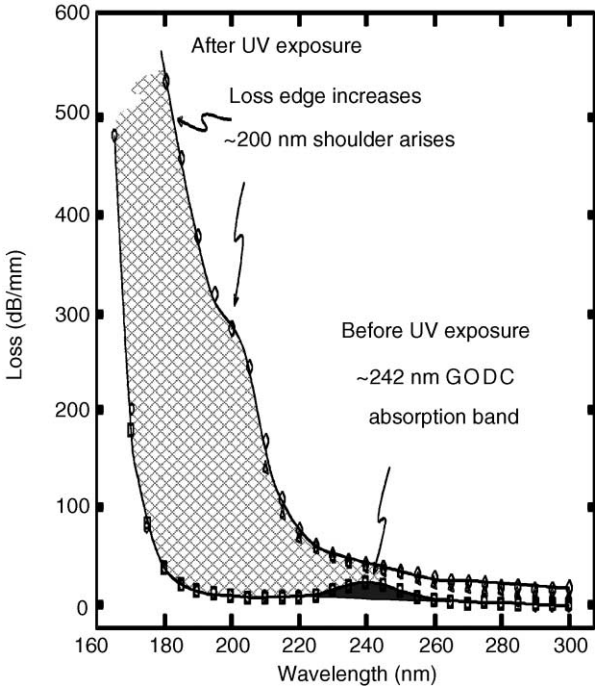

Figure 5 UV absorption spectrum of Ge-doped silica before and after irradiation with 242 nm light, showing bleaching of the Ge-oxygen deficient defect feature at 242 nm.

242 nm resulting from germanium oxygen deficient centers is bleached, indicating that these defects are modified during exposure. The infrared index change results both from this bleaching and from the change in the UV absorption edge at ~190 nm. Secondly, absorption of UV causes the silica matrix to contract. This compaction and the resulting stress distribution also change the refractive index.

Both mechanisms are enhanced by the presence of hydrogen in the silica lattice. The hydrogen reacts with oxygen, thus increasing the number of UV-absorbing germanium oxygen-deficient centers. As a result, in hydrogen loaded fibers, more of the Ge atoms participate in the index change, explaining the large increase in photosensitivity. The number of oxygen-deficient defects may also be increased during fiber manufacture by collapsing the fiber preform in a low-oxygen atmosphere. Such fibers show increased photosensitivity without the need for hydrogen loading. Co-doping a Ge-doped fiber with boron has also been shown to increase the level of photosensitivity of a fiber for a given level of index change in the core.

An important aspect of UV-induced index changes is that they require thermal annealing to ensure long-term stability. Sufficient exposure to elevated temperatures can completely erase the refractive index change in some Ge-doped gratings. Gratings can be completely erased by several hours of heating to greater than 500 °C. Thermal stability has been described by an activation energy model which assumes a distribution of energies for the defects giving rise to the refractive index change. Therefore, at a given anneal temperature a fixed fraction of the index change will quickly decay, leaving only stable defects that easily survive at lower temperatures. By annealing at several temperatures for a fixed time, a relationship between temperature and time required for a given refractive index decay may then be derived and used in accelerated aging tests of fiber gratings. For 20-year grating reliability of ~1% decrease in UV-induced refractive index change, a typical Ge-doped grating requires annealing at 140 °C for 12 hours.

Grating Inscription

The first method used in UV grating inscription is known as 'internal writing'. In this method light propagating in the fiber causes a standing wave to form within the core, and UV photosensitivity from a two-photon process results in permanent grating formation. Both LPG and FBG resonances have been fabricated using this method. The technique is inflexible, however, because the grating parameters are not easily controlled.

Another important advance that made possible the widespread use of fiber gratings is the 'transverse side-writing' technique. In this method, a UV interference pattern is projected through the side of the fiber onto the core region. The first demonstration of this technique employed a free space interferometer to produce the UV fringes. A significant improvement on this technique employs a zero-order nulled phase mask to generate the interference pattern. The phase mask acts to split the incident beam, and these two then form the interference pattern. The method is shown in Figure 6. The advantage of the phase mask

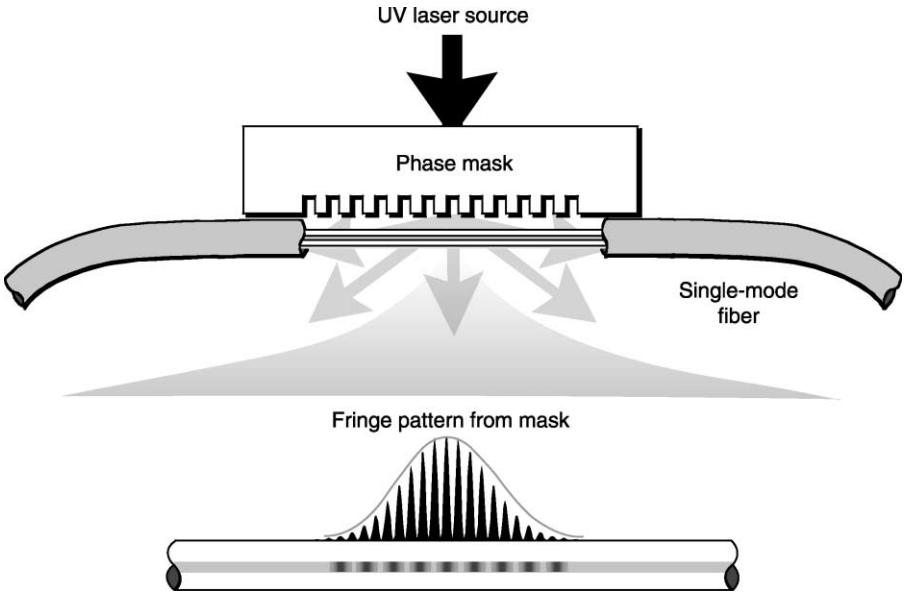

Figure 6 Phase mask fabrication of a fiber grating.

technique is that the fringes are very stable, since the UV beams propagate only a short distance. Another important technique for writing fiber gratings is the 'point-by point' writing method. In a point-by-point technique the UV interference pattern is modulated and translated along a fiber in such a way that a long grating may be formed. Although complex and sensitive, such methods can yield gratings as long as a few meters and also allow for the fabrication of complex grating profiles. Point-by-point methods have been used to fabricate broadband chirped dispersion compensating gratings and Bragg reflectors with very low dispersion.

LPGs may also be fabricated with UV irradiation. An amplitude mask is typically used. Requirements for beam coherence are greatly reduced because of the long period (typically a few hundred microns). Other techniques may also be used to fabricate LPGs. The fiber may be periodically deformed by heating or with periodic microbends. Dynamic LPGs may also be produced by propagating acoustic waves along the fiber.

Applications

Fiber gratings are key enabling technologies in a number of important applications. In this section we review these, highlighting the unique functionalities that can be provided by fiber gratings.

Fiber Grating Strain and Temperature Sensitivity

Fiber gratings are sensitive to both strain and temperature and may therefore be used as sensors. Both LPG and FBG resonances change with strain and temperature. LPGs show greater but more complicated sensitivity and typically FBGs are used in such applications. Strain sensitivity arises from the fact that gratings are extended in length. Because fibers are very thin (diameter $\sim 125\ \mu m$), significant extension is possible. A smaller strain sensitivity arises from the stress optic effect. Typical sensitivity at 1550 nm is ~ 1 pm/1 $\mu\varepsilon$ in FBGs. Temperature sensitivity arises from temperature dependence of the refractive index and gives rise to a change order 0.011 nm/°C of temperature change of the FBG. FBG strain sensors have been applied to map stress distributions and can be employed in a distributed manner with many Bragg reflectors in one fiber being examined with one detector.

These sensitivities may also be used to make fiber grating filters tunable. Temperature changes are more stable but typically give 1–2 nm of change in an FBG resonance. Strain tuning is more difficult to package commercially but can give up to 4 nm in extension and more than 10 nm in compression. Passive thermal stabilization of grating resonances may also be achieved by designing packages in which strain and temperature variations cancel each other.

Fiber Grating Stabilized Diode Lasers and Fiber Lasers

One of the first important commercial applications of fiber gratings was in stabilization of fiber coupled diode lasers. Normally these lasers operate on several cavity modes making the output unstable. If feedback is provided in the form of a narrowband reflection then the laser output will be only in this narrow bandwidth. The fiber grating is implemented in the fiber pigtail of the diode laser and typically provides a few percent reflectivity over a bandwidth of ~ 1 nm. The application is depicted schematically in Figure 7.

More generally, fiber gratings have been used to realize fiber laser cavities and fiber distributed feedback lasers. One important example is the cascaded Raman resonator fiber laser, in which several FBGs recycle Raman pump light to produce high-power, fiber coupled light at any design wavelength.

Optical Add/Drop Multiplexers

Another important commercial FBG application is the optical add/drop multiplexer (see Figure 8). These are key components in wavelength division multiplexed (WDM) networks. WDM networks transmit large amounts of data through a single fiber by modulating several optical carrier wavelengths and sending all the wavelengths through a single fiber. The optical add/drop multiplexer allows individual wavelengths to be added or dropped from a given fiber.

Fiber Bragg gratings are useful in this application because of the very narrow resonances that are achievable (typically a few tenths of a nm at 1550 nm). For wavelengths close to the Bragg wavelength an FBG strongly reflects. The reflectivity and bandwidth are determined by the depth of the index modulation and grating length, as discussed earlier. These degrees of freedom make fiber gratings ideal filters to be used in wavelength division multiplexed lightwave networks, in which multiple channels are transmitted along long lengths of optical fiber. Figure 8 illustrates schematically the principle of

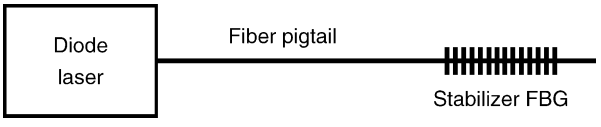

Figure 7 Fiber Bragg grating stabilized diode laser. The fiber grating reflector in the laser pigtail provides a small level of feedback to stabilize the laser output power and wavelength.

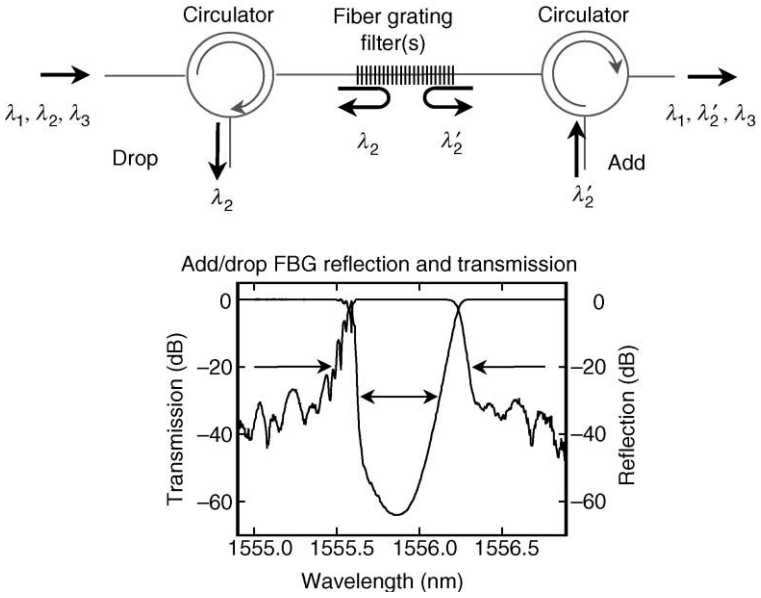

Figure 8 Top: Add/drop node employing fiber grating reflector. Bottom: characteristic reflection and transmission spectrum of an add/drop fiber grating filter.

a fiber grating based add/drop multiplexer. The grating is located between two three-port optical circulators. (A circulator is a bulk optic element that allows transmission only from port n to port $n+1$.) Different channels are incident upon the grating from the left and only one particular channel undergoes reflection at the grating. Note that by carefully designing the grating properties the reflectivity in the adjacent channel can be made to be negligible. This one channel is reflected and re-routed by the three-port circulator. The remainder of the channels are transmitted through the grating. The grating also enables the 'add' functionality. In this case light originating from a different part of the optical network enters the link again through an optical circulator and is reflected off the fiber grating.

Gain-Flattening Loss Filters

A primary strength of fiber gratings is the diversity of filter shapes that is achievable through modification of the grating profile. Gain-flatteners are an important application requiring such filter design. Gain-flattening filters are important in WDM telecommunications systems in order to smooth the wavelength dependence of fiber amplifiers (such as Er or Raman amplifiers). Both LPGs and FBGs may be employed as gain flattening filters. The desired loss spectrum is translated into a corresponding grating profile. LPGs have the advantage of low return loss, but the LPG resonance wavelengths and strengths are very sensitive to the fiber geometry, making the computation of the grating profile less accurate. FBGs may also be used in both tilted and untilted form; however they typically have back-reflections that require careful fiber grating growth or an isolator to suppress back-reflections. Figure 9 shows an example of a gain equalizing loss filter using LPGs.

Dispersion Compensator

Chromatic dispersion can limit the transmission distances and capacities of long-haul fiber links. Chromatic dispersion arises from the variation in propagation velocity with wavelength. An initially sharp pulse is thus dispersed and begins to overlap with adjacent pulses resulting in degraded signal quality. A key technology for long-haul fiber links is therefore 'dispersion compensation'. The most common solution has been 'dispersion compensating fiber' (DCF), which is simply fiber in which the chromatic dispersion has been engineered to be the exact opposite of the dispersion in the fiber link. Limitations of DCF include nonlinearities, higher-order dispersion, and lack of tunability. Fiber gratings offer an alternative approach that overcomes the problems.

Fiber Bragg gratings can provide strong chromatic dispersion when operated in reflection with a three-port circulator (see Figure 10). In this case the grating period is made to vary along the length of the grating. This means that different wavelengths in a pulse reflect at different positions in the grating. This gives rise to wavelength-dependent group delay and therefore chromatic dispersion. The advantage of the fiber grating compared to DCF is that the device can be made to be very compact, with potentially lower

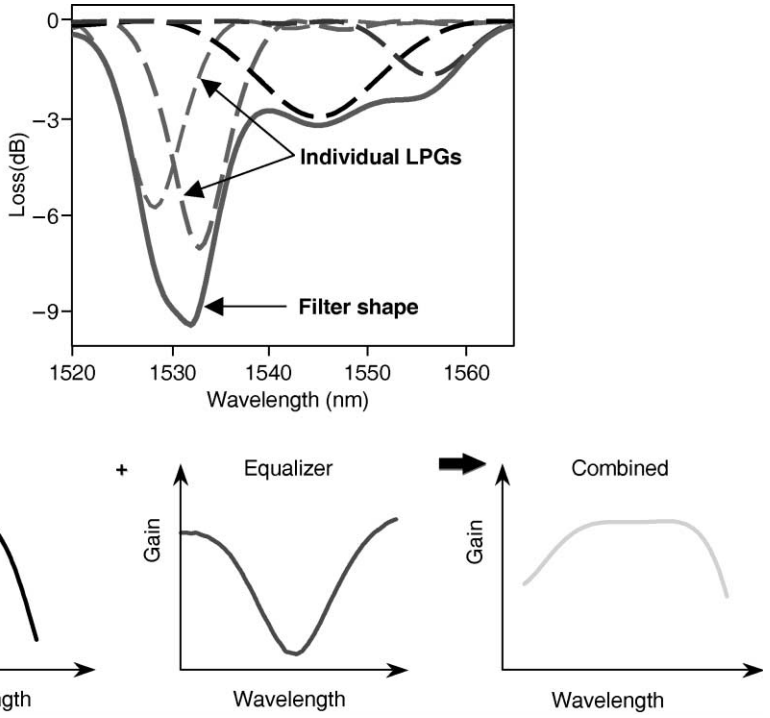

Figure 9 Long-period grating gain equalizer. Several individual gratings (dashed line) are combined to produce the overall shape (solid line).

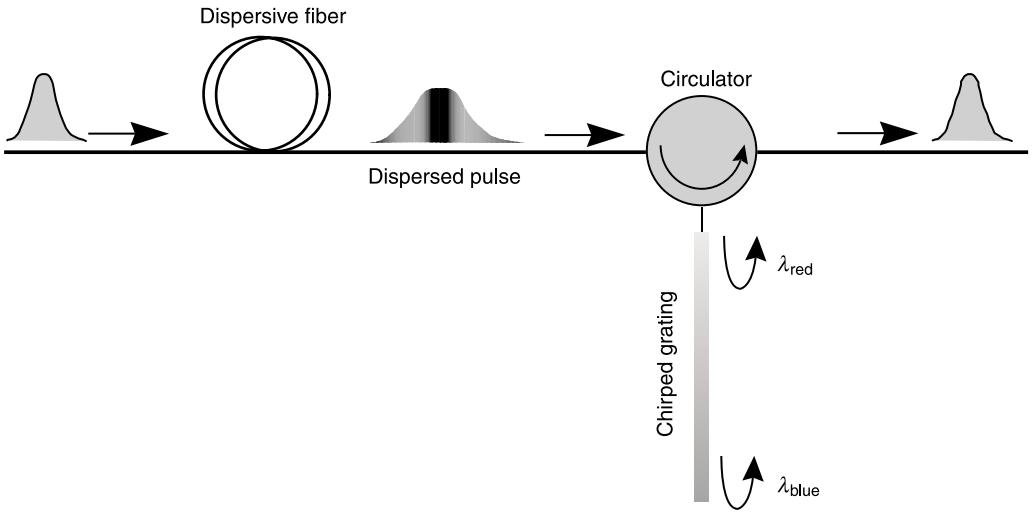

Figure 10 Chirped fiber grating dispersion compensator.

insertion loss, reduced optical nonlinearity, and controllable optical characteristics. In particular fiber gratings offer the possibility of engineering the chromatic dispersion to allow for compensation of dispersion slope and other degradations such as polarization mode dispersion.

Optical Monitors

Fiber gratings may also be employed as compact optical taps coupling core guided light to the radiation modes propagating outside the fiber (see Figure 3b). When a conventional Bragg grating is tilted with respect to the fiber axis it can scatter light out of the fiber in a highly directional manner. The angle of scatter is also wavelength dependent because of the phase matching condition discussed above. This wavelength dependence may form the basis of a compact wavelength monitor. The fiber grating is used to simultaneously couple light out of the fiber and separate the wavelengths. A simple

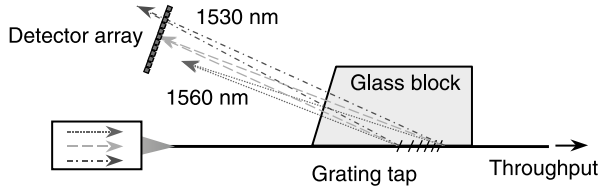

Figure 11 Fiber grating wavelength monitor. The fiber grating acts to scatter light out of fiber and simultaneously disperse the light.

detector array can then measure a spectrum of all the channels in a typical WDM system (see Figure 11).

Fiber grating taps may also scatter light in a polarization sensitive manner. This may be achieved by tilting the fiber grating by 45° with respect to the fiber axis. The resulting broadband taps may be employed in compact polarization monitoring schemes in which detectors are placed on the outside of the fiber to detect light at specific polarizations.

Advanced Topic in Fiber Gratings

Fiber Gratings in Air–Silica Microstructured Optical Fibers

Air–silica microstructure fibers (ASMFs), also known as 'holey' fibers, are fibers with air regions running along their length and allow for more complicated modal properties than conventional silica-doped fiber. It has been shown that fiber gratings can be UV written into photosensitive regions of various types of microstructure fibers. ASMF gratings open new possibilities for fiber grating devices. In addition, they are useful in studying the guidance properties of ASMFs, because they can selectively excite higher-order modes of the fiber. The phase matching condition may be used to derive the effective indices of the higher-order modes and mode profiles may be recorded by imaging a cleaved surface. Such measurements agree well with standard beam propagation computations. Figure 12 shows an example of a mode field image generated with a FBG.

One important application of ASMF gratings is a widely tunable LPG filter. Such filters employ a 'hybrid waveguide' formed by infusing a polymer into the air regions. Because the polymer index is much more sensitive to temperature than silica, the guidance properties of the cladding modes may be tuned. Thus, widely tunable LPG filters may be formed. Moreover, because the cladding modes are confined within an 'inner cladding' such filters are insensitive to external index, allowing for instance,

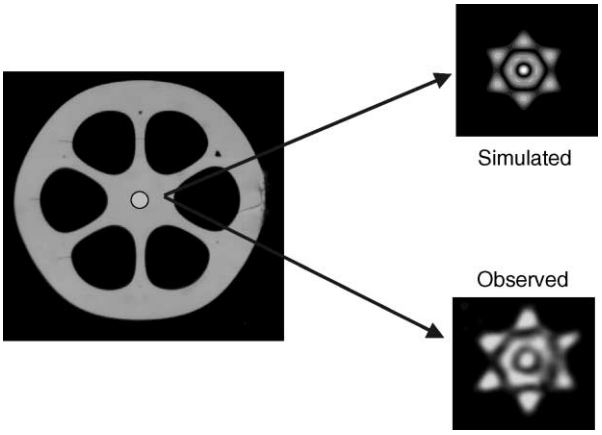

Figure 12 Cross-section of an air–silica microstructure fiber along with measured and simulated modes guided by the air regions.

the use of on-fiber, thin film heaters for power-efficient temperature tuning.

Nonlinear Optics in Fiber Gratings

The linear properties of fiber gratings are well understood and as explained earlier lead to a number of interesting phenomena and applications. When the peak intensity of the optical field is very high a new class of nonlinear effects can occur. These optical nonlinearities arise from the intrinsic nonlinearity of the material system in which the grating is inscribed. In the case of optical fibers, the dominant nonlinearity is third-order nonlinearity which manifests itself in the refractive index of the material depending on the peak intensity of the optical field: $n = n_0 + n_2 I$. This nonlinearity gives rise to a number of dramatic nonlinear effects in fiber gratings, including all-optical switching, bistability, multistability, soliton generation, pulse compression, and wavelength conversion.

To understand these effects we consider an intense optical field incident upon a fiber grating with a central wavelength tuned inside the stopband of the grating where the reflectivity is high. At low intensities the pulse is reflected and only a small amount of light leaks through the grating. As the intensity of the incident optical field is increased the optical nonlinearity becomes significant and results in shifting of the local Bragg wavelength of the grating. This in turn can lead to an increase in transmission of light through the grating and bistable operation.

Theoretical studies of the continuous wave nonlinear properties of periodic media show that such media can exhibit switching as well as bistability and multistability. This prediction has been confirmed

experimentally in a variety of geometries, such as in semiconductors, and in colloidal crystals. Experiments studying nonlinear effects in gratings can also be performed in optical fiber gratings. In these experiments short optical pulses are typically used in order to obtain the very high intensities. This has several key advantages. The first of these is that long, high-quality Bragg gratings can be permanently imprinted into the core of optical fibers by side illumination with interfering ultraviolet beams (see above). This allows for very long interaction lengths (compared to picosecond pulse lengths) and enables nonlinear propagation phenomena to be studied in detail. These include a number of propagation phenomena, such as the formation and propagation of Bragg solitons, modulational instability, and pulse compression. The second advantage is that although the nonlinearity is weak, it has a response time of the order of a few femtoseconds, and thus acts essentially instantaneously on the scale of all but the shortest optical pulses. Finally, the ability to engineer the fiber grating offers a number of unique geometries and potential applications of nonlinear fiber gratings.

A key idea in the interpretation of nonlinear optics in fiber Bragg gratings is the Bragg soliton. Briefly, in these solitons the enormous dispersion provided by the fiber Bragg grating is balanced by the fiber nonlinearity. This is analogous to the optical soliton that has been demonstrated in standard single-mode fiber where the dispersion is predominantly associated with the intrinsic material properties of silica. Since the dispersion of a Bragg grating can be five orders of magnitude larger than that of unprocessed fiber, Bragg solitons can be observed in gratings of only a few centimeters in length, thus rivaling the compactness of other soliton geometries, such as spatial solitons. Of course this implies that the required optical intensities to generate Bragg solitons are correspondingly higher than in uniform media.

Figure 13 shows an example of experimental results when the peak intensity of a pulse incident upon a fiber grating was approximately 10 GW/cm^2 and the incident pulse is tuned to the anomalous dispersion regime of the grating. In particular, Figure 13 shows the transmitted intensity versus time for different values of detuning. By varying the strain on the grating, we can change the detuning of the input pulse, and thus tune to different points on the dispersion curve. Note also from Figure 13 that far from the photonic bandgap edge, where the grating-induced dispersion is negligible, the pulse is unaffected and propagates through the grating at the speed of light. Closer to the edge of the photonic bandgap the pulse is substantially compressed due to the formation of a Bragg soliton. In addition to this compression, the transmitted pulse is substantially delayed in time as a result of the reduced group velocity of the pulse propagating through the grating.

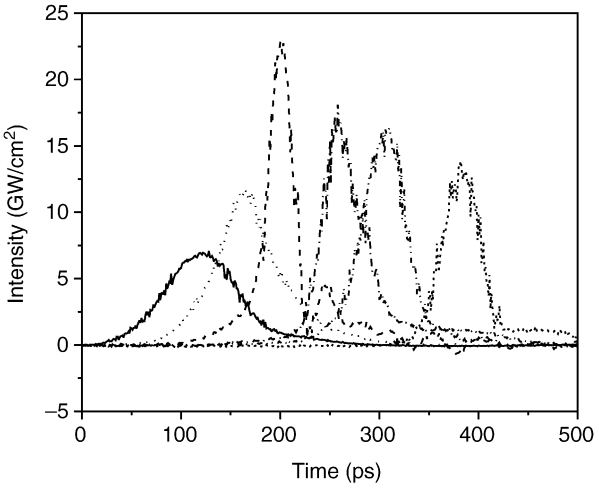

Figure 13 Pulse compression associated with nonlinear pulse propagation through a fiber Bragg grating. Compression is associated with the formation of a Bragg soliton when the incident pulse is tuned just outside of the photonic bandgap formed by the grating.

List of Units and Nomenclature

cw	Continuous wave
FBG	Fiber Bragg grating
LPG	Long-period grating

Introduction

Coherent optical information processing is almost entirely based on the Fourier-transform property of a lens. A Fourier-transform lens is actually an ordinary lens. If the input transparency is placed in the front focal plane of the lens and illuminated with coherent collimated light (planewave), the amplitude function in the back focal plane of the lens will be the Fourier transform of the input transparency as shown in Figure 1. A coherent optical processor usually consists of two lenses, as shown in Figure 2, thus it performs two Fourier transforms successively. The first lens transforms the input function from space domain into frequency domain, and the second lens transforms back the frequency function from frequency domain to the output function in space domain.

Fourier Transform Property of Lens

Recently, the Fourier-transform property of lenses has been explained, simply using the concept of linear system and geometrical optics. In contrast, the Fourier-transform property of lenses is traditionally analyzed, based on the Fresnel–Kirchhoff diffraction theory involving quadratic phase terms (eqns [2] and [3]). In this article, we adopt the simple geometrical theory based on geometrical optics.

We start our discussion by looking at Figure 1. Consider that a coherent point source is at the center of the front focal plane of the lens, which is denoted by plane (x, y). The point source generates a collimated beam parallel to the optical axis. The amplitude function at the back focal plane of the lens, which is denoted by plane (u, v), can be described as unity. Consequently, we can express mathematically:

$$f(x, y) = \delta(x, y) \qquad [1]$$

$$F(u, v) = 1 \qquad [2]$$

where $f(x, y)$ is the amplitude function in the front focal plane, and $F(u, v)$ is the amplitude function in the back focal plane.

If the point source shifts a distance a along the y-axis, the amplitude function in the front focal plane is

$$f(x, y) = \delta(x, y + a) \qquad [3]$$

The off-axis point source generates a tilted collimated beam. If we place a screen in the plane (u, v), we will see uniform intensity across the screen similar to that which would be seen when the source is centered on the axis. Mathematically, it means:

$$|F(u, v)|^2 = 1 \qquad [4]$$

However, the phase of the amplitude function is not uniform, since the collimated beam is not parallel to

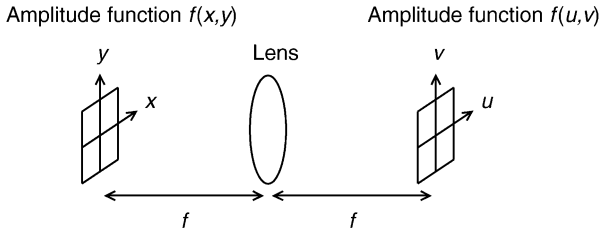

Figure 1 A lens Fourier-transforms amplitude function $f(x, y)$ in the front focal plane to amplitude function $F(u, v)$ in the back focal plane.

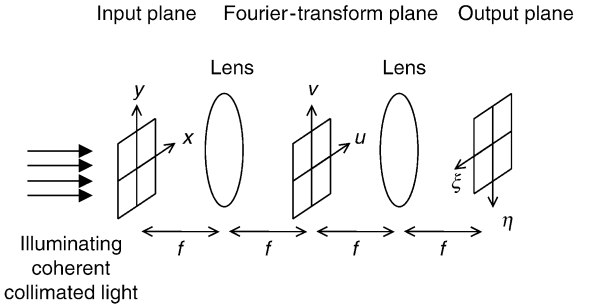

Figure 2 A pair of lenses form 4-f coherent optical processor.

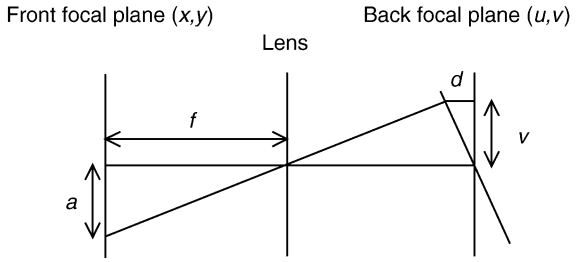

Figure 3 Calculation of phase function in the back focal plane (u, v) based on geometrical optics.

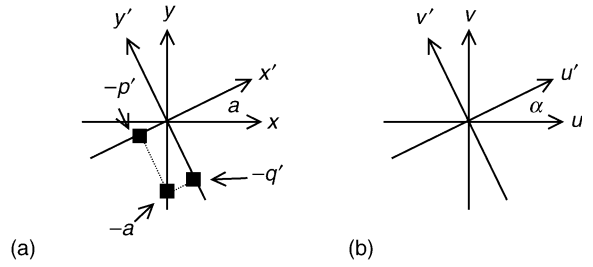

Figure 4 (a) Front focal plane coordinate system (x, y) is rotated by α. (b) Similarly, back focal plane coordinate system (u, v) is rotated by α.

the optical axis. In other words, plane (u, v) is not parallel to the wavefront.

If the phase at the center of plane (u, v) is considered zero, the phase at any point at plane (u, v) can be calculated referring to Figure 3. Using simple geometry, we know that

$$d(u, v) = \frac{a}{f} v \qquad [5]$$

where $d(u, v)$ is the optical path difference. Correspondingly, the phase is

$$\phi(u, v) = \frac{2\pi}{\lambda f} av \qquad [6]$$

where λ is the wavelength of light.

In complex representation, the amplitude function is expressed as

$$F(u, v) = A(u, v) \exp[i\phi(u, v)] \qquad [7]$$

where $A(u, v)$ and $\phi(u, v)$ are magnitude and phase of the amplitude function, respectively. From eqn [4], we know that

$$A(u, v) = |F(u, v)| = 1 \qquad [8]$$

Substituting eqns [8] and [6] into [7] yields

$$F(u, v) = \exp\left(i \frac{2\pi}{\lambda f} av\right) \qquad [9]$$

Equation [9] is the amplitude function in the back focal plane of the lens, when the amplitude function in the front focal plane of the lens is given by eqn [3].

Consider now that coordinate (x,y) is rotated by angle α to new coordinates (x',y') as shown in Figure 4a. The amplitude function in the front focal plane now becomes

$$f(x', y') = \delta(x' + p', y' + q') \qquad [10]$$

where

$$p' = a \sin \alpha \qquad [11a]$$

$$q' = a \cos \alpha \qquad [11b]$$

Correspondingly, coordinate (u, v) is also rotated by the same angle α to new coordinates (u', v') as shown in Figure 4b. The old coordinates u and v can be described in terms of new coordinates u' and v' as follow:

$$u = u' \cos \alpha - v' \sin \alpha \qquad [12a]$$

$$v = u' \sin \alpha + v' \cos \alpha \qquad [12b]$$

Substituting eqn [12b] into eqn [6] yields

$$\phi(u', v') = \frac{2\pi}{\lambda f} a(u' \sin \alpha + v' \cos \alpha) \qquad [13]$$

Further, substituting eqns [11a] and [11b] into [13] yields

$$\phi(u', v') = \frac{2\pi}{\lambda f}(p'u' + q'v') \qquad [14]$$

Thus, the amplitude function in the back focal plane of lens is

$$F(u', v') = \exp\left[i\frac{2\pi}{\lambda f}(p'u' + q'v') \right] \qquad [15]$$

For convenience, we now change parameters x' and y' to x and y, u' and v' to u and v, p' and q' to $-p$ and $-q$. Equations [10] and [15] become

$$f(x, y) = \delta(x - p, y - q) \qquad [16]$$

$$F(u, v) = \exp\left[-i\frac{2\pi}{\lambda f}(pu + qv) \right] \qquad [17]$$

We may simply consider that $f(x, y)$ is an input function and $F(u, v)$ is an output function of a system, since they are both physically the same amplitude functions. If there are two mutually coherent point sources at $(0, 0)$ and $(0, -a)$ with different amplitudes k and l in the front focal plane, the input function is

$$f(x, y) = k\delta(x, y) + l\delta(x, y + a) \qquad [18]$$

These two point sources will generate two collimated beams. Since they are mutually coherent, two collimated beams will interfere, and the resultant amplitude function in the back focal plane is simply the superposition of two beams, which is

$$F(u, v) = k + l \exp\left(i\frac{2\pi}{\lambda f} av \right) \qquad [19]$$

Thus, the lens is a linear system when the light is coherent. Furthermore, if input function $f(x, y)$ is a group of mutually coherent point sources with different amplitudes (i.e., an optical transparency illuminated with a planewave), it can be expressed as follows:

$$f(x, y) = \int\int_{-\infty}^{\infty} f(p, q)\delta(x - p, y - q)\mathrm{d}p\ \mathrm{d}q \qquad [20]$$

Since the lens is a linear system, output function will be the same superposition as follows:

$$F(u,v) = \int\int_{-\infty}^{\infty} f(p,q)\exp\left[-i\frac{2\pi}{\lambda f}(pu+qv) \right]\mathrm{d}p\,\mathrm{d}q \qquad [21]$$

By again changing parameters p and q to x and y, respectively, eqn [21] becomes

$$F(u,v) = \int\int_{-\infty}^{\infty} f(x,y)\exp\left[-i\frac{2\pi}{\lambda f}(xu+yv) \right]\mathrm{d}x\,\mathrm{d}y \qquad [22]$$

which is the optical Fourier transform of the input function $f(x,y)$.

4-f Coherent Optical Processor

If the amplitude function in the front focal plane of a lens is denoted by $f(x, y)$, then the amplitude function in the back focal plane is simply $F(u, v)$ given in eqn [22], which is the Fourier transform of $f(x, y)$. Mathematically, $f(x, y)$ can also be derived from $F(u, v)$ (eqn [4]). After neglecting the normalization factor, it can be expressed as follows:

$$f(x, y) = \int\int_{-\infty}^{\infty} F(u, v)\exp\left[i\frac{2\pi}{\lambda f}(xu + yv) \right]\mathrm{d}u\,\mathrm{d}v \qquad [23]$$

The normalization factor $(1/\lambda f)^2$ is caused by the coordinate scale factor λf in the Fourier-transform plane (u, v).

Equations [22] and [23] are Fourier transform and inverse Fourier transform, respectively. The operation of Fourier transform is represented by a notation $F\{\cdot\}$, and inverse Fourier transform is $F^{-1}\{\cdot\}$.

Two Fourier transform lenses can be combined into a two-lens processor, which is better known as a 4-f optical processor, as shown in Figure 2. Figure 2 illustrates the principle of a 4-f optical processor, in which $f(x, y)$, $F(u, v)$, and $f(\xi, \eta)$ are amplitude functions in input, Fourier transform, and output planes, respectively. Since $F(u, v)$ is the function of spatial frequency, Fourier-transform plane is also called a frequency plane. Since a lens performs only Fourier transform, to perform inverse Fourier transform, the output plane must be rotated by 180°. Thus, orientations of ξ and η correspond to $-x$ and $-y$.

In practice, $f(x, y)$ is represented by an optical mask, which can be a film transparency or a spatial light modulator. The optical mask with $f(x, y)$ amplitude transmittance is illuminated with collimated coherent light to produce the amplitude function $f(x, y)$. The Fourier transform $F(u, v)$ is physically formed in the frequency plane. The frequency content of the input function $f(x, y)$ can be directly altered by placing an optical mask in the frequency plane. Finally, an image with amplitude function $f(\xi, \eta)$ is formed in the output plane. Notice that all detectors, including our eyes, detect intensity that is the square of amplitude.

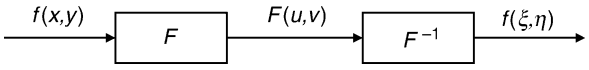

Figure 5 Block diagram of 4-f coherent optical processor.

According to eqn [22], $F(u, v)$ can be expressed in terms of $f(x, y)$ as

$$F(u, v) = F\{f(x, y)\} \quad [24]$$

Similarly, the amplitude function in the output plane must be

$$f(x', y') = F\{F(u, v)\} \quad [25]$$

where (x', y') is the coordinate of the output plane having the same orientation as (x, y) in the input plane. This function can be expressed in terms of inverse Fourier transform as follows:

$$f(-x', -y') = F^{-1}\{F(u, v)\} \quad [26]$$

A rotated coordinate (ξ, η), shown in Figure 2, substitutes $(-x', -y')$, such that

$$f(\xi, \eta) = F^{-1}\{F(u, v)\} \quad [27]$$

Thus, the successive operations can be simply illustrated by the diagram shown in Figure 5.

Spatial Filtering

The origin of optical information processing can be traced as far back as the work of Abbe of 125 years ago. His interest at that time concerned the theory of microscopy in order to establish a scientific approach to microscope design. He found that a larger aperture resulted in higher resolution. An object under the microscope, whose size was of the order of the wavelength of light, diffracted the illuminating light, i.e., the straight light was bent. If the aperture of the objective lens was not large enough to collect all of the diffracted light, the image did not correspond exactly to that object. Rather, it related to a fictitious object whose complete diffracted light pattern matched the one collected by the objective lens. These lost portions are associated with the higher spatial frequency. Their removal will result in a loss in image sharpness and resolution. The basic ideas of Abbe's theory were later clarified in a series of experiments by Porter in the early 1900s.

Since the late 1940s, the possibility of applying coherent optical techniques to image processing had been explored. In 1960, Cutrona *et al*. presented an optical system using lenses to perform Fourier transforms. Thus, every Fourier transformation in the processor can be realized by a lens. The power of this architecture is its capability of forming Fourier spectra and also being cascaded.

Consider an image formed by an optical system such as a camera; because of the error or limitation of the system, the perfect point in the object may smear. If we consider that the original object is the collection of a large number of very fine points, the formed image will be the collection of the same number of blurred spots, instead of fine points. Thus, the image formation can be expressed by convolution. The blurred spot is represented by the impulse response $h(x, y)$, which is the characteristic of the optical system.

When the input is a point (an impulse), its amplitude function is a delta function $\delta(x, y)$, and the output amplitude function is $h(x, y)$. The observed image is the intensity function $|h(x, y)|^2$. Since it indicates the spread of a point, $|h(x, y)|^2$ is called the point spread function.

The output image function $o(x, y)$ is the convolution of input function $f(x, y)$ and the impulse response $h(x, y)$ as follows:

$$o(x, y) = \int\int_{-\infty}^{\infty} f(p, q)h(x - p, y - q)\mathrm{d}p\ \mathrm{d}q \quad [28]$$

Notice that $h(x - p, y - q)$ is the blurred spot centered at (p, q). $H(u, v)$, $F(u, v)$, and $O(u, v)$ are Fourier transforms of $h(x, y)$, $f(x, y)$, and $o(x, y)$, respectively. Substitution of

$$h(x-p,y-q)=\int\int_{-\infty}^{\infty} H(u,v) \times\exp\left[i\frac{2\pi}{\lambda f}[(x-p)u+(y-q)v]\right]\mathrm{d}u\,\mathrm{d}v \quad [29]$$

then

$$F(u,v)=\int\int_{-\infty}^{\infty} f(p,q)\exp\left[-i\frac{2\pi}{\lambda f}(pu+qv)\right]\mathrm{d}p\,\mathrm{d}q \quad [30]$$

yields

$$o(x,y)=\int\int_{-\infty}^{\infty} F(u,v)H(u,v)\exp\left[i\frac{2\pi}{\lambda f}(xu+yv)\right]\mathrm{d}u\,\mathrm{d}v \quad [31]$$

Since

$$o(x,y)=\int\int_{-\infty}^{\infty} O(u,v)\exp\left[i\frac{2\pi}{\lambda f}(xu+yv)\right]\mathrm{d}u\,\mathrm{d}v \quad [32]$$

we obtain

$$O(u,v)=H(u,v)F(u,v) \quad [33]$$

The function $H(u,v)$, which is the Fourier transform of the impulse response $h(x,y)$, is called transfer function. Actually, $H(u,v)$ changes the spectrum of input function $F(u,v)$ to become $O(u,v)$ and the spectrum of the output function becomes $H(u,v)F(u,v)$.

The first application of spatial filtering may be the restoration of a photograph. The image formed by a camera is a collection of spots. If the image is in focus, the size of the spots is very fine, and thus the image looks sharp. If the image is out of focus, the spot size is fairly large and the image is blurred. Interestingly, an out-of-focus image can be restored using spatial filtering technique.

Consider that the original image is $f(x, y)$. Because it is out of focus, a point in the image becomes a spot expressed by $h(x, y)$. If the image is in focus, $h(x, y)$ is a delta function. If the in-focus image is $f(x, y)$, its frequency function is $F(u, v)$. The defocused image $o(x, y)$ is expressed by eqn [28], and its frequency function is $F(u,v)H(u,v)$. To produce the in-focus image, the frequency function must be $F(u, v)$. Thus $F(u,v)H(u,v)$ must be multiplied by the filter function of $1/H(u,v)$ to produce $F(u,v)$ only. The filter of $1/H(u,v)$ can be made from a photographic plate to provide its magnitude, and a glass plate having two values of thickness to provide $+1$ and -1 signs. The glass plate is essentially a phase filter. The photographic plate with varying density function is an amplitude filter. By passing frequency function $F(u,v)H(u,v)$ through the combination of amplitude and phase filters, it will result in $F(u,v)$ only. When $F(u,v)$ is again Fourier transformed by a lens, an in-focus image $f(x, y)$ will be produced.

Complex Matched Spatial Filtering

The restoration of a photograph mentioned above, utilizes the filter function $1/H(u,v)$, which has positive and negative real values. We will see an application in which the filter function is a complex function. A complex function filter can be produced by a single hologram, instead of using a combination of a phase filter and an amplitude filter. The complex matched spatial filter can perform a correlation, as first demonstrated by Vander Lugt. The complex filter is actually a Fourier transform hologram proposed by Leith and Upatnieks.

The synthesis of a complex filter is shown in Figure 6. First, a function $g(x, y)$ is displayed in the input plane by a transparency or spatial light modulator and illuminated with a collimated coherent light beam. Its Fourier-transform $G(u,v)$ is generated in the back focal plane of the lens. The hologram is made in the Fourier-transform plane by recording the interference pattern of $G(u,v)$ and the reference beam $R(u,v)$. $R(u,v)$ is an oblique collimated beam, having magnitude of unity, which is expressed mathematically as

$$R(u,v) = \exp(iau) \qquad [34]$$

and

$$a = \frac{2\pi \sin \alpha}{\lambda} \qquad [35]$$

where α is the angle of the reference beam and λ is the wavelength of light.

The transmittance of the recorded hologram will be

$$\begin{aligned} T(u,v) &= |G(u,v) + R(u,v)|^2 \\ &= |G(u,v)|^2 + 1 + G(u,v)\exp(-iau) \\ &\quad + G^*(u,v)\exp(iau) \end{aligned} \qquad [36]$$

where * denotes the complex conjugate. The hologram, which is called a complex matched spatial filter, is then placed back in the Fourier-transform plane, as shown in Figure 7. A new input function $f(x, y)$ is displayed in the input plane. The Fourier-transform of input function, $F(u,v)$ will be generated in the Fourier-transform plane. The amplitude of light,

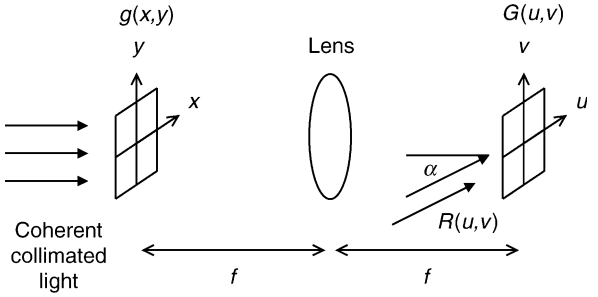

Figure 6 Synthesis of complex matched spatial filter is the recording of Fourier-transform hologram.

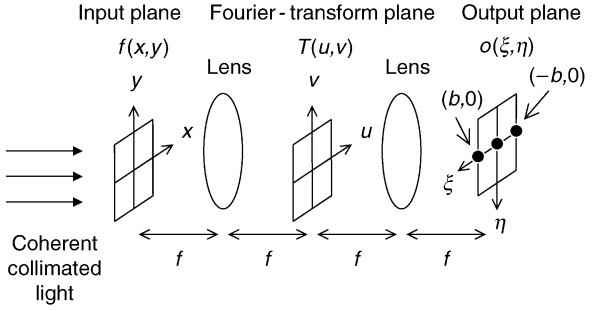

Figure 7 Optical processing using complex matched spatial filter in a 4-f processor.

immediately after the complex matched spatial filter, is

$$\begin{aligned} F(u,v)T(u,v) = {} & (|G(u,v)|^2 + 1)F(u,v) \\ & + F(u,v)G(u,v)\exp(-iau) \\ & + F(u,v)G^*(u,v)\exp(iau) \end{aligned} \quad [37]$$

The second lens then produces the inverse Fourier transform of $F(u,v)T(u,v)$ in the output plane:

$$\begin{aligned} F^{-1}\{F(u,v)T(u,v)\} = {} & F^{-1}\{(|G(u,v)|^2 + 1)F(u,v)\} \\ & + F^{-1}\{F(u,v)G(u,v)\exp(-iau)\} \\ & + F^{-1}\{F(u,v)G^*(u,v)\exp(iau)\} \end{aligned} \quad [38]$$

The first term will be at the center of the output plane. The second and the third terms will appear at $(b,0)$ and $(-b,0)$ in (ξ,η) plane, respectively, where

$$b = f\sin\alpha \quad [39]$$

and f is the focal length of lens.

We are now in a position to analyze the inverse Fourier transform of $F(u,v)G(u,v)$ and $F(u,v)G^*(u,v)$. Referring to eqns [28]–[33], the inverse Fourier transform of $F(u,v)G(u,v)$ is the convolution of $f(\xi,\eta)$ and $g(\xi,\eta)$. Thus, the complex matched spatial filtering can also be applied to the restoration of photography mentioned previously without using the combination of amplitude and phase filters.

The inverse Fourier transform of $F(u,v)G^*(u,v)$ is derived as follows:

$$\begin{aligned} o_3(\xi,\eta) = {} & \int\int_{-\infty}^{\infty} F(u,v)G^*(u,v) \\ & \times \exp\left[i\frac{2\pi}{\lambda f}(\xi u + \eta v) \right] du\, dv \end{aligned} \quad [40]$$

Substitute

$$\begin{aligned} F(u,v) = {} & \int\int_{-\infty}^{\infty} f(\alpha,\beta) \\ & \times \exp\left[-i\frac{2\pi}{\lambda f}(\alpha u + \beta v) \right] d\alpha\, d\beta \end{aligned} \quad [41]$$

and

$$\begin{aligned} G^*(u,v) = {} & \int\int_{-\infty}^{\infty} g^*(-p,-q) \\ & \times \exp\left[-i\frac{2\pi}{\lambda f}(pu + qv) \right] dp\, dq \end{aligned} \quad [42]$$

into eqn [40], one obtains

$$\begin{aligned} o_3(\xi,\eta) = {} & \int\int_{-\infty}^{\infty} f(\alpha,\beta) \int\int_{-\infty}^{\infty} g^*(-p,-q) \\ & \times \int\int_{-\infty}^{\infty} \exp\left[i\frac{2\pi}{\lambda f}(\xi - \alpha - p)u \right. \\ & \left. + (\eta - \beta - q)v \right] du\, dv\, dp\, dq\, d\alpha\, d\beta \end{aligned}$$

$$\begin{aligned} o_3(\xi,\eta) = {} & \int\int_{-\infty}^{\infty} f(\alpha,\beta) \int\int_{-\infty}^{\infty} g^*(-p,-q) \\ & \times \delta(\xi - \alpha - p, \eta - \beta - q) dp\, dq\, d\alpha\, d\beta \end{aligned}$$

$$o_3(\xi,\eta) = \int\int_{-\infty}^{\infty} f(\alpha,\beta) g^*(\alpha - \xi, \beta - \eta) d\alpha\, d\beta \quad [43]$$

Equation [43] is the correlation of $f(x,y)$ and $g(x,y)$. It is apparent that the correlation output $o_3(\xi,\eta)$ will achieve the maximum when $f(x,y)$ is identical to $g(x,y)$. If $f(x,y)$ and $g(x,y)$ are different, the correlation function will be a flat function with minor random fluctuation. Optical correlators using complex matched spatial filters have been applied to automatic pattern recognition.

Joint Transform Correlator

Alternatively, the joint transform correlator can perform a correlation without recording a complex matched spatial filter in advance. In addition to the correlation, the joint transform correlator can also be used as a general optical processor.

A transparency with amplitude transmittance $f(x,y)$ is centered at $(-a,0)$, and a second transparency with amplitude transmittance $g(x,y)$, is centered at $(a,0)$. The two transparencies are illuminated by a coherent collimated beam and jointly Fourier transformed by a single lens as shown in Figure 8. In the back focal plane of the lens, the amplitude function $S(u,v)$ is

$$\begin{aligned} S(u,v) = {} & \int\int_{-\infty}^{\infty} [f(x+a,y) + g(x-a,y)] \\ & \times \exp\left[-i\frac{2\pi}{\lambda f}(xu + yv) \right] dx\, dy \end{aligned} \quad [44]$$

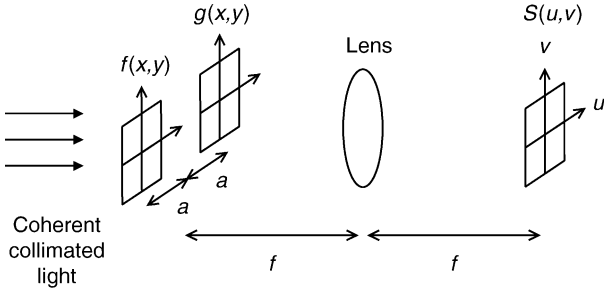

Figure 8 Joint Fourier transform of two input functions.

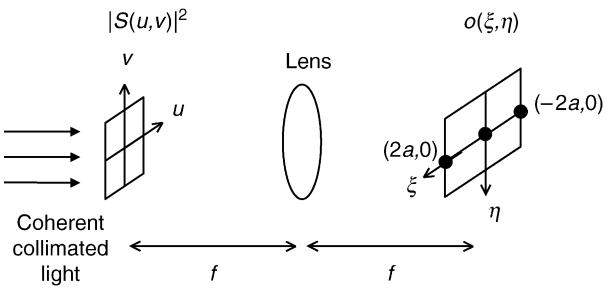

Figure 9 Fourier transform of the joint power spectrum.

$S(u,v)$ is the joint Fourier spectrum of $f(x,y)$ and $g(x,y)$. It can be written as

$$S(u,v) = F(u,v)\exp\left[i\frac{2\pi}{\lambda f}au\right] + G(u,v)\exp\left[-i\frac{2\pi}{\lambda f}au\right] \quad [45]$$

where $F(u,v)$ and $G(u,v)$ are Fourier transforms of $f(x,y)$ and $g(x,y)$, respectively.

If a square-law detector is placed in the back focal plane of the lens, the recorded pattern of joint power spectrum $|S(u,v)|^2$ is

$$|S(u,v)|^2 = |F(u,v)|^2 + F(u,v)G^*(u,v)\exp\left[i\frac{4\pi}{\lambda f}au\right] + F^*(u,v)G(u,v)\exp\left[-i\frac{4\pi}{\lambda f}au\right] + |G(u,v)|^2 \quad [46]$$

where * denotes the complex conjugate. A photographic plate is a square-law detector and can be used to record $|S(u,v)|^2$. When the developed plate is placed in the input plane, as shown in Figure 9, the input transmittance is $|S(u,v)|^2$ as given in eqn [46].

The inverse Fourier transform of the joint power spectrum $|S(u,v)|^2$, in the back focal plane of the lens, is

$$o(\xi,\eta)=\int\int_{-\infty}^{\infty}|S(u,v)|^2\exp\left[i\frac{2\pi}{\lambda f}(\xi u+\eta v)\right]\mathrm{d}u\,\mathrm{d}v \quad [47]$$

which consists of four terms, according to eqn [46]. We now analyze this equation term by term. The first term is

$$o_1(\xi,\eta)=\int\int_{-\infty}^{\infty}|F(u,v)|^2\exp\left[i\frac{2\pi}{\lambda f}(\xi u+\eta v)\right]\mathrm{d}u\,\mathrm{d}v \quad [48]$$

which is the auto-correlation of $f(x,y)$

$$o_1(\xi,\eta)=\int\int_{-\infty}^{\infty}f(\alpha,\beta)f^*(\alpha-\xi,\beta-\eta)\mathrm{d}\alpha\mathrm{d}\beta \quad [49]$$

The second term is

$$o_2(\xi,\eta)=\int\int_{-\infty}^{\infty}F(u,v)G^*(u,v)\exp\left[i\frac{4\pi}{\lambda f}au\right]\times\exp\left[i\frac{2\pi}{\lambda f}(\xi u+\eta v)\right]\mathrm{d}u\,\mathrm{d}v \quad [50]$$

which is

$$o_2(\xi,\eta)=\int\int_{-\infty}^{\infty}f(\alpha,\beta)g^*[\alpha-(\xi+2a),\beta-\eta]\mathrm{d}\alpha\mathrm{d}\beta \quad [51]$$

Equation [51] is the correlation between $f(x,y)$ and $g(x,y)$, shifted by $-2a$ in the ξ-axis direction.

Similarly, the third term will be the correlation between $g(x,y)$ and $f(x,y)$, shifted by $2a$ in the ξ-axis direction:

$$o_3(\xi,\eta)=\int\int_{-\infty}^{\infty}g(\alpha,\beta)f^*[\alpha-(\xi-2a),\beta-\eta]\mathrm{d}\alpha\mathrm{d}\beta \quad [52]$$

And the fourth term is

$$o_4(\xi,\eta)=\int\int_{-\infty}^{\infty}g(\alpha,\beta)g^*(\alpha-\xi,\beta-\eta)\mathrm{d}\alpha\mathrm{d}\beta \quad [53]$$

which is the auto-correlation of $g(x,y)$ and overlaps with the first term at the center of the output plane.

From the analysis given above, it is understood that the correlation of $f(x,y)$ and $g(x,y)$, and the correlation of $g(x,y)$ and $f(x,y)$, are shifted by $-2a$ and $2a$, respectively, along the ξ-axis. The correlation outputs are centered at $(-2a,0)$ and $(2a,0)$ in the back focal plane of the lens. If $f(x,y)$ and $g(x,y)$ are the same, the two correlation outputs are identical. The first and fourth terms are the autocorrelations of $f(x,y)$ and $g(x,y)$, centered at $(0,0)$. Thus the second and third terms, which are correlation signals, can be isolated. A versatile real-time joint transform

correlator, using inexpensive liquid crystal televisions, is widely used in laboratory demonstration.

Introduction

Lenses are carefully shaped pieces of transparent material used to form images. The term 'transparent' does not necessarily mean that the lens is transmitting visible light. The element germanium, well-known in the transistor industry, is a light-gray opaque crystal which forms images with infrared radiation, and provides the optics for night-vision instruments. The lenses used in cameras, telescopes, microscopes, and other well-known applications, are made from special glasses or – more recently – from plastics. Hundreds of different optical glass formulas are listed in the manufacturers' catalogues. Plastics have come into use in recent years because it is now possible to mold them with high precision. The way in which lenses form images has been studied for several hundred years, resulting in an enormous and very complicated literature. In this article, we show how this theory can be simplified by introducing the restriction that lenses are perfect. This limitation provides an easy introduction to the image forming process. A companion article **Geometrical Optics:** Aberrations, will deal with imperfect components, showing how their defects degrade images and how corrections are made.

The Cardinal Points and Planes of an Optical System

The location, size and orientation of an image are items of information which a designer needs to know. The nature of the image can be determined by a simple model of an optical system, based on two experimental observations. The first is well-known and is pictured in Figure 1. Parallel rays of light passing through a double convex lens (a simple magnifying glass, for example) should meet at the focal point or focus, designated as F'. For rays from the right side of the lens, another such point F exists at an equal distance from the lens. The other experiment uses the lens to magnify (Figure 2a). The amount of magnification decreases as the lens is brought closer to 'ISAAC NEWTON' (Figure 2b), and when the lens touches the paper, object and image are approximately the same size. The locations of object and image corresponding to equality in size are called the unit or principal points H and H', respectively, and the set of four points F, F', H, and H' are the cardinal points. Therefore, the planes through these points normal to the axis of the lens are the cardinal planes. Figure 3 shows an object whose image we can now determine. The coordinate orientation in this figure may appear strange at first. It is customary in optics to designate the lens axis as OZ, and the other two axes form a right-handed system. The x-axis then lies in the

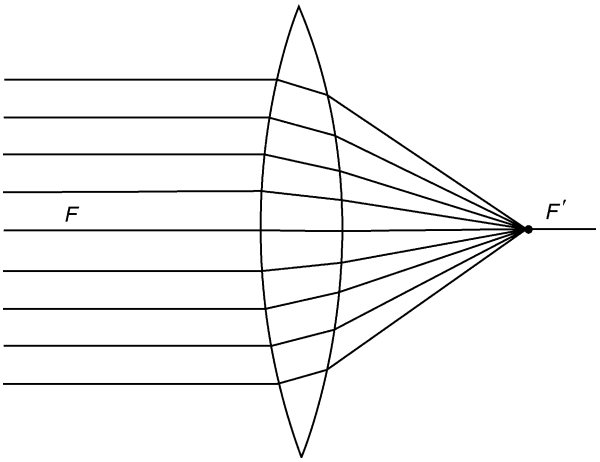

Figure 1 Focal points of a double convex lens.

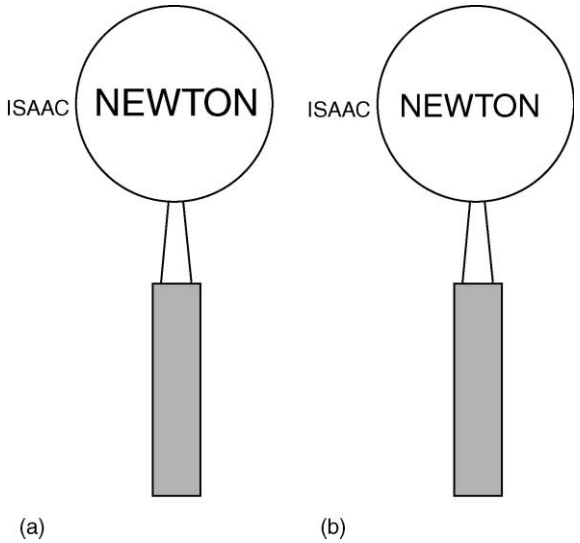

Figure 2 Magnification by a double convex lens. The magnification in (a) is reduced when the lens is brought closer to the image (b).

plane of the figure; the y-axis, coming out of the paper and perpendicular to it, is not shown. The object, of height x, is placed to the left of the focal point F. The cardinal points occur in the order F, H, H', F', since we expect – based on the experiment corresponding to Figure 2 – that the unit points are very close to the lens. Another fact to be demonstrated later is that H and H' are actually inside the lens. Two rays are shown leaving the point P at the top of the object. The ray which is parallel to the axis strikes the unit plane through H and continues to the right, completely missing the lens. The ray then meets the unit plane through H' at a point which must be a distance x from the axis. To understand why, we recognize that if the object were relocated so as to lie

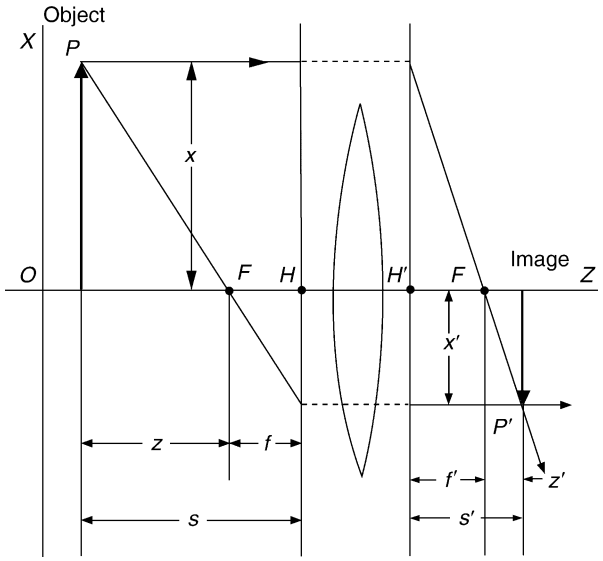

Figure 3 Ray tracing using cardinal points and planes.

on the object-space unit plane, the ray emerging at the other unit plane will be at a distance x from the axis; as required by the definition of these planes. We then assume that the ray is bent or refracted at the unit plane at H' and proceeds to, and beyond, the focal point F'. The second ray, from P through the focal point F, is easily traced since the lens is indifferent to the direction of the light. Assume temporarily that we know the location of the image point P'. Let a parallel ray leave this point and travel to the left. The procedure just given indicates that this ray will strike the unit plane at H', emerge at the other unit plane, be refracted so as to pass through F and reach the object point P. Then reversing the direction of this ray, it will start at P, emerge at the unit plane H' and travel parallel to the axis, intersecting the other ray at P'. The distance between F and H is called the object space focal length f, with f' being the corresponding image space quantity. Simple geometry, making use of the similar triangles and the distances indicated in this diagram, can be used to derive the Newton lens equation or the equivalent Gauss lens equation. Detailed derivations of these two equations will be found in either of the sources listed in the Further Reading at the end of this article. It is not usually made clear in physics texts that these equations apply only to the special case of a single, thin lens, and we shall not apply them here. The image in this figure is real, inverted, and reduced. That is, it is smaller than the object, oriented in the opposite direction, and can be projected onto a screen located at the image position. This result can be verified by using an ordinary magnifier to form the image of a distant light source on a sheet of white paper.

Paraxial Matrices

To consider how light rays behave in optical systems, we introduce the index of refraction n of a material medium, defined as the ratio of the velocity of light c in a vacuum to its velocity v in that medium, or:

$$n = \frac{c}{v} \qquad [1]$$

The velocity of light in air is approximately the same as it is in a vacuum. A light ray crossing the interface between air and a denser medium such as glass will be bent towards the normal to the surface. This is the phenomenon of refraction and the amount of bending is governed by Snell's law, which has the form:

$$n \sin \theta = n' \sin \theta' \qquad [2]$$

where n and n' are the indices of refraction of the two media and θ and θ' are the angles as measured from the normal. Figure 4 shows a ray of light leaving an object point P and striking the first surface of a lens at point P_1. It is refracted there, and proceeds to the second surface. All rays shown lie in the z, x-plane or meridional plane, which passes through the symmetry axis OZ. The amount of refraction is specified by Snell's law, eqn [2], which we shall now simplify. The sine of an angle can be approximated by the value of the angle itself, if this value is small when expressed in radians (less than 0.1 rad), and

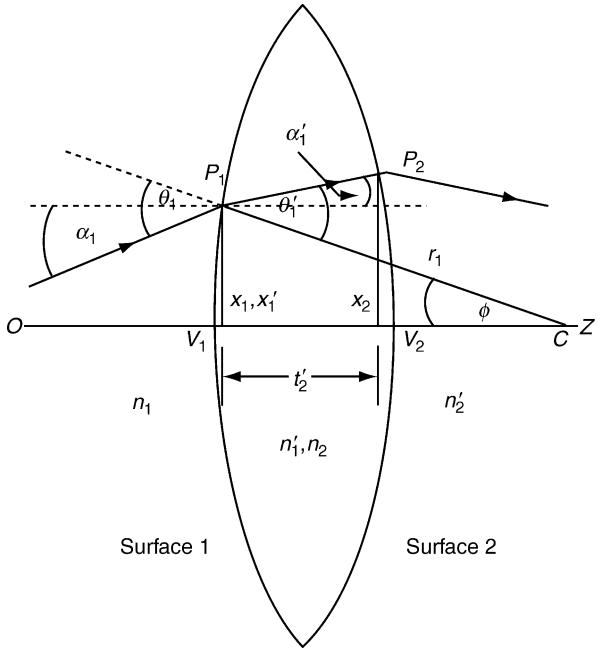

Figure 4 Ray passing through a double convex lens.

Snell's law simplifies to

$$n_1 \theta_1 = n_1' \theta_1' \qquad [3]$$

This is called the paraxial form of Snell's law; the word paraxial means 'close to the axis'. It turns out, however, that the Snell's law angles are not convenient to work with, and we eliminate them with the terms:

$$\theta_1 = \alpha_1 + \phi, \qquad \theta_1' = \alpha_1' + \phi \qquad [4]$$

where α_1 is the angle which the incident ray makes with the axis OZ, α_1' is the corresponding angle for the refracted ray, and ϕ is the angle which the radius r_1 (the line from C to P_1) of the lens surface makes at the center of curvature C. This particular angle can be specified as

$$\sin \phi = \frac{x_1}{r_1} \qquad [5]$$

but using the paraxial approximation simplifies this to

$$\phi = \frac{x_1}{r_1} \qquad [6]$$

Substituting for the angles gives

$$n_1' \alpha_1' = \frac{n_1 - n_1'}{r_1} + n_1 \alpha_1 \qquad [7]$$

Notice that the distance from the point P_1 to the axis is labeled as either x_1 or x_1'. This strange notation leads to the trivial relation

$$x_1 = x_1' \qquad [8]$$

and this can be combined with eqn [7] to obtain the matrix equation:

$$\begin{pmatrix} n_1' \alpha_1' \\ x_1' \end{pmatrix} = \begin{pmatrix} 1 & -k_1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} n_1 \alpha_1 \\ x_1 \end{pmatrix} \qquad [9]$$

where the constant k_1 is called the refracting power of surface 1 and is defined as

$$k_1 = \frac{n_1' - n_1}{r_1} \qquad [10]$$

To review the procedure for matrix multiplication, the first element $n_1' \alpha_1'$ in the one-column product matrix is calculated by multiplying the upper left-hand corner of the 2×2 matrix with the first element of the one-column matrix to its right, obtaining $1(n_1 \alpha_1)$, and to this is added the product $-k_1 x_1$ of the upper right-hand element in the 2×2 matrix and the second member of the one-column matrix. This square matrix is called

the refraction matrix R_1 for surface 1, defined as

$$R_1 = \begin{pmatrix} 1 & -k_1 \\ 0 & 1 \end{pmatrix} \qquad [11]$$

Next, we look at what happens to the ray as it travels from surface 1 to surface 2. As it goes from P_1 to P_2, its distance from the axis becomes

$$x_2 = x_1' + t_1' \tan \alpha_1' \qquad [12]$$

or using the paraxial approximation for small angles:

$$x_2 = x_1' + t_1' \alpha_1' \qquad [13]$$

Another approximation we shall use is to regard t_1' as being equal to the distance between the lens vertices V_1 and V_2. Using the identity:

$$\alpha_2 = \alpha_1' \qquad [14]$$

leads to a second matrix equation:

$$\begin{pmatrix} n_2\alpha_2 \\ x_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ t_1'/n_1' & 1 \end{pmatrix} \begin{pmatrix} n_1'\alpha_1' \\ x_1' \end{pmatrix} \qquad [15]$$

where the 2×2 translation matrix T_{21} is defined as

$$T_{21} = \begin{pmatrix} 1 & 0 \\ t_1'/n_1' & 1 \end{pmatrix} \qquad [16]$$

To get an equation which combines a refraction followed by a translation, we take the one-column matrix on the left side of eqn [9] and substitute it into eqn [15] to obtain

$$\begin{pmatrix} n_2\alpha_2 \\ x_2 \end{pmatrix} = T_{21} R_1 \begin{pmatrix} n_1\alpha_1 \\ x_1 \end{pmatrix} \qquad [17]$$

Note that the 2×2 matrices appear in right to left order and that the multiplication of two square matrices is an extension of the rule given above. This equation gives the location and slope of the ray which strikes surface 2 after a refraction and a translation. To continue the ray trace at surface 2, we introduce a second refraction matrix R_2 by expressing k_2 in terms of the two indices at this surface and the radius. Then eqn [17] is extended to give the relation:

$$\begin{pmatrix} n_2'\alpha_2' \\ x_2' \end{pmatrix} = R_2 T_{21} R_1 \begin{pmatrix} n_1\alpha_1 \\ x_1 \end{pmatrix} \qquad [18]$$

This process can obviously be applied to any number of components. The product of the three 2×2 matrices in the above equation is known as the system matrix S_{21} and it completely specifies the effect of the lens on the incident ray passing through it. It is also written as

$$S_{21} = R_2 T_{21} R_1 = \begin{pmatrix} b & -a \\ -d & c \end{pmatrix} \qquad [19]$$

where the four quantities a, b, c, and d are known as the Gaussian constants. They are used extensively in specifying the behavior of a lens or an optical system. We now state the sign and notation conventions which are necessary for the application of paraxial matrix methods:

1. Light normally travels from left to right.
2. The optical systems we deal with are symmetrical about the z-axis. The intersections of the refracting or reflecting surfaces with this axis are the vertices and are designated in the order encountered as V_1, V_2, etc.
3. Positive directions along the axes are measured from the origin in the usual Cartesian fashion, so that horizontal distances (that is, along the z-axis) are positive if measured from left to right. Angles are positive when measured up from the z-axis.
4. Quantities associated with the incident ray are unprimed; those for the refracted ray are primed.
5. A subscript denotes the associated surface.
6. If the center of curvature of a surface is to its right, the radius is positive, and vice versa.
7. There is a special rule for mirrors to be explained below.

Using the Gaussian Constants

Figure 5 shows the double convex lens of Figure 4 with the assumed locations of the cardinal points indicated. These positions, which we shall now determine accurately, are at distances designated as l_F, l_F', l_H, and l_H' and are measured from the associated vertex. The object position can be called t, a positive quantity which is measured to the right from object to the first vertex, or it can be called t_1 if measured in the opposite direction. For the first choice, the matrix specifying the translation from object to lens will have the quantity t/n_1 in its lower left-hand corner. However, it is both logical and convenient to use the first vertex as the reference point. Hence, we replace t/n_1 in the translation matrix with the quantity $-t_1/n_1$, and remember to specify t_1 as a negative number when calculating the image position. The equation connecting object and image is obtained by starting with this matrix, multiplying it by the system matrix of eqn [19], and finally by a translation matrix

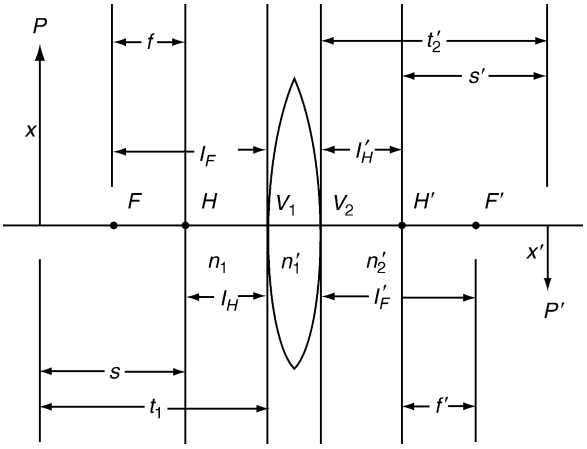

Figure 5 Definitions of cardinal plane locations.

corresponding to the translation t_2' from lens to image to obtain:

$$\begin{pmatrix} n_2'\alpha_2' \\ x' \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ t_2'/n_2' & 1 \end{pmatrix} \begin{pmatrix} b & -a \\ -d & c \end{pmatrix} \times \begin{pmatrix} 1 & 0 \\ -t_1/n_1 & 1 \end{pmatrix} \begin{pmatrix} n_1\alpha_1 \\ x \end{pmatrix} \quad [20]$$

where α or α_1 is the angle that the ray from the top of the object makes with the z-axis. This equation takes the initial value of the inclination α and of the position x of the ray leaving the object, and determines the final values, α' and x' at the image. The product of the three 2×2 matrices on the right-hand side can be consolidated into a single matrix called the object-image matrix $S_{P'P}$. Then eqn [20] can be written as

$$\begin{pmatrix} n_2'\alpha_2' \\ x' \end{pmatrix} = S_{P'P} \begin{pmatrix} n_1\alpha_1 \\ x \end{pmatrix} \quad [21]$$

and this matrix has the complicated form:

$$S_{P'P} = \begin{pmatrix} b + \dfrac{at_1}{n_1} & -a \\ \dfrac{bt_2'}{n_2'} + \dfrac{at_1t_2'}{n_1n_2'} - d - \dfrac{ct_1}{n_1} & c - \dfrac{at_2'}{n_2'} \end{pmatrix} \quad [22]$$

If we put this matrix into the previous equation, we obtain an unsatisfactory result: the value of x' will depend on the angle α_1 made by the incident ray, as can be seen by multiplying the two matrices on the right side. The ratio of x' to x is called the magnification m; that is

$$m = \frac{x'}{x} \quad [23]$$

A perfect image can be formed only if the magnification is determined solely by the object distance and the constants of the lens. To eliminate this difficulty, the lower left-hand element in the matrix, eqn [22] is required to be equal to zero, and the magnification is then:

$$m = \frac{x'}{x} = c - \frac{at_2'}{n_2'} \quad [24]$$

The determinant of this matrix is unity, since it is the product of three matrices whose individual determinants are unity. It follows that

$$\frac{1}{m} = b + \frac{at_1}{n_1} \quad [25]$$

so that

$$\begin{pmatrix} n_2'\alpha_2' \\ x' \end{pmatrix} = \begin{pmatrix} 1/m & -a \\ 0 & m \end{pmatrix} \begin{pmatrix} n_1\alpha_1 \\ x \end{pmatrix} \quad [26]$$

Using the fact that the lower left-hand element of the matrix eqn [22] is zero shows that

$$\frac{t_2'}{n_2'} = \frac{d + ct_1/n_1}{b + at_1/n_1}, \qquad \frac{t_1}{n_1} = \frac{d - bt_2'/n_2'}{-c + at_2'/n_2'} \quad [27]$$

This equation connects the object distance t_1 with the image distance t_2', both quantities being measured from the appropriate vertex. This relation is known as the generalized Gauss lens equation. It applies to all lens systems, no matter how complicated.

We can determine the location of the unit planes by letting $m = 1$. This t_2' in eqn [27] is the location l_H' of the image space unit plane, and it becomes

$$l_H' = \frac{n_2'(c-1)}{a} \quad [28]$$

This relation expresses the location of the unit plane on the image side as the distance from V_2 to H'. Similarly, the location of H with respect of V_1 is

$$l_H = \frac{n_1(1-b)}{a} \quad [29]$$

To locate the focal planes, consider a set of parallel rays coming from infinity and producing a point image at F'. The terms containing t_1 in eqn [27] are

much larger than d or b, and this relation becomes

$$l'_F = \frac{n'_2 c}{a} \qquad [30]$$

Letting t'_2 become infinite in the right-hand half of eqn [27], the location of F is given by the equation

$$l_F = \frac{-n_1 b}{a} \qquad [31]$$

The focal lengths f and f' shown in **Figure 5** were defined earlier as the distances between their respective focal and unit planes. Hence

$$f' = l'_F - l'_H = \frac{n'_2}{a} \qquad [32]$$

and

$$f = l_F - l_H = \frac{-n_1}{a} \qquad [33]$$

If we let $n_1 = n'_2 = 1$ for air, these become

$$-f = f' = \frac{1}{a} \qquad [34]$$

The Gaussian constant a is thus the reciprocal of the focal length in air. Even when the lens is not in air, it is still true that $f' = -f$ if the lens is in a single medium. It is also true regardless of whether or not the lens is symmetric.

It is customary in optics to work with a consistent set of units, such as centimeters or millimeters, and the sign conventions used for x and y are the standard Cartesian rules. As mentioned above, curved surfaces which open to the right have a positive radius and vice versa. As an example, let a double convex lens have radii of 2.0 and 1.0, respectively, an index of refraction of 1.5, and a thickness of 0.5. These quantities are then denoted as

$$r_1 = +2.0, \qquad r_2 = -1.0, \qquad t'_1 = t_2 = +0.5$$
$$n_1 = 1.0, \qquad n'_1 = 1.5 = n_2, \qquad n'_2 = 1.0 \qquad [35]$$

By eqn [10]:

$$k_1 = \frac{n'_1 - n_1}{r_1} = \frac{1.5 - 1.0}{2.0} = 0.25 \qquad [36]$$

and

$$k_2 = \frac{1.0 - 1.5}{-1.0} = 0.50 \qquad [37]$$

The system matrix S_{21} is

$$S_{21} = R_2 T_{21} R_1 = \begin{pmatrix} 1 & -0.50 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0.5/1.5 & 1 \end{pmatrix} \begin{pmatrix} 1 & -0.25 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0.83 & -0.71 \\ 0.33 & 0.92 \end{pmatrix} \qquad [38]$$

and we note that the determinant is

$$(0.83)(0.92) - (0.71)(-0.33) = 1.00 \qquad [39]$$

This property of the system matrix provides a very useful check on the accuracy of matrix multiplications. The locations of the four cardinal points can be determined from the formulas given above and their locations are shown in the scale drawing of **Figure 6**. Since we know how to locate the cardinal points of a lens, we are in a position to ray trace in a precise manner, using the method of **Figure 3** and adding a third ray. After locating F, H, H', and F', we no longer need the lens; the cardinal planes with the proper separation are fully equivalent to the lens they replace. This is very much like what electrical engineers do when they replace a complicated circuit with a black box; this equivalent circuit behaves just like the original. Ray tracing becomes more complicated when we deal with diverging lenses (**Figure 7**), but the procedure gives above still applies. Parallel rays spread apart and do not come to a focus on the right-hand side of the lens. However, if the refracted

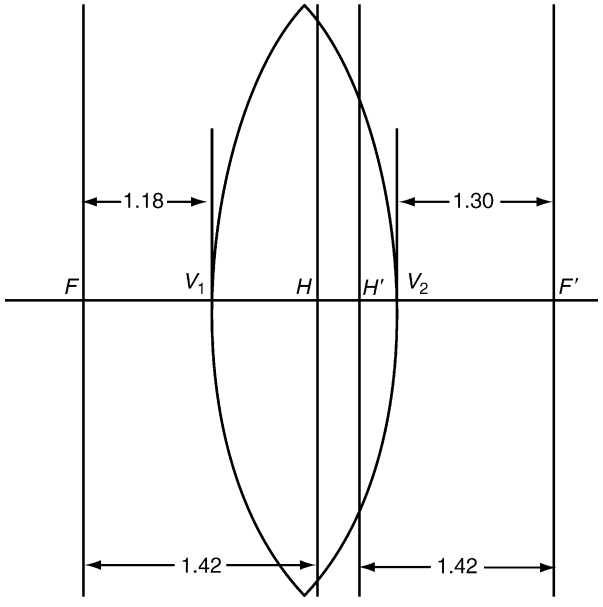

Figure 6 Positions of cardinal planes for an asymmetric lens.

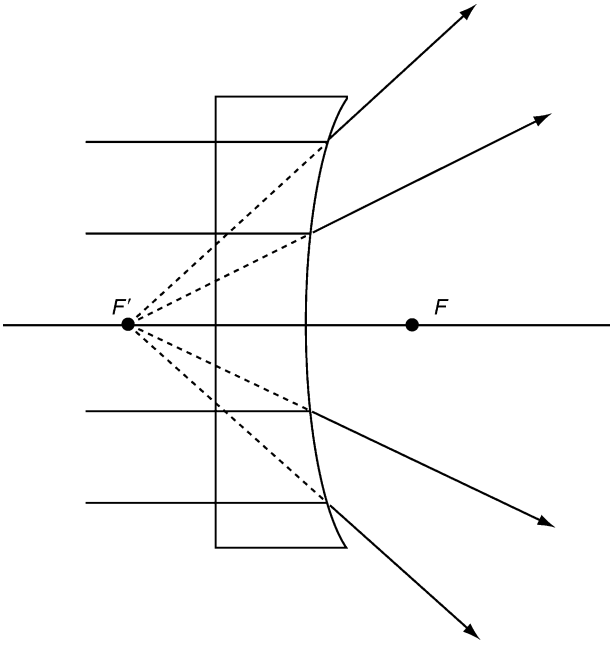

Figure 7 Ray tracing for a planar-concave lens.

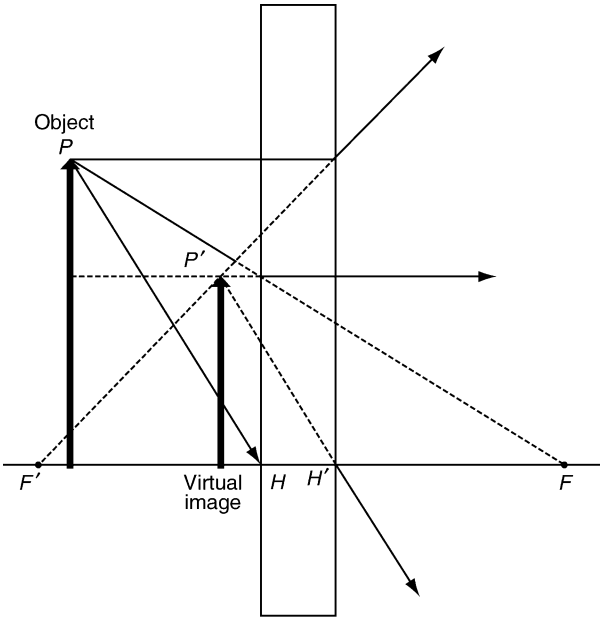

Figure 9 Formation of a virtual image by a concave lens.

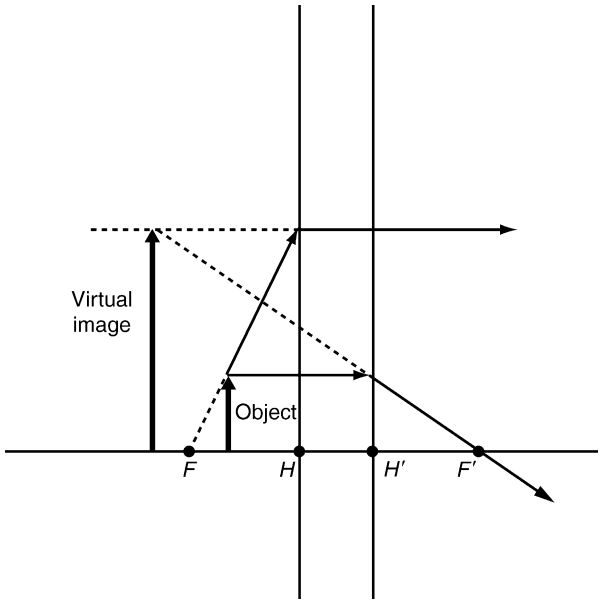

Figure 8 Formation of a virtual image by a convex lens.

rays are extended backwards, these extensions will meet as indicated. This behavior can be verified quantitatively by using the formulas developed above. It will be found that F and F' have exchanged places, but H and H' retain their original positions inside the lens. If an object is placed between the focal point F and the first vertex of a convex lens (Figure 8), then our usual procedure produces two rays which do not intersect in image space. The ray from the object which is parallel to the axis is refracted downward so that it does not intersect the other ray in image space. However, the extensions to the left of these two rays meet to form an image which is erect, magnified, and virtual. This is the normal action of a magnifying lens; the image can be seen but cannot be projected onto a screen, unlike the real, inverted image of Figure 3. This ray tracing diagram confirms what would be seen when a double convex lens is used to magnify an object lying close to the lens. For the double concave lens of Figure 9, a parallel ray leaves an object point P and is refracted upward at the unit plane H' in such a way that its extension, rather than the ray itself, passes through F'. The ray headed for F is refracted at H before it can reach the object-space focal plane and becomes parallel to the axis. The third ray, going from P to H, emerges at H' parallel to its original direction and its extension to the left passes through the image point P' already determined by the intersection of the other two rays. The resulting virtual image is upright and reduced. All three rays in this diagram behave exactly like the corresponding rays in Figure 3; the only change is the use of the extensions to locate the image. The eye receives the diverging rays from P and believes that they are coming from P'.

Nodal Points and Planes

Let a ray leave a point on the z-axis at an angle α_1, and have an angle α_2' when it reaches image space.

Since $x = 0$ at the starting point, eqn [26] shows that

$$n'_2\alpha'_2 = n_1\alpha_1/m \qquad [40]$$

The ratio of the final angle to the initial angle in this equation is the angular magnification μ, which is then

$$\mu = n_1/mn'_2 \qquad [41]$$

The locations of object and image for unit angular magnification are called the nodal points, labeled as N and N'. The above definition shows that the linear and angular magnification are reciprocals of one another when object and image are in air or the same medium. The procedure that located the unit points will show that the nodal points have positions given by

$$\frac{l_N}{n_1} = \frac{(n'_2/n_1) - b}{a} \qquad [42]$$

and

$$\frac{l'_N}{n'_2} = \frac{c - (n_1/n'_2)}{a} \qquad [43]$$

When the two indices are identical, these relations are identical to those for the points H and H'. That is why the rays from P to H and H' to P' in Figure 3 are parallel.

Compound Lenses

A great advantage of the paraxial matrix method is the ease of dealing with systems having a large number of lenses. To start simply, consider the cemented doublet of Figure 10: a pair of lenses for which surface 2 of the first element and surface 1 of the second element match perfectly. The parameters of this doublet are given in the manner shown below.

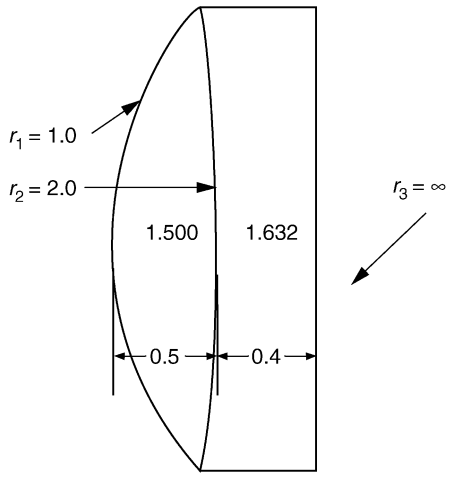

Figure 10 Specification for a cemented doublet.

It is understood that the first entry under r is r_1, the second entry is r_2, and so on. Note that this doublet has only three surfaces; if the two parts were separated by an air space, producing an air-spaced doublet, then there would be four surfaces to specify. The values of the indices n' and the spacings t' are placed between the values of r. The constants of the doublet are then

r	n'	t'
1.0		
	1.500	0.5
−2.0		
	1.632	0.4
∞		

[44]

Note that surface 3, which is flat, has a radius of infinity. Numbering the vertices in the usual manner, the system matrix is

$$S_{31} = R_3T_{32}R_2T_{21}R_1 \qquad [45]$$

where

$$k_2 = (n'_2 - n_2)/r_2 = (1.632 - 1.500)/-2.0 \qquad [46]$$

Approximations for Thin Lenses

An advantage of paraxial matrix optics is the ease of obtaining useful relations. For example, combining the several expressions for the Gaussian constant a, we obtain:

$$a = -\frac{n_1}{f} = \frac{n'_2}{f'} = k_1 + k_2 - \frac{k_1k_2t'_1}{n'_1} \qquad [47]$$

and using the definitions of k_1 and k_2 with the lens in air leads to

$$\frac{1}{f'} = (n'_1 - 1)\left[\frac{1}{r_1} - \frac{1}{r_2} + \frac{(n'_1 - 1)t'_1}{n'_1r_1r_2}\right] \qquad [48]$$

which is the lensmakers' equation. It tells how to find the focal length of a lens from a knowledge of its material and geometry. This derivation is much more direct than what you will usually find. This equation becomes simpler when we are dealing with thin lenses – those for which the third term in brackets can be neglected by assuming that the lens thickness

is approximately zero. Then

$$\frac{1}{f'} = (n'_1 - 1)\left[\frac{1}{r_1} - \frac{1}{r_2}\right] \qquad [49]$$

which is the form often seen in texts. We then realize that the original form is valid for lenses of any thickness, but the thin lens form can be used if the spacing is much less than the two radii. It is also seen that when the thickness is approximately zero, then

$$b = c = 1 \qquad [50]$$

and the unit planes have locations

$$l_H = l'_H = 0 \qquad [51]$$

Thus, they are now coincident at the center of the lens. A ray from any point on the object would pass undeviated through the geometrical center of the lens, as is often shown in the elementary books. These new values of the Gaussian constants give a system matrix of the form:

$$S_{21} = \begin{pmatrix} 1 & -1/f' \\ 0 & 1 \end{pmatrix} \qquad [52]$$

This matrix contains a single constant, the focal length of the lens, so that the preliminary design of an optical system is merely a matter of specifying the focal length of the lenses involved and using the resulting matrices to determine the object-image relationship. We also note that this matrix looks like a refraction matrix; the non-zero element is in the upper right-hand corner. This implies that the refraction–translation–refraction procedure that actually occurs can be replaced, for a thin lens, by a single refraction occurring at the coinciding unit planes. Ophthalmologists take advantage of the thin lens approximation by specifying focal lengths in units called diopters. The reciprocal of the focal length in meters determines its refraction power in diopters. For example, a lens with $f' = 10$ cm will be a 10 diopter lens. If two lenses are placed in contact, the combined power is the sum of the individual powers, for multiplying matrices of the above form gives the upper right-hand element as $(-1/f'_1 - 1/f'_2)$.

The Paraxial System for Design or Analysis

The material given in this article can serve as the basis for an organized way of taking the specifications of an optical system and using them to gain a full understanding of this system. We shall demonstrate it with a practical example which has some interesting features. Chemical engineers have long known that the index of refraction of a liquid can be determined by observing the empty bore of a thick glass tube with a telescope having a calibrated eyepiece and then measuring the magnification of the bore when the liquid flows through it. Consider a liquid with an index of 1.333 and a tube with bore radius of 3 cm, outer radius of 4 cm, and glass of index equal to 1.500. The first step is to specify the parameters of the optical system. These are the radii $r_1 = -3$, $r_2 = -4$ and the thickness $t'_1 = 1$, regarding the tube as a concentric lens with an object to its left; the indices $n_1 = 4/3$ (fractions are convenient), $n'_1 = 3/2$, $n'_2 = 1$. Calculating the elements of the two refraction matrices and the translation matrix, the system matrix is

$$S_{21} = \begin{pmatrix} 1 & -1/8 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 2/3 & 1 \end{pmatrix}\begin{pmatrix} 1 & 1/18 \\ 0 & 1 \end{pmatrix} \qquad [53]$$

Multiplying, the Gaussian constants are

$$a = 2/27, \quad b = 11/12, \quad c = 28/27, \quad d = -2/3 \qquad [54]$$

An important check is to verify that $bc - ad = 1$, as is the case here. The expressions given previously for the positions of the cardinal points then lead to the values

$$\begin{aligned} &l_H = 3/2, \qquad l'_H = 1/2, \qquad l_F = -16\ 1/2, \\ &l'_F = 14, \qquad l_N = -3, \qquad l'_N = -4 \end{aligned} \qquad [55]$$

These points are shown in Figure 11. Although the same scale has been used for both horizontal and vertical distances, this is usually not necessary; the vertical scale, which merely serves to verify the magnification, can be arbitrary. The entire liquid column is the object in question, but it is simpler to use a vertical radius as the object. Then the image, generated as described in all the previous examples,

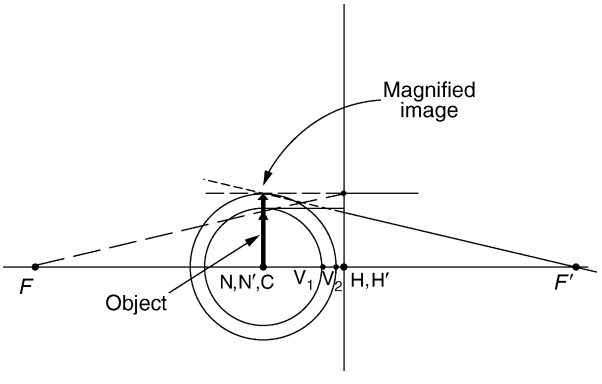

Figure 11 Ray tracing diagram for a thick-walled glass tube.

coincides with the object and it is enlarged, erect, and virtual. We confirm the image location shown by using the generalized Gaussian lens equation, giving

$$t' = [(-2/3) + (28/27)(-3)/(4/3)]/[(11/12) + (2/27)(-3)/(4/3)] = -4 \quad [56]$$

and this agrees with the sketch. The denominator of this expression was shown to be the reciprocal of the magnification $1/m$ with a value of 3/4, and m itself can be calculated from t' as $c - at' = 4/3$; this is another important check on the accuracy of the calculation; the sketch obeys this conclusion, and the purpose of this analysis is confirmed.

Reflectors

To show how reflecting surfaces are handled with matrices, consider a plane mirror located at the origin and normal to the z-axis (Figure 12). The ray which strikes it at an angle α_1 leaves at an equal angle, resulting in specular reflection. Since $k = 0$ for a flat surface, the refraction matrix reduces to the unit matrix and by eqn [9]:

$$n'_1\alpha'_1 = n_1\alpha_1 \quad [57]$$

This contradicts Figure 12, since α_1 and α'_1 are opposite in sign.

If, however, we specify that

$$n'_1 = -n_1 \quad [58]$$

then the difficulty is removed. Hence, reflections involve a reversal of the sign on the index of refraction, and two successive reflections restore the original sign. For a mirror, the refraction power is

$$k_1 = \frac{n'_1 - n_1}{r_1} = \frac{-1 - (1)}{r_1} = -\frac{2}{r_1} \quad [59]$$

The system matrix for a single refracting surface thus becomes

$$S_{11} = R_1 = \begin{pmatrix} 1 & -k_1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 2/r_1 \\ 0 & 1 \end{pmatrix} \quad [60]$$

with

$$a = -2/r_1, \qquad b = c = 1, \qquad d = 0 \quad [61]$$

The connection between object and image can be expressed as

$$\begin{pmatrix} n'_1\alpha'_1 \\ x'_1 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ t'/n'_1 & 1 \end{pmatrix} \begin{pmatrix} b & -a \\ -d & c \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -t/n_1 & 1 \end{pmatrix} \begin{pmatrix} n_1\alpha_1 \\ x_1 \end{pmatrix} \quad [62]$$

and using the same procedure that was applied to eqns [28]–[31], the locations of the six cardinal points are

$$l_F = -n_1 b/a, \quad l'_F = n'_1 c/a$$

$$l_H = n_1(1-b)/a, \quad l'_H = n'_1(c-1)/a \quad [63]$$

$$\frac{l_N}{n_1} = \frac{(n'_1/n_1) - b}{a}, \quad \frac{l'_N}{n'_1} = \frac{c - (n_1/n'_1)}{a}$$

so that for the spherical mirror:

$$l_F = \frac{(-1)(1)}{-2/r_1} = \frac{r_1}{2} = l'_F \quad [64]$$

$$l_H = l'_H = 0 \quad [65]$$

and

$$l_N = \frac{-1-1}{-2/r_1} = r_1 \quad [66]$$

but

$$\frac{l'_N}{-1} = \frac{1-(-1)}{-2/r_1}, \quad l'_N = r_1 \quad [67]$$

Since r_1 is negative, these equations show that the unit points lie on the vertex, the foci coincide halfway between the center of curvature and the

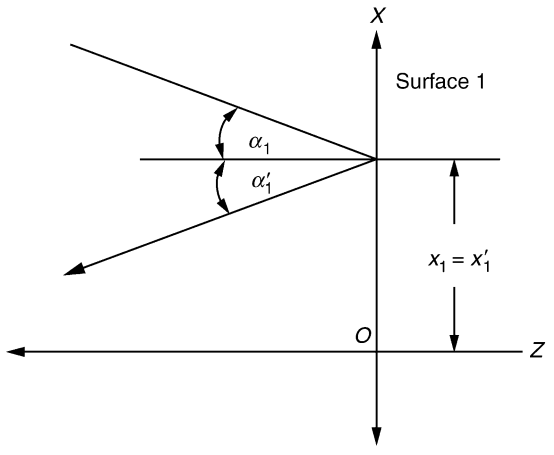

Figure 12 Specular reflection.

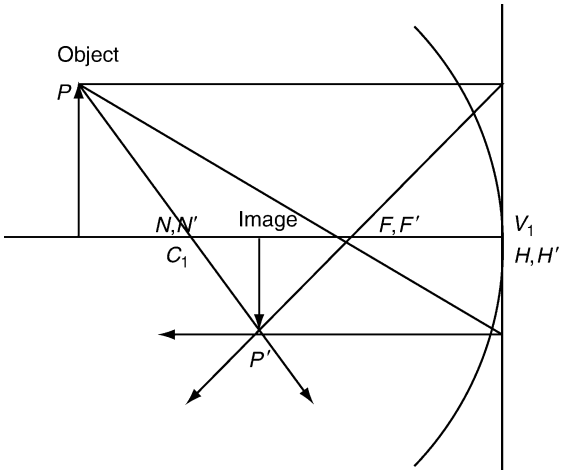

Figure 13 Ray tracing for a concave mirror.

vertex, and the nodal points are at this center. The perfect focusing is a consequence of the paraxial approximation. The true situation is presented in **Geometrical Optics:** Aberrations. Ray tracing for this mirror uses the procedure developed for lenses, which applies to optical systems of any complexity. Figure 13 shows an object to the left of the center of curvature. The ray from P parallel to the axis goes to H' and then through F', while the ray through F goes to H and then becomes parallel to the axis. Their intersection at P' produces a real, inverted image. The third set of rays represents something different: it requires a knowledge of the nodal point locations. The ray from P to N should be parallel to the ray from N' to P', by definition; in this example, they meet this requirement by being colinear.

As an example of the power of matrix optics to simplify the design or analysis of an optical system involving lenses and mirrors, consider an object that is 15 units to the left of a converging lens, with focal length $f' = 10$. A concave mirror, of radius $r_1 = 16$, is 20 units to the right of the lens. The refraction power of the mirror is $k_1 = (-1 - 1)/-16 = 1/8$ and using the thin lens form of the system matrix, the combined matrix is

$$\begin{pmatrix} 1 & -1/8 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 20 & 1 \end{pmatrix}\begin{pmatrix} 1 & -1/10 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} -3/2 & 1/40 \\ 20 & -1 \end{pmatrix} \quad [68]$$

This gives the constants a, b, c, and d, from which we find that the image is $-4\ 4/9$ units to the left of the mirror, its magnification is $-8/9$, and it is inverted. Compare the simplicity of this procedure with the usual way of doing this calculation, which involves first finding the image in the lens and then using that image as a virtual object.

Conclusion

It has been shown that the use of paraxial matrices provides a simple approach to an understanding of the kind of optical systems that provide perfect images. Further details and derivations of expressions given here will be found in the Further Reading below.

Introduction

The article **Geometrical Optics:** Lenses and Mirrors, describes image formation by components which are optically perfect. The images may be magnified or reduced and they may be erect or inverted, but they are otherwise faithful replicas of the object. This behavior is a consequence of ray tracing based on an approximate or paraxial form of Snell's law which we write as

$$n\theta = n'\theta' \quad [1]$$

where n and n' are the indices of refraction on either side of an interface and θ and θ' are the angles of incidence and refraction. If, however, the following exact form of Snell's law:

$$n \sin\theta = n' \sin\theta' \quad [2]$$

governs the ray behavior, as is the case when the rays have large inclinations with respect to the symmetry axis, then it is necessary to devise a more involved ray

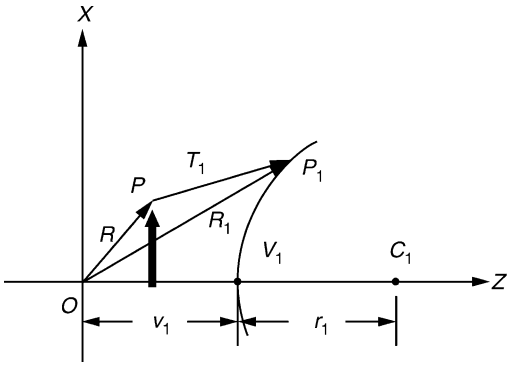

Figure 1 Ray tracing in the meridional plane.

tracing procedure. Figure 1, which shows the first surface of a lens, will be used to explain how this procedure works. A ray leaves the object point P and strikes the lens surface at the point P_1. Rays which lie completely in the plane ZOX are said to be meridional; this is the plane which passes through the symmetry axis, just as meridians on the Earth's surface are determined by planes through the geographic axis. By regarding the various distances in the figure as vectors, it is possible to start with the initial coordinates of the ray and with the direction-cosines which specify its slope and find the coordinates of the point P' where the ray strikes the lens surface. A derivation of the equation governing this process will be found in the text of A Nussbaum (see Further Reading). This derivation involves only elementary algebra and vector analysis, and will be found simpler than the usual textbooks treatment of ray tracing procedures. The equation is

$$T_1 = \frac{F}{-E + \sqrt{E^2 - c_1 F}} \qquad [3]$$

where

$$E = Bc_1/2 = c_1[(z - v_1)N + xL] - N \qquad [4]$$

and

$$F = Cc_1 = c_1\left[(z - v_1)^2 + x^2\right] - 2(z - v_1) \qquad [5]$$

Knowing the coordinates z and x of the starting point P of the ray, as well as its starting cosines N and L, plus the curvature c_1 or radius $r_1 = 1/c_1$ of the lens surface and the location v_1 of the surface's vertex, we can readily calculate the length T_1 of the ray. Then its components on the two axes give the coordinates of P'. Next, we need to find the slope of the ray after it is refracted at the lens surface, and this can be calculated from Snell's law combined with the behavior of the incident and refracted rays regarded as vectors. Again we invoke the reference cited above for a derivation of the equations giving the value of the direction-cosines after refraction; these expressions are

$$n'_1 N'_1 = K_1/c_1 + n_1 N_1 - K_1 z_1 \qquad [6]$$

and

$$n_1 L'_1 = n_1 L_1 - K_1 x_1 \qquad [7]$$

where K_1 is known as the refracting power and has the definition

$$K_1 = c_1(n'_1 \cos\theta' - n_1 \cos\theta) \qquad [8]$$

The ray can now be traced to the next surface knowing the lens thickness, and then to the image plane. These two sets of equations, when incorporated into a computer program of about two dozen lines, will trace meridional rays to any desired accuracy through an optical system containing an arbitrary number of lenses and spherical reflectors. As an example, consider a symmetric double convex lens with radii of 50 units at surface 1, −50 units at surface 2, a thickness of 15 units, and an index of 1.50. Rays parallel to the axis – one at 0.2 units above the axis, a second one at 2 units above the axis, and a third one at 20 units above the axis – are started well to the left and traced to the paraxial focal plane, which is at 47.368 units from the second surface. The ray that is 0.2 units above the axis will cross the focal plane at the axis; this is a paraxial ray, passing through the paraxial focal point F'. The ray which is 2 units above the axis crosses the focal plane slightly below the focal point, and is therefore not quite paraxial, while the ray which starts at 20 units above the axis falls well short of the focal point, intersecting the axis before it reaches the focal plane. This behavior indicates that the lens possesses a defect known as spherical aberration and these calculations imply that spherical aberration should be defined as the failure of nonparaxial rays to conform to the behavior of paraxial rays. This definition does not appear in optics texts, and the few definitions that are given appear to be incorrect. As clearly indicated in **Geometrical Optics:** Lenses and Mirrors, the focal point of a lens is strictly a paraxial concept and it is a constant, obtainable from the parameters of the lens or lens system. It is meaningless to speak of a focal point as defined by a pair of nonparaxial rays; this infinite set of ray-pairs determines a corresponding number of intersection points, all of which fall short of the true focal point F'. This situation is nicely illustrated by the next figure, which shows a large number of parallel rays, the central ones being paraxial and the others behaving differently. The rays which are very close to the axis will meet as

expected at the focal point F'. The rays a little farther out – the intermediate rays – will cross the axis just a little to the left of F', and those near the edge of the lens – the *marginal* rays – will fall very short, as indicated. Rotating this diagram about the axis, we realize that spherical aberration produces a very blurry circular image at the paraxial plane. The three-dimensional envelope of the group of rays produced by this rotation is known as the caustic surface and the narrowest cross-section of this surface, slightly to the left of the paraxial focal plane, is called the circle of least confusion. If this location is chosen as the image plane, then the amount of spherical aberration can be reduced somewhat. Other methods of improving the image will be considered below. Figure 2 was obtained by adding a graphics step to the computer program described above. Figure 3 shows how to define spherical aberration quantitatively. Two kinds of aberration are specified in this figure. The place where the ray crosses the axis, lying to the left of F', is at a distance, measured from the paraxial focus, called the longitudinal spherical aberration (LSA), while the distance below the axis at the focal plane is the transverse spherical aberration (TSA). To reduce this aberration, note in Figure 2 that the amount of refraction at the two surfaces of the lens for marginal rays is not the same. Equalizing the refraction at the two surfaces will improve the situation. Suppose we alter the lens while keeping the index, thickness, and focal length constant; only the radii will change. This can be done if the new radii satisfy the paraxial equation giving the focal length in terms of the lens constants. The process of varying the shape of lens, while holding the other parameters constant, is called *bending the lens*. This can be easily accomplished by a computer program, obtaining what are known as optimal shape lenses, which are commercially available. To study their effect on spherical aberration, define the shape factor σ of a lens as

$$\sigma = \frac{r_2 + r_1}{r_2 - r_1} \qquad [9]$$

from which $\sigma = 0$ for a symmetric lens ($r_1 = -r_2$). Figure 4a shows the monitor screen for a symmetric lens, and Figure 4b illustrates the result of lens bending. This lens has had the curvature of the first surface raised and the second surface has been flattened to keep the focal length constant. Let us now consider what lens designers can do about spherical aberration. Brouwer in his book (see Further Reading) gives the specifications for a cemented doublet consisting of a double convex lens followed by a lens with two concave surfaces. The longitudinal spherical aberration of the front lens alone varies as shown in Figure 5. The way that the designer arranged for the marginal rays to meet at the paraxial focus, rather than falling short, was to recognize that a diverging lens following the front element would refract the rays away from – rather than closer to – the axis. When this second component is added, we would expect the behavior shown in Figure 6. Note that the value of LSA for the doublet has been enormously reduced, as indicated by the horizontal scale change. Spherical aberration can be reduced in more elaborate systems as part of the design process. Telescopes, in particular, make use of corrector plates which are placed in front of the large mirrors.

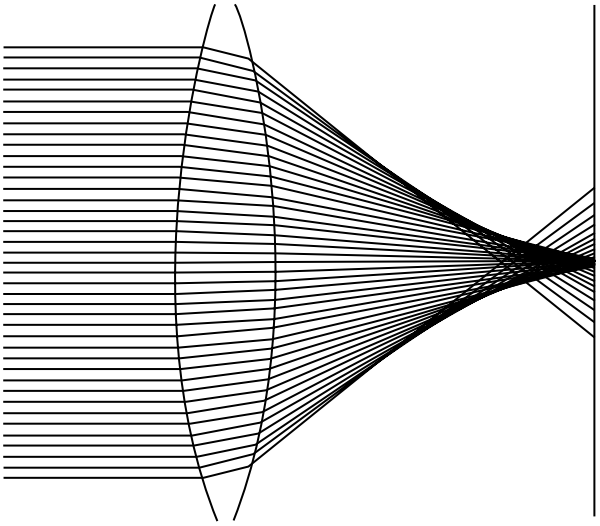

Figure 2 Spherical aberration for parallel meridional rays.

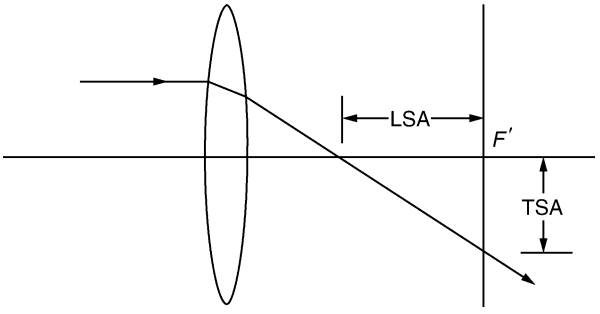

Figure 3 Definitions of transverse and longitudinal spherical aberration.

Coma

We have seen how to trace nonparaxial, meridional rays and found that spherical aberration appears because the intermediate and marginal rays do not behave like the central rays. We now wish to deal

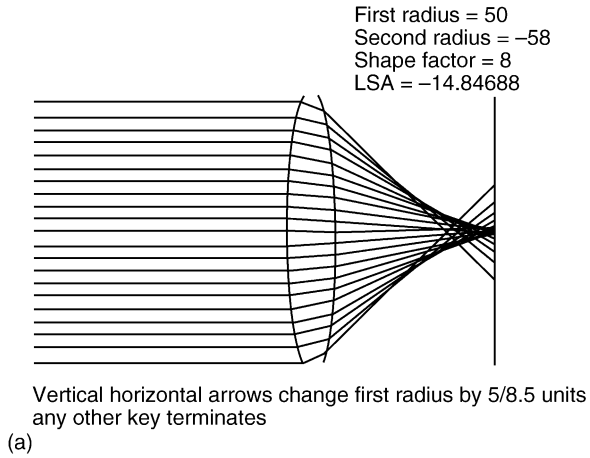

Figure 4 Lens bending as performed numerically.

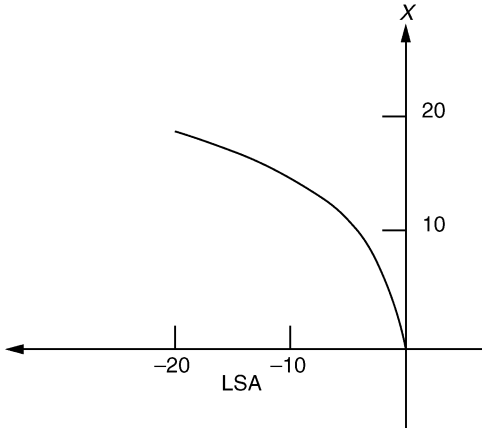

Figure 5 Spherical aberration for a single lens.

with rays that do not lie in a meridional plane; these are nonmeridional or skew rays. Calculating the behavior of such a ray would appear to be a complicated problem, but it turns out to be a simple extension of what has already been accomplished. Let a skew ray start at an arbitrary point in space with coordinates x, y, and z and let it have direction

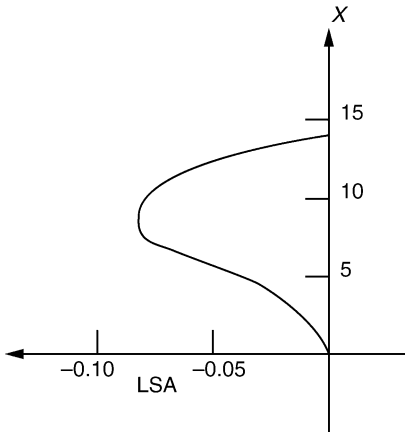

Figure 6 Reduction of spherical aberration by a doublet.

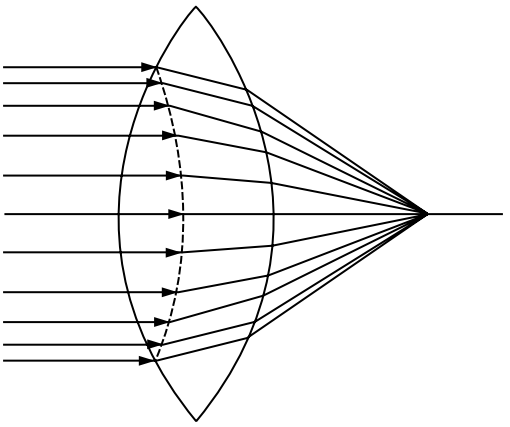

Figure 7 Configuration used to illustrate coma.

cosines L, M, and N with respect to OX, OY, and OZ. The points P and P_1 in Figure 1 are now out of the plane ZOX and when the vectors in this figure are expressed as the sum of three, rather than two, components, the equations given above for meridional rays acquire terms in y and M which have the same form as those for x and L. Now trace a set of skew rays chosen to lie on a cylinder (Figure 7) which is centered about the z-axis of a lens, so that all the rays are meridional. These rays are fairly far from the axis, so that they are also nonparaxial, but they all meet at a common image point, forming a cone whose apex is this image point. Then give this cylinder a downward displacement while holding fixed the intersection point of each ray with the dotted circle on the front of the lens. The tilting of the cylinder changes all its rays – except the top and the bottom rays – from meridional to skew. In addition, the cone on the image side will then tilt upwards; it should not change in any other way if the skew rays continue to meet at a well-defined apex. But this is not what happens in a simple lens, as will now be explained.

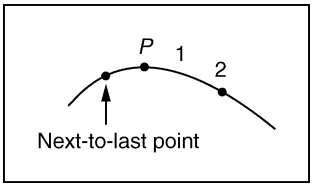

Figure 8 Starting a coma plot.

Let the top and bottom meridional rays meet at a point P in image space (Figure 8) and use this point to determine the location of an image plane. The skew ray just below the uppermost ray in Figure 7 will pass through this plane fairly close to the intersection point. Let us guess (and confirm later) that it will pass through a point slightly to the right of P and a little below it, as we observe this plane from the lens position. This is point 1 in Figure 8. The next skew ray on the front of the lens will strike the image plane still farther below and to the right, producing point 2 in the figure. As we continue to trace these rays down the front half of the circle, we realize that a ray almost at the bottom of Figure 7 will have to be very close to the lower meridional ray and that its image point is just below but to the left of P; this is the point labeled 'next-to-last' in Figure 8. All of these points join to form a closed curve. The back halves of the dotted circle and of the ray cylinder are not shown in the figure, but since we are again starting at P in Figure 8, the pattern will repeat itself. That is, we get a second closed curve which – by symmetry – should be identical to the first curve. This is a most unusual effect; double-valued phenomena are quite rare. To confirm this prediction, we use the skew ray equations, and trace the pattern formed by a set of concentric cylinders of different sizes. The appearance of the coma pattern generated by the computer is shown in Figure 9. Each half-circle on the front side of the lens produces a closed figure (an approximation to a circle) as an image. If coma were the only aberration (when it is called ideal coma), the plots would be the perfect, coinciding circles of Figure 10. The comet-like shape explains where the name comes from. We can picture the generation of these circles in the way shown in this figure. The ray through the geometrical center of the lens produces a point in the paraxial focal plane. The top and bottom rays (the meridional rays) from the circles of increasing size produce points which define image planes that are successively closer to the lens; this is a consequence of spherical aberration. Moving the top ray parallel to itself and along the half-circle generates the image plane pattern. The lines tangential to the coma circles make an angle of 60° with each other, as can be seen by measurement on the computer output. Most optics

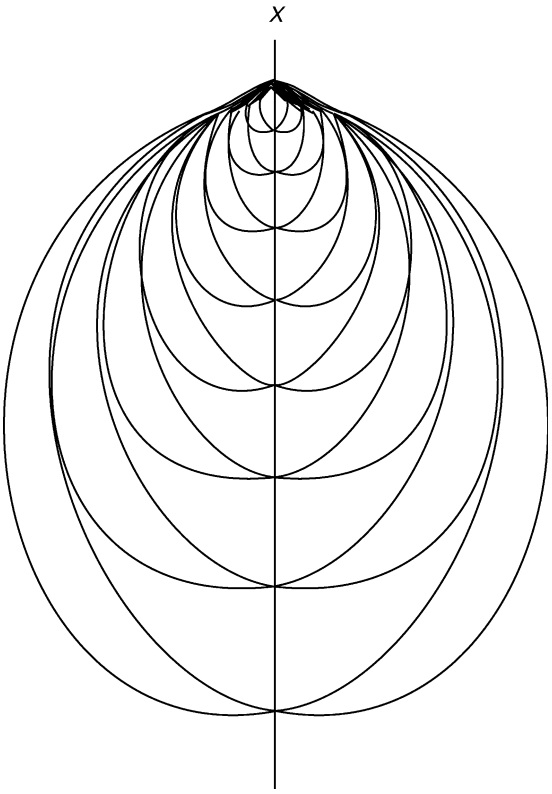

Figure 9 Coma as calculated numerically.

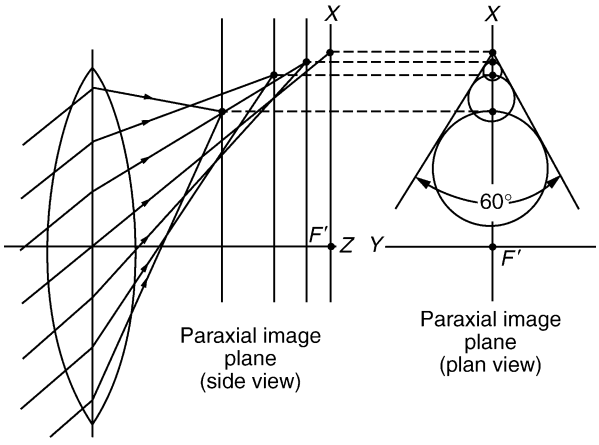

Figure 10 Customary way of illustrating coma.

books look at coma in a way different from that given here. Coma has been defined by WJ Smith (see Further Reading) as the variation of magnification with aperture, analogous to the definition of spherical aberration as the variation of focal length with aperture. And as was previously mentioned, focal length and magnification are purely paraxial concepts, not applicable to the description of aberrations. The definition that comes from the arguments

given above is that coma is the failure of skew rays to match the behavior of meridional rays, just as spherical aberration is the failure of meridional rays to match the behavior of paraxial rays. Most texts show coma in its ideal form.

Astigmatism

We have shown that spherical aberration is the failure of meridional rays to obey the paraxial approximation and coma is the failure of skew rays to match the behavior of meridional rays. To see the connection between these two aberrations, consider the object point P of Figure 11. This very complicated diagram can actually be very helpful in understanding the third of the five geometrical aberrations. Let P be the source of a meridional fan: this is the group of rays with the top ray labeled PA and the bottom ray is PB. If the lens is completely corrected for spherical aberration, this fan will have a sharp image point P_T' lying directly below the z-axis. Now let P also be the source of a fan bounded by the rays PC and PD. This fan is at right-angles to the other one; we can think of these rays as having the maximum skewness possible. If the lens has no coma, this fan also will produce a sharp image point P_s' which, for a converging lens, will be farther from the lens than the tangential focal point. In other words, even though the lens has been fully corrected for both aberrations, the two corrections will not necessarily produce a common image. In the figure, the meridional fan is called a tangential fan and the skew fan is called a sagittal fan; these are the terms commonly used by lens designers. The failure of the sagittal and tangential rays to produce a single image in a lens corrected for both spherical aberration and coma is known as astigmatism. Astigmatism, coma, and spherical aberration are the point aberrations that an optical system can have. We have already noted that spherical aberration is the only one that can be associated with a point on the z-axis; the others require an off-axis object. Astigmatism is very common in the human eye; to see how it shows up, look at the sagittal image point P_s' of Figure 11. This point is a distance z_s, from the x,y-plane. A plane through this point will have a line image on it, the sagittal line, due to the tangential fan, which has already come to a focus and is now diverging. The converse effect, producing a tangential line, occurs at the other image plane. If we locate an image plane halfway between the two, then both fans contribute to the image and in the ideal case it will be a circle. As the image plane is moved forwards or backwards, these images become ellipses and eventually reduce to a sagittal or a tangential line, as shown in Figure 12. Because there are two different

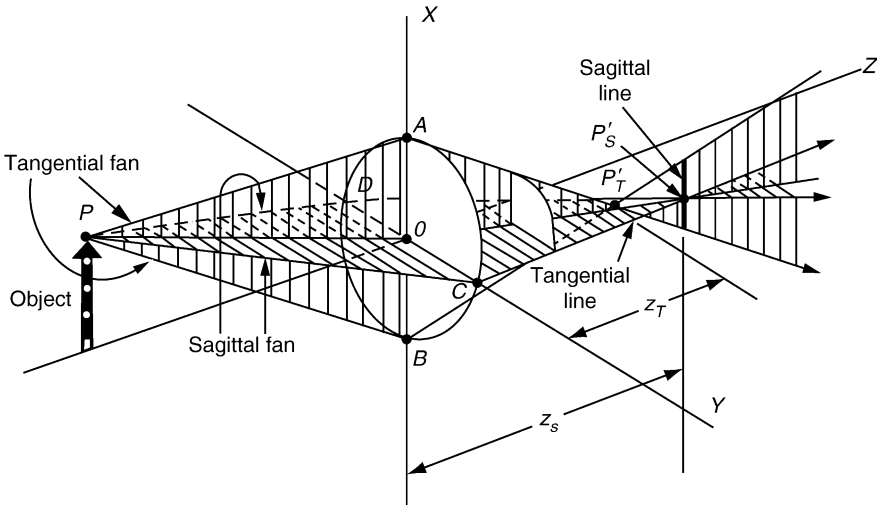

Figure 11 Tangential and sagittal fans displaying astigmatism.

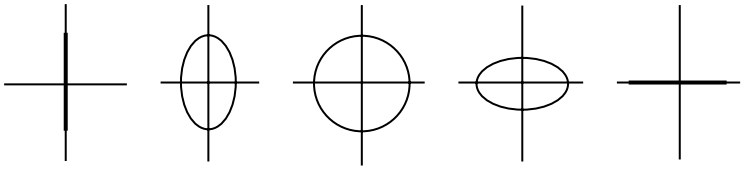

Figure 12 Astigmatic image patterns.

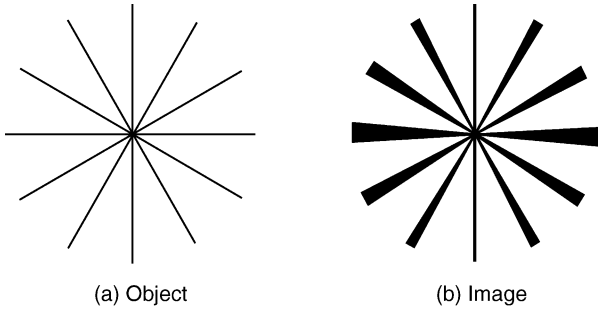

Figure 13 Image degraded by astigmatism.

image planes, an object with spokes (Figure 13) will have an image for which the vertical lines are sharp and the others get gradually poorer as they become more horizontal, or vice versa, depending on which image plane is chosen. Eye examinations detect astigmatism if the spokes appear to go from black to gray. This example of the effect of astigmatism was often based on a radial pattern of arrows, which explains the origin of the word sagittal, derived from the Latin 'sagitta' for arrow.

Curvature of Field and Distortion

Having covered the three point aberrations, there are two lens defects associated with extended objects. If we move the object point P in Figure 11 closer to or farther from the z-axis, we would expect the positions of the tangential and sagittal focal planes to shift, for it is only when the paraxial approximation holds that these image points are independent of x. Hence, we obtain the two curves of Figure 14, which shows what astigmatism does to the image of a two-dimensional object. If the astigmatism could be eliminated, the effect would be to make these curved image planes coincide, but we have no guarantee that the common image will be flat, or paraxial. The resulting defect is called Petzval curvature or curvature of field. For a single lens, the Petzval surface can be flattened by a stop in the proper place, and this is usually done in inexpensive cameras. Petzval curvature is associated with the z-axis. If we take the object in Figure 11 and move it along the y-axis, then all rays leaving it are skew and this introduces distortion, the aberration associated with the coordinates normal to the symmetry axis. Distortion is what causes vertical lines to bulge outward (barrel distortion) or inward (pincushion distortion) at the image plane, as shown in Figure 15. A pinhole camera will have no distortion, since there are no skew rays, and a single thin lens with a small aperture will have very little. Placing a stop near the lens to reduce astigmatism and curvature of field introduces distortion because, as

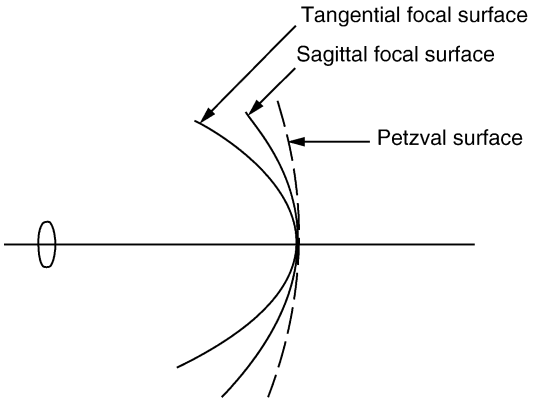

Figure 14 Petzval of field curvature.

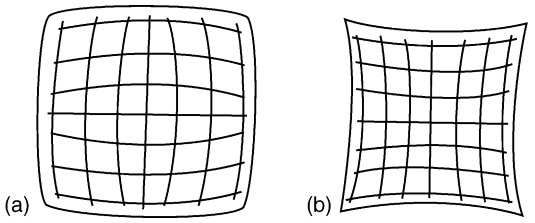

Figure 15 Barrel and pincushion distortion.

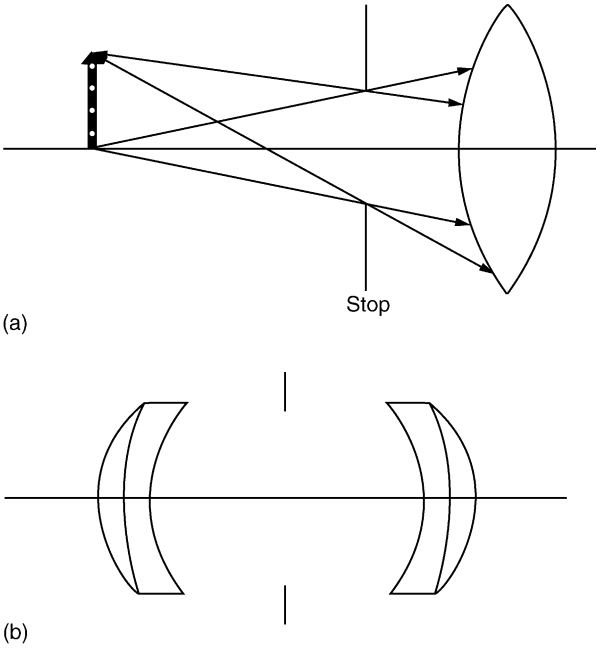

Figure 16 (a) Distortion-creating stop. (b) Symmetric-component lens that reduces distortion.

shown in Figure 16a, the rays for object points far from the axis are limited to off-center sections of the lens. The situation in this figure corresponds to barrel distortion; placing the stop on the other side of the lens produces pincushioning. Distortion can be

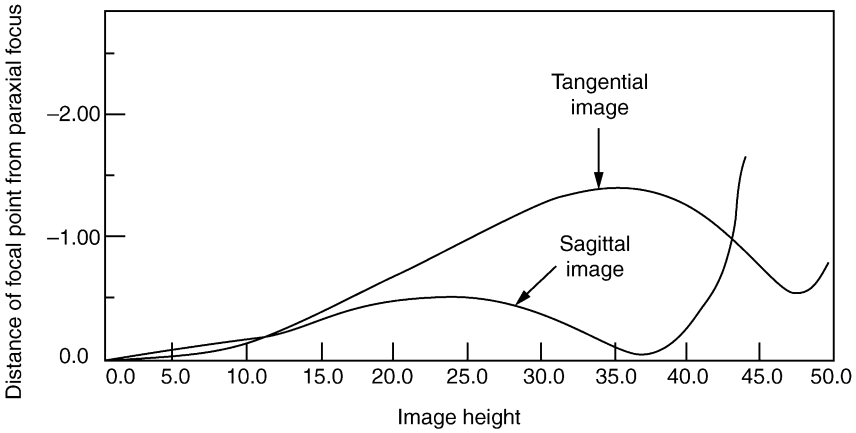

Figure 17 Reduction of astigmatism through design.

therefore reduced by a design which consists of two identical groupings (Figure 16b), with the iris diaphragm placed between them; the distortion of the front half cancels that of the back half. Figure 17 shows the output for a calculation using approximate formulas rather than exact ray tracing. Note that the designer has arranged for astigmatism to vanish at the lens margin. This example indicates the nature of astigmatism in a system for which the coma and the spherical aberration are low but not necessarily zero; it is the failure of the tangential and sagittal image planes to coincide.

Nonspherical Surfaces

So far, we have considered optical systems that use only spherical or plane reflecting and refracting surfaces. However, many astronomical telescopes use parabolic and hyperbolic surfaces. In recent years, nonspherical or aspheric glass lenses have become more common because they can be mass produced by computer-controlled machinery and plastic lenses can be molded with very strict tolerances. Ray tracing procedures given above can easily be extended to the simplest kind of aspheric surfaces: the conic sections. Iterative procedures may be applied to surfaces more complicated than the conic sections. A well-known example is the curved mirror; a spherical reflecting surface will have all the aberrations mentioned here, but a parabolic mirror will bring parallel rays to a perfect focus at the paraxial focal point, thus eliminating the spherical aberration. Headlamp reflectors in automobiles are a well-known example. A plano-convex lens with this defect corrected will be one whose first surface is flat and whose second surface is a hyperbola with its eccentricity equal to the index of refraction of the glass composing the lens. One form of astronomical telescope, which has a large primary concave mirror to collect the light and reflect it back to a smaller secondary convex mirror, is the Ritchey–Chrétien design of 1924. Both mirrors are hyperbolic in shape, completely eliminating spherical aberration. This is the design of the Hubble space telescope. The two-meter diameter primary mirror, formed by starting with a spherical mirror and converted to a hyperbola by computer-controlled polishing, was originally fabricated incorrectly and caused spherical aberration. From a knowledge of the computer calculations, it was possible to design, build, and place in orbit a large correcting optical element which removed all the aberrations from the emerging image.

Conclusion

The three-point aberrations and the two extended object aberrations have been defined and illustrated. Simple ways of reducing them have been mentioned, but the best way of dealing with aberrations is in the process of lens design. In addition, there is a completely separate defect known as chromatic aberration. All the above calculations are based on ray tracing for a single wavelength (or color) of visible light. However, the index of refraction of a transparent material varies with the wavelength of the light passing through it, and a design good for one value of the wavelength will give an out-of-focus image for any other wavelength. It has been known for many years that an optical system composed of two different kinds of glass will provide a complete correction for two colors – usually red and blue – and other colors will be partially corrected. Such lenses are said to be achromatic. For highly demanding applications, such as faithful color reproductions

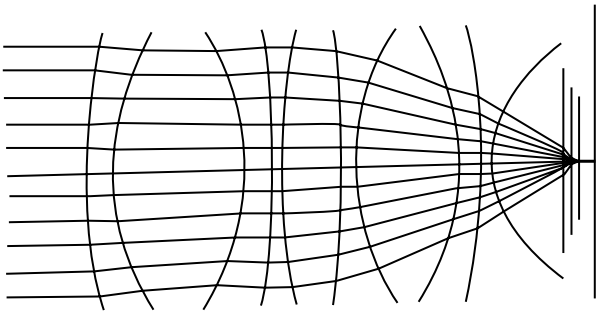

Figure 18 High-power high-resolution microscope objective.

of works of art, it is possible to design elaborate and expensive lenses which correct for yellow light as well. This kind of optical system is said to be apochromatic. With perfect imaging at the two ends and the middle of the visible spectrum, the color error elsewhere is virtually nonexistent. As an example of a design which is free of all aberrations – geometric and chromatic – Figure 18 shows the ray trace for a high-power aberration-free and apochromatic microscope objective. Note that the trace shows parallel rays brought to a focus inside the cover glass; in use, the light source would be a point on the slide and the light would converge at the eyepiece.

Prisms

A Nussbaum, University of Minnesota, Minneapolis, MN, USA

Introduction

Prisms are solid structures made from a transparent material (usually glass). Figure 1 shows the simplest type of prism – one that has many uses. The vertical sides are two identical rectangles at right angles to each other and a larger third rectangle is at 45° to the other two. The top and bottom are 45°–45°–90° triangles. The most common applications of prisms are:

1. To bend light in a specified direction
2. To fold an optical system into a smaller space
3. To provide proper image orientation
4. To combine or split optical beams, using partially reflecting surfaces
5. To disperse light in optical instruments such as spectrographs.

Single Prisms as Reflectors

A prism like that of Figure 1 can act as a very effective reflector; it is more efficient than a mirror since there is no metal coating to absorb light. Figure 2 shows a light ray entering the prism at right angles to one of the smaller sides, reflected at the larger side, and emerging at right angles to the other small side. The path shown is determined by Snell's law. This law has the form:

$$n \sin \theta = n' \sin \theta' \qquad [1]$$

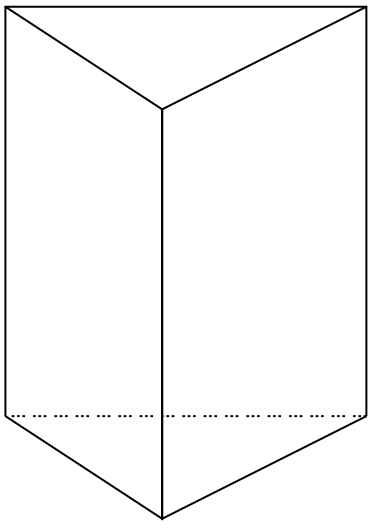

Figure 1 A 45–45–90 degree prism.

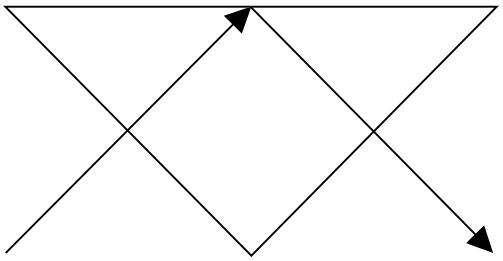

Figure 2 Total internal reflection by a prism.

This indicates that a ray of light making an angle θ to the normal at the interface between media of indices of refraction n and n', will be refracted and the angle to the normal becomes θ'. Notice that the light ray strikes the surface where the reflection takes place at an angle of 45° to the normal; this angle is too large to permit it to emerge from the prism after refraction. To understand why, we recognize that when the ray is able to leave the glass, Snell's law requires that the emerging angle be larger than the incident angle. The largest possible incident angle – known as the critical angle – will correspond to an emerging angle of 90°; that is, this ray will be parallel to the interface. For an index of 1.50, as an example, the critical angle θ_c satisfies Snell's law in the form:

$$1.5 \sin \theta_c = 1.0 \sin 90° \qquad [2]$$

from which $\theta_c = 41.8°$. The ray shown in the figure will therefore remain in the glass. Furthermore, since the indices appearing on both sides of Snell's law are now those of the glass, then the incident and refracted angles must be identical, and the prism reflects the ray in the same way that a mirror would. This phenomenon is known as total internal reflection.

This prism has an important application as an optical component of a fingerprint machine, whose action depends on modifying the total internal reflection which normally occurs. Figure 3 shows the prism and the reflecting behavior of Figure 2, with a person's finger pressed against the long side. When the ray strikes a place on the surface corresponding to a valley in the fingerprint pattern, the index at this region is that of air, and the ray is reflected in the usual manner. But a ray striking a portion of the prism which lies immediately below a raised section of the skin will make an angle with the normal which is now smaller than the critical angle, since the index is much greater than that of air, so that the ray will cross the interface and be absorbed by the finger. The reflected beam, with the fingerprint pattern sharply reproduced, is sent to a detector and the resulting signal goes to a computer, where it is processed and used to drive a printer. The fingerprint cards generated by this kind of equipment are sharper than those done by the traditional smeared-ink method. It is possible to observe the phenomenon just described by looking at your fingers while holding a glass of water – the fingerprints will show up in an enhanced manner. In addition to the better quality, the manufacturer of one version of this equipment has incorporated a feature in their computer program which can detect attempts by the person being fingerprinted to degrade the image.

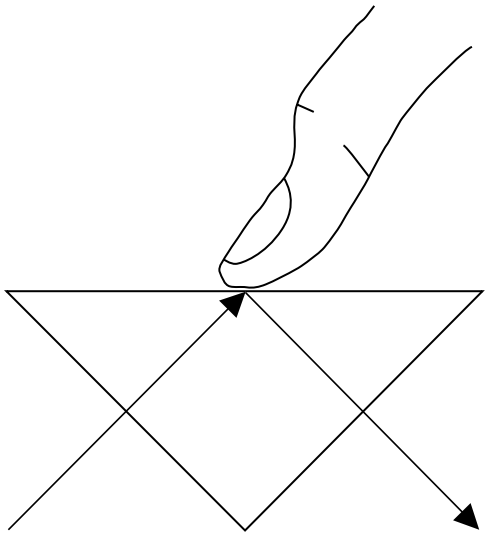

Figure 3 Use of a prism to produce a fingerprint.

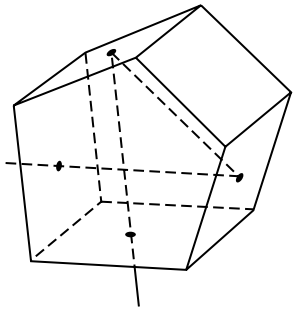

Figure 4 A pentaprism.

A more elaborate single prism – one with five sides – is the pentaprism of Figure 4, used extensively in single lens reflex cameras. This prism does not take advantage of the total internal reflection process, as described above. Below the bottom face is a mirror at a 45° angle. Light from the camera's lens is reflected upward and emerges from the left-hand face where the scene being photographed is observed by the eye.

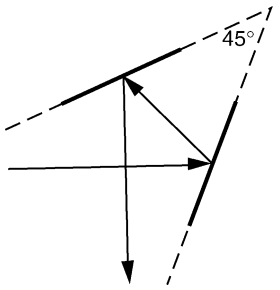

Figure 5 Action of coated faces of a pentaprism.

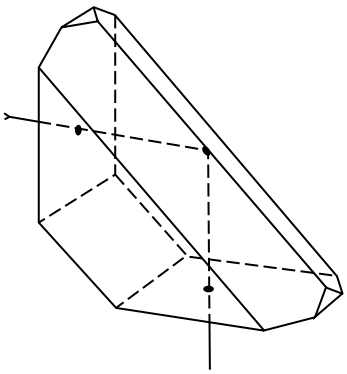

Figure 6 Amici prism.

Since there are two reflections, the reversal caused by a single mirror is eliminated. The camera's mirror is hinged and when the exposure button is pressed, it flies up and the incoming light can reach the film. The two reflecting faces, which lie at an angle of 45° to one another (Figure 5), are coated. To see why this is necessary, note that the two angles in the isosceles triangle formed by the light ray and the face extensions must equal (180° − 45°)/2 or 67.5°. This ray must then lie at an angle of 90° − 67.5° to the normal, or 22.5°, which is much less than the critical angle needed for reflection.

There are at least a dozen other forms of prism which have been designed and used. For example, the Amici prism (Figure 6) is a truncated right-angle prism with a roof section added to the hypotenuse face. It splits the image down the middle and thereby interchanges the right and left portions. These prisms must be very carefully made to avoid producing a double image. One use is in telescopes to correct the reversal of an image.

Double Prism Reflectors

Another extensive application of prisms is their use in pairs as components of telescopes and binoculars. The most widely used is a pair of Porro prisms: two right angle prisms arranged as shown in Figure 7. The double change in direction has two effects; it eliminates image reversal and it shortens the spacing between objective and eyepiece lenses, making the binoculars lighter and more compact. It is possible to calculate how light rays behave in Porro prisms with a ray tracing procedure. This method involves the use of 4×4 matrices and its development is rather complicated. A simple understanding of the way light passes through this optical component can be based on Figure 8, which shows the two prisms separated for clarity. An arbitrary ray (the heavy line) coming from the object will be reflected at a 45° angle at each of the four faces that it strikes. Using two line segments at right angles as an object, the ray from the top of the vertical arrow and the ray from the end of the horizontal arrow will behave as indicated. The image is then identical to the object but rotated by 180°. Since the optics of the binoculars – the combined effect of the objective and the eyepiece – result in an inverted image, the Porro prism corrects this problem.

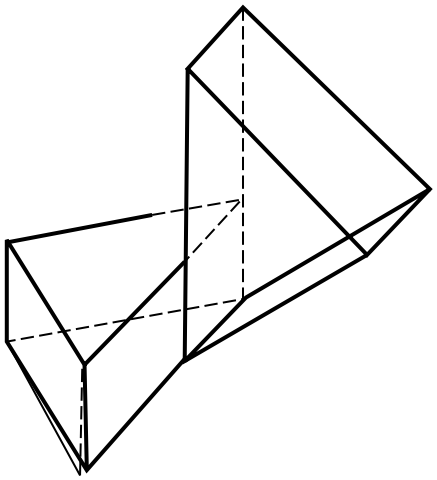

Figure 7 A pair of Porro prisms.

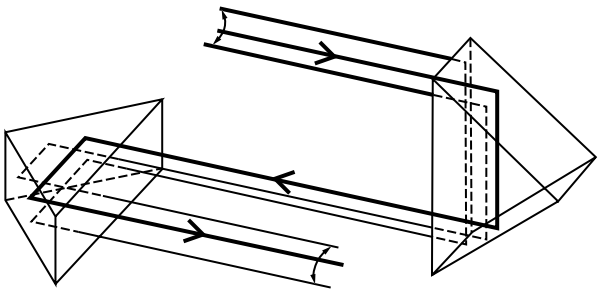

Figure 8 Action of Porro prisms.

Prisms as Instruments

Prisms are the crucial optical element in many laboratory instruments. To show how they can be used to measure the index of refraction of transparent materials – solids or liquids – consider the prism of Figure 9, with apex angle A. Light comes to the prism at an incident angle i, enters the prism at the angle of refraction r, crosses the prism and is refracted a second time when it emerges, the associated angles being designated as r' and i'. When the ray leaves the prism, it is traveling in a direction which represents an angular deviation δ from its original orientation. This deviation is the sum of the individual changes in direction at each face, or

$$\delta = (i - r) + (r' - i') \qquad [3]$$

For the triangle formed by the projected normals, which meet at the angle A:

$$r = r' + A \qquad [4]$$

Hence

$$\delta = i + i' - A \qquad [5]$$

The minimum value of the deviation is an important property of the prism; we find it by differentiation to obtain:

$$\mathrm{d}\delta = \mathrm{d}i + \mathrm{d}i' = 0 \qquad [6]$$

Differentiation of the form of Snell's law valid at each interface, namely:

$$\sin i = n \sin r, \quad \sin i' = n \sin r' \qquad [7]$$

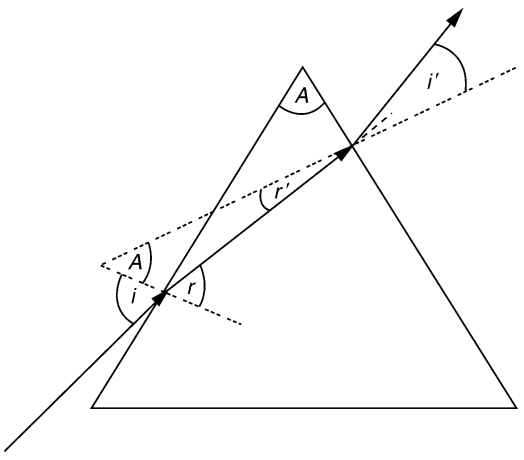

Figure 9 Calculation of prism deviation.

gives

$$\mathrm{d}i = n \cos r \, \mathrm{d}r / \cos i \qquad [8]$$

$$\mathrm{d}i' = n \cos r' \, \mathrm{d}r' / \cos i'$$

$$= n \cos r' \, \mathrm{d}r / \cos i' \qquad [9]$$

where $\mathrm{d}r'$ can be replaced by $\mathrm{d}r$, as obtained from the equation connecting r, r', and A. It now follows that:

$$\mathrm{d}\delta = n\Big[\{\cos r / \sqrt{(1 - n^2 \sin^2 r)}\} - \{\cos(A - r) / \sqrt{(1 - n^2 \sin^2(A - r)}\}\Big]\mathrm{d}r = 0 \qquad [10]$$

from which

$$\cos^2 r\{1 - n^2 \sin^2(A - r)\} = \cos^2(A - r)\{1 - n^2 \sin^2 r\} \qquad [11]$$

or:

$$\cos^2 r = \cos^2(A - r) \qquad [12]$$

and finally:

$$r = A/2, \quad r' = A/2, \quad i' = i \qquad [13]$$

The differentiation thus leads to the conclusion that the ray enters and leaves the prism in a symmetrical manner. The amount of deviation is now:

$$\delta = 2i - A \qquad [14]$$

or:

$$i = (\delta + A)/2 \qquad [15]$$

and:

$$n = \sin i / \sin r = \sin\{(\delta + A)/2\} / \sin(A/2) \qquad [16]$$

Using this expression to calculate n as a function of δ, it is found that δ is a minimum, so that a measurement of the minimum deviation produced by a prism gives the value of its index of refraction in a direct and accurate way. This method can also be used for liquids; a triangular glass cell with walls of reasonable thickness is made very accurately and used to measure δ. The refraction due to the walls does not affect the measurement, since the refraction occurring at the entrance wall is equal but opposite to that at the exit wall.

The description of prism behavior given so far assumes that we are dealing with monochromatic light; that is light of a single wavelength or single

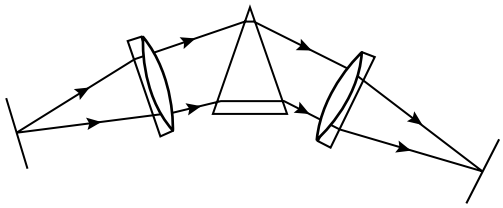

Figure 10 A prism spectrometer.

color in the visible spectrum. However, the index n of a prism varies with wavelength and white light passing through a prism will undergo dispersion – each component of a beam will emerge at a different angle and can be observed. The prisms that are part of expensive glass chandeliers display such an effect. This property of a prism is used in spectrometers – instruments which can measure the wavelength of light. Figure 10 shows a schematic diagram of this kind of instrument of high quality. Note that the light is brought into and taken out of the spectrometer with doublets. As shown in **Geometrical Optics:** Aberrations, doublets can be designed to be achromatic – that is, they focus light throughout the spectrum in approximately the same way. Various kinds of spectrometers have been put into use, with the ability to resolve closely spaced wavelengths being a crucial factor in the design.

Introduction

Holography captures the phase and amplitude of light reflected from, or transmitted through, an object. In visual terms it captures 'true' three-dimensional space and any objects which are placed within that space. This is very different from the various optical illusions, including perspective drawing and painting, which 'trick' the eye into thinking it is seeing a dimensional image on a flat surface. Not surprisingly, artists have been intrigued by display holography since reports about it became more public in the early 1960s.

Since much of the information about the holographic process was originally published in professional scientific and optics journals, which the artistic community rarely read, or had access to, the transfer of practical information from optical scientist to visual artist was slow. As less technical reports about holography began to appear in publications, such as *Scientific American*, and art journals, such as *Leonardo*, more artists became aware of the possibilities holography offered. It is now over 50 years since its invention by Dennis Gabor, and art holography can be found in public and private collections around the world, ranging from major museums, through academic art galleries to large individual collections.

For the purpose of this article, holography can be defined as a section of a broad optical field, encompassing display holograms produced by artists, creative individuals, and groups. These works are often produced through independent or self-driven research, but can also be the result of a commissioned project. Holographic art works tend not to be produced specifically for commercial gain (although some do sell for large amounts and can be editioned in the same way prints or photographs, to increase their salability or make them more accessible to a wider audience). It is incredibly difficult to assess the number of artists working in this field today, as no specific research has been carried out, but it can be estimated as between 50–100 individuals worldwide, which includes those who have shown work in curated group and solo exhibitions. This relatively small number has made an enormous impact and includes artists who have made holography their main medium of expression, as well as those, more established in other media, who have extended their creative vocabulary by embracing the holographic process. Salvador Dali for example, had holograms made of his sculptural compositions in the early 1970s, and Bruce Nauman used the process to capture a series of self-portraits in the 1960s. Apart from these well known and established contemporary artists, much of the pioneering work has been driven by individuals

who have concentrated on holography as their medium of choice.

Some artists build their own optical studio in which to experiment in a hands-on environment, some collaborate with scientific and research establishments, where the work, facilities and expertise is shared, and others design and supervise the production of their work which is produced for them by a commercial company. All of them produce a unique contribution to the visual arts.

Early Exploration

Holography offers a unique method of recording and reproducing three dimensions on a flat surface without the need for special glasses (for stereoscopic viewing), lenses (such as lenticular viewing) or linear perspective which, since the Renaissance, has been our main method of tricking the eye into believing that an image recedes into the distance and displays three dimensions.

Many of the very early works produced by artists concentrated on the obvious still life nature of the medium and explored the unusual phenomenon of objects 'frozen' in holographic space. Almost all of these early works were recorded using continuous wave helium neon lasers, either in scientific/research facilities, which artists had arranged to use, or in collaboration with established scientists and optical imaging researchers.

As early as 1969, British artist Margaret Benyon was experimenting with this new medium. Her laser transmission hologram 'Picasso', is a recording of images taken from Pablo Picasso's painting 'Demoiselles D'Avignon'. Here Margaret Benyon took a copy of the painting, cut out the characters, placed them in a three-dimensional spatial arrangement, with real objects, and then made a hologram of this 'scene'. Picasso attempted to show, through many of his paintings, multiple views of the same subject on a two-dimensional surface, one of the main thrusts of Cubism in the late twentieth century. Benyon achieved this in 'real space' by recording a hologram of the flat reproductions. By doing so, she demonstrated that holography automatically achieved what Picasso, and many other key contemporary visual artists, had been trying to do for years.

Holographic Black Holes

It has been known, from the very early days of holographic research that, when using a continuous wave laser to record a hologram, if any object in the scene moves more than half the wavelength of light, no interference pattern will be produced and therefore no recording of the object will take place. Unlike photography, where if an object moves during the exposure, it will become blurred, in holography it will simply not be recorded. Clearly, if no recording can be made, optical researchers working with holography, while noting the phenomenon, would not necessarily feel the need to make holograms which would fail. Several artists, on the other hand, not confined by research deadlines, have acknowledged this strange phenomenon and exploited this limitation of the holographic process. One of the very early examples is 'Hot Air' (Figure 1), a laser transmission hologram by Margaret Benyon and now in the Australian National Gallery Collection. Produced in 1970, it shows a three-dimensional composition of a jug, cup, and the artist's hand. The jug and cup were filled with hot water and during the recording of the holographic plate, with a continuous wave laser, the heat from the hot water disturbed the air above these objects. This tiny amount of movement resulted in the area above the jug and cup not being recorded. Similarly, the artist's hand moved slightly during the exposure and therefore did not record. Strangely, when viewing the resulting laser transmission hologram, the hand is visible. What is displayed is a holographic hand-shaped black hole, the three-dimensional recording of the space once occupied by the hand; the dimensional recording of the absence of an object.

Figure 1 'Hot Air', Margaret Benyon 1970. Laser transmission hologram. Copyright © 1970 M. Benyon. Reproduced with permission.

> Artists in display holography place continual demands on the technology. Their natural tendency is to break rules. I believe that most successful holographic artists belong to this 'suck it and see' category of experimentalists. On hearing about the 'rules' of holography, they break them, just to see what happens. (Margaret Benyon, PhD Thesis, 1994).

Benyon started by breaking the rules and has continued to develop from these early pioneering laser transmission works, which helped establish a visual 'vocabulary' including many important social and political issues.

Other artists have exploited the 'limitations' of the holographic process to produce visually stunning works which question how we look at the three-dimensional world and question what is 'real'. Rick Silberman (USA) developed a shadowgram technique where the hologram is made of a laser illuminated ground glass screen. Objects are placed in front of this luminous surface and their three-dimensional silhouette is recorded. The viewer of the hologram is looking at the space where the object used to be. A pivotal work in this field is 'The Meeting' 1979 (Figure 2), a white light reflection hologram which had been recorded in such a way as to cause the three-dimensional shadow of a wine glass to protrude out of the holographic plate and be viewable several centimeters in front of it, between the observer and the holographic emulsion. The actual wine glass used in the recording has been broken and what remains (the base, stem, and small part of the bowl of the glass) is placed on a platform attached to the holographic plate. When viewing the work head on, the missing parts of the broken glass are recreated, in three dimensions, by the holographic shadow. When viewed obliquely, from the side for example, only the broken (real), glass is visible. Not only does this piece have an element of performance in the recording, breaking, mounting, and reconstruction of the wine glass, it also explores questions of visual perception and concepts of reality.

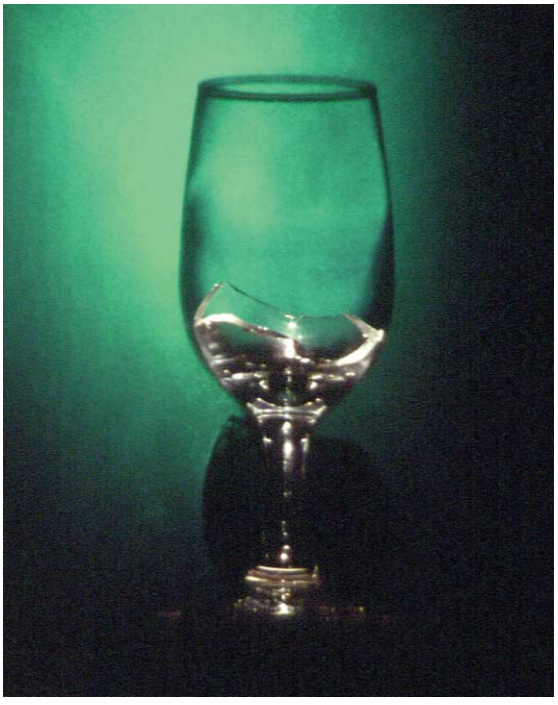

Figure 2 'The Meeting', Rick Silberman 1979. White light reflection hologram (shadowgram). Copyright © 1980 ATP. Reproduced with permission.

The recording of the shadow of an object, or objects, has now become commonplace in creative holography, with many artists employing techniques to mix different objects together, change their color and rearrange them in space. One advantage of this technique is that dependence on absolute stability of the objects used is reduced. The objects are 'encouraged' to move during the recording process and so create 'negative' images. Steve Weinstock (USA), Marie-Andrée Cossette (Canada), Michael Wenyon and Susan Gamble (USA/UK) have all contributed to this area in some of their early works.

Public Display

As the technology and optical processes of holography have developed, so greater flexibility, and public accessibility, have emerged. The single most important aspect has been the ability to display holograms in white light.

Emmett Leith and Uris Upatnieks invented laser transmission holography in 1964. They demonstrated the practicalities of Gabor's original invention, by utilizing laser light, to produce three-dimensional images. To display these recorded images, laser light needed to be shone through the holographic plate, at the original angle used by the recording reference beam (off-axis). The results were breathtaking, with full visual parallax in all directions. Although it was the laser light which made the recording and reconstruction of these unusual images possible, the laser was also a limiting factor. Each time a hologram was displayed, a laser was required. This relegated the technique to displays in scientific conferences, laboratories, or other locations with optical equipment. What was needed was a technique allowing holograms to be displayed without the need for this expensive and dangerous laser light. White light holography was the answer.

Although a laser is still required to record the original hologram, by using a copying technique, a

restricted aperture or one step process, the resulting holograms can be reconstructed using a small source of white light such as a spotlight or even direct sunlight. As expensive lasers were no longer needed to display holograms, large public exhibitions could be mounted. Gallery and museum spaces could include holography in their exhibitions and individuals could buy and display holography in domestic locations. This technique also benefited the commercial display market, where holograms could now be used for advertising and promotional events.

Stephen Benton (USA) (1942–2003), inventor of white light transmission (rainbow) holography in 1968, made a major contribution to the use of the medium by artists. His technique not only allowed holograms to be viewed in white light, but they were extremely bright and offered the possibility of creating multicolor images. His 'Crystal Beginnings' 1977, (Figure 3), shows just how much space can be created with very simple points of light. Benton even taught master classes for artists so that he could explain how his technique functioned and explain the mathematics involved. He also worked with several artists to help them realize their individual projects.

Harriet Casdin-Silver (USA) was one of the first pioneering artists to work with Benton and produced several key works now seen as integral to the art of holography. Their early collaboration 'Cobweb Space', 1972, sculpted pure light and was one of the very first art holograms to be displayed using Benton's rainbow hologram technique. A later work, 'Equivocal Forks', 1977, exists in different formats; as a laser transmission hologram showing the pseudoscopic display of domestic folks which protrude, inside out, from the holographic plate, and as a number of white light transmission holograms, of the same image, which were shown in an outdoor installation mounted by The Center for Advanced Visual Studies, part of the Massachusetts Institute of Technology. This demonstrated to a wide, nonscientific, audience, that holograms could be accessible, easily illuminated and weatherproof. Casdin-Silver has continued to produce art holography and has, most recently, worked with large-scale portraiture.

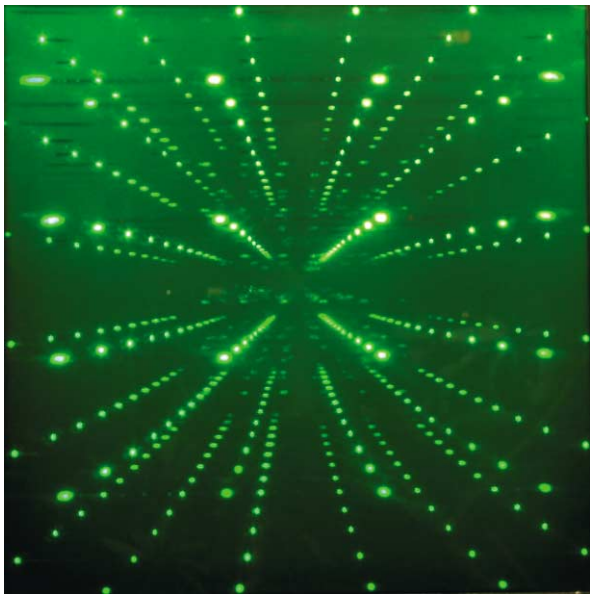

Figure 3 'Crystal Beginnings' Stephen Benton 1977, White light transmission (rainbow) hologram. Jonathan Ross Collection, London, UK. One of the best known works by the inventor of the rainbow hologram. Copyright © 2004 J. Ross. Reproduced with permission.

Although Benton's process increased the accessibility of holography, an earlier technique, invented by Yuri Denisyuk (Russia) in 1962, allowed holograms to be recorded in a single step and then displayed using white light. The political situation between the USSR and the rest of the world during the early 1960s meant that information and results from much of this early work was not openly accessible, and communication between Denisyuk and other key researchers in holography was limited. However, as soon as details of the Denisyuk technique became more widely available in the 1970s, artists began to embrace it as a practical alternative.

The work of Nicholas Phillips (UK), whose research improved chemical processing of display holograms during the late 1970s, helped artists and the rest of the holographic field to achieve much better results when making reflection holograms, a technique favored in Europe. He was also heavily involved with the rock band, 'The Who', and their Holoco company which mounted two very successful exhibitions of display holography at the Royal Academy of Art, London, at this time. Artists who might not have come across the holographic phenomenon became aware of its potential due to its presence in one of the UK's more traditional art venues. Other large exhibitions in the late 1970s and early 1980s in USA, Sweden, and Japan also highlighted the immense possibilities holography offered to a nonscientific community of gallery visitors.

As interest in all aspects of holography increased, dedicated spaces opened to sell, display, and archive the output from artists, scientists, and commercial producers. One of the most influential of these was the Museum of Holography, located in the SoHo art district of Lower Manhattan, New York (Figure 4). From 1976 through to 1992, it regularly mounted group and solo exhibitions by artists, giving many of

Figure 4 Dr Dennis Gabor, inventor of holography with, Posy Jackson, Director of the Museum of Holography, during his visit to the Museum in March, 1977. Copyright © 1977 Paul D. Barefoot. Reproduced with permission.

them their first major exposure to a museum-going public. There were displays relating to the scientific, commercial, and industrial usage of the medium, as well as exceptionally popular traveling exhibitions. 'Through the Looking Glass', which traveled worldwide, allowed early display holography to be experienced by thousands of people who would not normally have come into contact with the medium. In the Summer of 1981, over 300,000 visitors saw 'Through the Looking Glass' during the 11 weeks it was on view at the Israel Museum, Jerusalem.

After the Museum of Holography closed in 1992, its entire collection was purchased by the MIT Museum, Boston, USA, and now forms part of the largest museum collection of creative and scientific holography in the world. The New York museum was not an isolated venue. During the late 1970s and early 1980s, museums of holography opened in Chicago, Paris, and Pulheim (near Cologne). Galleries were also founded in many major cities to sell art and commercial holograms.

Stability Solutions

Although being able to display holograms using inexpensive sources of white light allowed the medium to become much more accepted as a display process, there has always been the cost and complexity of the optical laboratories needed to record the holograms in the first place. Few artists were able to equip their studios with 'off the shelf' optical components and precision-built isolation tables most often found in scientific and research labs. The solution was to replace the commercially built isolation table with much less expensive sand tables.

Sand box holography revolutionized the field for independent artists. By building a wood or brick box filled with sand, resting on car inner tubes, artists were able to hand-make their own isolation tables. Inexpensive optics, mounted onto plastic pipes were simply thrust into the sand, allowing complex optical recording setups to be constructed. Surprisingly, many key artworks have been produced using this technique, which opened the field to anyone with basic construction skills and a laser.

The laser has remained an expensive element in the holography studio but, most recently, the prospect of replacing this with laser diodes has offered a much more economic alternative. Not only can light from these diodes provide more compact optical setups to record holograms, they can also be used to display them. Significant progress has been made in both diode recording and display, which is opening up new opportunities for the visual artist. Almost all of the early practitioners in the field were attracted to holography because of the laser transmission holograms they saw. They have a depth and dimensional quality which is extremely different from the white light viewable holograms we tend to see today. Now, with the possibility of displaying holograms illuminated by inexpensive laser diodes, the laser transmission hologram is set, once again, to be a viable medium for artists.

Object Holography

Many artists were attracted to holography because of its unusual three-dimensional properties. However, they did not have the resources to make holograms of large objects or scenes, so scaled these down and constructed small sculptural settings for recording. One of the pioneering artists in this area was Dan Schweitzer (1946–2001). Originally an actor and familiar with theatrical staging, many of his holograms are populated by tiny figures placed in specially built 'theatrical' settings. Holography not only recorded these specially constructed miniature 'rooms', but the resulting images were realistic enough to suggest to the viewer that they were looking at a scaled-down life-size event. We do this regularly when looking at photographs and accept that they are a small-scale version of a larger scene. Traditional holography does not offer this 'scaling down' in the same way as photography. One celebrated example is Schweitzer's 'Thendara', 1978, where a sculpted, miniature figure sits and looks towards a window frame. He also produced a companion piece in which the physical model, used to make the earlier hologram, is on display as a piece of sculpture. Here the miniature window is the frame for a hologram displaying a previously recorded model of a landscape. As Schweitzer's technical skills

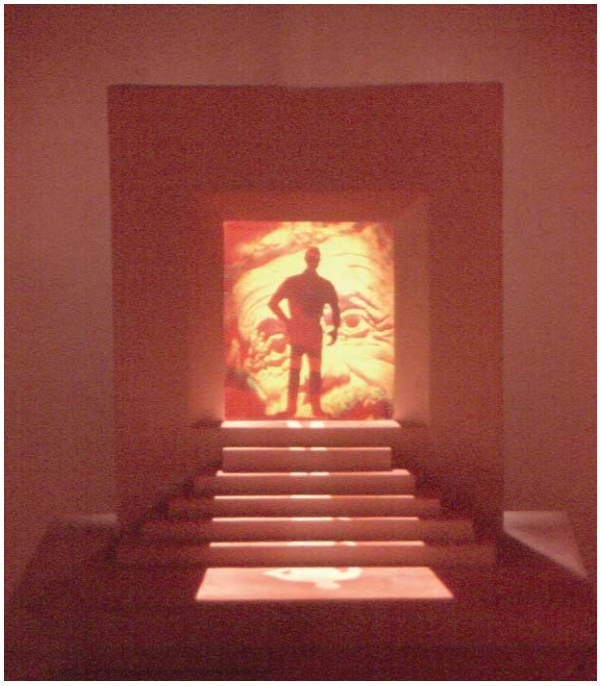

Figure 5 'Od Vent', Dan Schweitzer 1980, White light transmission hologram in sculptural mount. Copyright © 1980 ATP. Reproduced with permission.

developed, he began to produce complex multilayered works incorporating still-life models, hologram fragments, and optical animation to construct visual spaces which could not exist in the real world.

In his work 'Od Vent' (1980) (Figure 5), Schweitzer framed an exceptionally complex white light transmission hologram into a theatrical model of a doorway. The miniature stairs lead up to an opening, a portal into another world, in which the hologram is mounted. Illuminated from behind, the hologram displays multiple exposures, optical animation, and several superimpositions of objects as an observer moves from left to right in front of the piece. In this complex holographic world, the silhouette of the figure, standing in the door, casts a bright (negative) shadow down the miniature stairs. Not only are we able to look into an illusionary world through the holographic doorway, where at a certain point Einstein looks back at us, but the peculiarities of this holographic world extend into our own world as seen by the 'real' (negative) shadow cast down onto the stairs.

Another artist, who combined the use of multiple exposed objects displayed in a single space, is John Kaufman (USA). He established a reputation by recording objects (often rocks) collected from around his Californian holography studio. These found objects were captured in three dimensions and were then, through a multiple exposure and emulsion swelling technique, combined into a single still-life composition. He became expert at masking out areas of his objects so that they could appear in different, intense colors, and in many cases used the holographic process and multiple exposures to mix colors directly in the holographic space he was working with. In 'Stone Head' (1982) (Figure 6), for example, this relatively 'normal' stone is transformed by the use of intense color and the three-dimensional volume it occupies.

When considering how the hologram should be framed and displayed, several artists have utilized the mount in which the hologram sits as an integral part of a much more complex work. Frithioff Johansen (Denmark) recorded a hologram of smoke, freezing it in time and space using a pulsed laser (see below). This was then converted into a white light transmission hologram and mounted in a frame of granite. 'Hardware-Software 1' 1987–1988, allows the gallery visitor to not only view the massiveness of the granite structure, but also the delicate sculptural solidity of smoke 'frozen' in space.

Rebecca Deem (USA) recorded what appears to be an extremely simple hologram of a luminous tube, mounted onto a swivel at the end of an elegant metal support. In 'W/Hole Message' viewers can look into the small holographic plate and see the image of the tube extending away from them into the volume behind the plate. By flipping the hologram, on its swivel, to turn it over, the image in the hologram is also flipped and the tube appears in the viewer's space, between them and the plate. This three-dimensional pseudoscopic image, one of the attractive and unusual aspects of holographic display, is inside out, back to front, and upside down. The gallery visitor really does have a chance to view the whole message.

Text has become an important element in holography, as it is often incorporated in, onto, or around holographic displays. Eduardo Kac (Brazil) has produced several holograms, which display poems, words, and letters floating within the holographic space he has created.

Pearl John (UK) most recently produced a series of still-life holograms using a pulsed laser but with the added subtlety of writing onto the surface of her objects. In 'Breakfast' 2002 (Figure 7), for example, the slices of toast, making up the composition, have been laser etched with text which appears 'burnt' into the surface of the bread.

Pulsed Lasers

Continuous wave lasers placed limits on the holographic recording process and dictated that no movement in the recorded object could take place. We have seen that this 'problem' was exploited by artists at an early stage, but there was also a desire to capture living objects, in the form of the human figure. Pulsed laser holography was the solution. Because this type of laser generates a bright flash of coherent laser light, the intensity and duration of the pulse is enough to 'freeze' any physical movement during the recording process, allowing the recording of people, animals, or anything which moves and could be brought into an holography studio. Again, the cost and accessibility of this specialist equipment was prohibitive to artists, but they found ways of persuading scientists with pulsed lasers to help them. Early adopters of this technique were artists such as Ana Maria Nicholson (USA), Melissa Crenshaw and Sydney Dinsmore (Canada), Margaret Benyon (UK), Anait (USA), and Alexander (USA/UK). Recordings could now be made of live figurative compositions and individual portraits. Many of the artists, not content with producing the holographic version of a traditional photographic portrait, began to manipulate these recordings, distorting, multiple exposing and inverting these unusual three-dimensional images of people.

Holographic portraits do have an unusual quality, which painters or photographers have found difficult to deal with but art holographers have embraced. Some, like Ana Maria Nicholson (USA), have combined subtle processing techniques, to introduce color 'layers' into the portraits, combined with nonstandard views or compositions (see 'Awakening' 1993 (Figure 8)). Other artists, who emerged in the 1980s, produced complex, highly staged compositions, such as those from Patrick Boyd (UK), or they offered us a different view of the 'self portrait' like those by Martin Richardson (UK). Others, such as Shu-Min Lin (Taiwan), used the combination of multiple views of human figures recorded onto the same holographic plate. By walking past these displays, an animated effect could be experienced.

So much interest was generated in pulsed holography that several studios emerged for use by artists, including independent facilities and those within educational establishments. No longer was this the domain of the well funded scientific research facility. Several of these 'studios' still exist and are offering artists access to equipment through specialized artist-in-residence programs.

Abstraction

Although holography is an exceptional process for recording every detail of an object and the volume it occupies, many artists have wanted to work with the abstract and kinetic possibilities the process offers. Light can be recorded and displayed in three dimensions, it can be animated, inverted, compressed, sculpted, and projected. Douglas Tyler (USA), in his In the 'Dream Point Series' 1983 (Figure 9), recorded small laser transmission holograms but displayed them using normal white light, producing a smearing effect of the three-dimensional object. He then mounted these onto transparent surfaces (Plexiglas) and drew on the surface of the plastic to incorporate etched lines and shapes. Rudie Berkhout (Netherlands/USA) began his holographic exploration with stunning abstract landscapes made of luminous, multicolor, animated objects which took advantage of his mastery of the white light transmission technique. Most recently he has been recording reflection holograms which display undulating colored 'waves' of light as an observer moves past the hologram. These have been included in specially produced paintings for large-scale architectural commissions.

Sam Moree (USA) combines multiple images, exposures, diffraction gratings, and smaller holograms into a single work. The finished holograms display a complex series of image fragments and colors within the depth of the holographic space he has constructed. Ruben Nuñez (Venezuela), originally approached holography from a background in glass production and used the ability of the holographic process to 'capture' light reflecting and passing through his glass objects. The resulting white light transmission holograms display an abstract 'photonic' display of form and color. Fred Unterseher (USA), uses holography to record optical distortions and diffraction gratings which would display abstract patterns of light. Many of these early works were mandala images which displayed an intense kinetic effect as an observer walked past the surface of the holographic plate.

Pseudo Holograms

In 1973, Lloyd Cross invented the multiplex (integral) hologram technique which used sequential two-dimensional images recorded on movie film combined with white light (rainbow) hologram techniques. The result was a holographic stereogram, which gave viewers the illusion of seeing animated images in three dimensions. The final holographic sheet was displayed either curved or as a complete cylinder, which was often motorized so that viewers could stand in front of the unit and watch the animation take place as the hologram rotated. Such a display does give the impression that an observer can walk all the way round the image, enhancing its perceived three-dimensional effect.

As the original images are recorded photographically, there are several advantages – anything which can be recorded on inexpensive black and white movie film can be converted into a holographic display. Short animated sequences can be presented while accepted film techniques such as zoom, pan, tilt, and transitions can be incorporated into the finished sequence of images. Although very popular for advertizing and promotional campaigns during the 1980s, particularly in the USA, several artists used this technique. They could make the movie film sequences themselves and then send this film to a commercial producer for a hologram to be made for them. This offered an interesting balance in the creative process. The artist could concentrate on the filmic image, using facilities and photographic techniques they were familiar with and not have to learn the holographic process or build a holographic laboratory themselves. Artists such as Anait (USA) produced several experiments in the area, one of which showed her inside the holographic display,

writing, with spray cream, seemingly onto the holographic surface. Dieter Jung (Germany), used this technique to display a specially written poem which appeared to spiral around inside of the display.

Harriet Casdin-Silver used the technique to produce an unusual self-portrait. 'Woman', 1979 (Figure 10), is a multiplex hologram of the artist's head. Black and white film images were recorded of Casdin-Silver's head, through 360 degrees, and then each frame of film was converted into a thin white light transmission hologram. The artist chose not to display the resulting image in a normal cylindrical display, but to 'flatten' it out so that the front, sides, and back of her head could be seen, distorted, in a single head-on view.

As video and digital imaging processes have developed over the years they too have been combined with this pseudo holographic technique, opening up a wide avenue of possibilities. Video footage, computer generated modeling, or any process which can produce sequential 2-D images, can now be converted into an animated 3-D hologram. As digital video cameras and computer 3-D modeling software drop in price, and increase in sophistication, a whole new area of display has become available to the digital and video artist.

Multi Media

As in other areas of the visual arts, more than one medium or process are often combined. Doris Vila (USA) has produced complex environments combining large-scale holographic images which, rather than being illuminated with a single source of light, are reconstructed with multiple spotlights or via video projectors. The lighting is activated by sensors in the exhibition space, which are computer controlled and made to trigger certain sequences dependent on the input they receive from the movement of visitors.

Traditional illumination of a hologram involves a single point source of light shining onto, or through, the holographic plate. This will reconstruct a single image. If multiple lights are shone onto the hologram, multiple reconstructions of the single image will result. By using many independently controlled lights on one hologram, Vila has been able to create animation and kinetic effects as the resulting multiple images overlap. Using light from a video projector also allows the artist to combine a reconstructed holographic image with two-dimensional animated footage from the video projector.

Other artists to combine holograms with structures, interactive lighting and environments, sound, and installational displays include: Georges Dyens (Canada), Marie-Christiane Mathieu (Canada), Matthew Schreiber (USA), Philippe Boissonnet (Canada) Ana MacArthur (USA) and Shunsuke Mitamura (Japan).

Ikuo Nakamura (Japan/USA) has used multiple lighting of a single computer generated hologram to produce animated effects controlled by the viewer. In his 'Neuro Hologram' 1993 (Figure 11), brain waves from the viewer, wearing a special set of sensors on their head, are measured and converted into control signals for a number of lights behind the hologram. By relaxing, or becoming agitated, the viewer can change their brain waves and actively control the appearance of the hologram, causing multiple views of the holographic image to fade in and out, giving an impression of abstract animation.

Architectural Scale

One of the great limitations of holography has been the size of the holographic plates on which the light

sensitive emulsion is coated. These tend to be in the region of 20×23 cm, 30×40 cm, or meter-square formats. Generally, the larger the finished hologram, the larger the laboratory needed to produce it. This impacts a great deal on artists who do not have the facilities, or finances, to produce 'large' holograms. A solution has been to combine smaller holographic plates together, as a mosaic, to give the size and scale needed. In recent years, several artists have completed public commissions for large-scale interior and exterior holographic installations.

Setsuko Ishii, (Japan) has produced several installations in public spaces where individual holographic plates are mounted together to form a larger composite structure. Many of these pieces use holograms recorded on dichromate gelatin plates which produce an exceptionally bright image, ideal for public spaces, where visibility, from multiple angles, is important.

Michael Bleyenberg (Germany) produced an entire exterior holographic wall (13×5 meters) during 2002 (Figure 12), for the extension of a research building in Bonn. The installed graphic wall, 'EyeFire' (AugenFeuer), is made up of 26 smaller panels, each constructed from tiny holographic 'pixels' (holographic optical elements, HOE) to give an intense color effect. Working in collaboration with the Institute for Light and Building Technology, Cologne, Bleyenberg was able to design his graphic panels on a computer screen and have this information translated into the thousands of tiny holographic pixels which, when seen together, make up the complex and high intensity colour design.

Dieter Jung (Germany) has produced commissioned art works for large interior architectural spaces. In 'Perpetuum Mobile' 2001, located at the European Patent Office, The Hague, holograms are placed on the floor, which can be walked over, and an extensive holographic mobile structure hangs overhead. The light, and color, from the abstract holograms in the mobile sections, can be reflected in the abstract holographic floor and combine to produce an interior lightscape impossible to produce with more traditional media.

Holograms can be mass produced using a mechanical embossing process which transfers the optical contents of the original master hologram onto plastic sheeting for duplication in large runs. One novel use of this material has been the interior of the Canadian pavilion at Expo '92 (Figure 13). Melissa Crenshaw (Canada/USA) used huge quantities of embossed holographic material to cover the 3000 square foot interior walls of the specially built pavilion. Lighting was installed to illuminate this optical diffracting wall and the entire structure was covered in glass, over which water flowed. The resulting interior appeared to be a wall of liquid light which changed color and hue depending on where it was viewed from.

Sally Weber (USA) used holographic embossed material for several outdoor commissions. Structures were clad in embossed holographic sheets and made water resistant. Sunlight illuminated the installations to produce surfaces of constantly changing color. In direct (bright) sunlight, intense rainbow colors would be diffracted by the holographic surfaces. On an overcast day, pastel, more muted,

colors would appear. Although she is often known for these large-scale outdoor embossed works, one of her permanent commissions is housed in the Karl Ernst Osthaus-Museum, Hagen, Germany, where specially made holographic diffraction gratings are incorporated into an existing building. 'Signature of Source' 1997, (Figure 14), is a permanent, site-specific installation producing a line of light which enters the museum space from the skylight it is built into. This abstract line of pure color becomes a sculptural element within the space of the museum and is generated by the action of light from outside the building being manipulated and 'formed' as it passes through the holographic window.

One of the most celebrated and very early attempts to incorporate large-scale holograms into art works

Figure 15 'There's no Place Like Home', Paula Dawson 1979–1980. Laser transmission hologram of an entire room. Copyright © 1980 Paula Dawson. Reproduced with permission.

was the installation 'There's No Place Like Home' by Paula Dawson (Australia) in 1979–1980 (Figure 15). A laser transmission hologram of an entire room was recorded. The room was specially constructed, life size, and recorded onto a single holographic plate. The resulting hologram was then built into the window of a small 'house' constructed in the gallery. Visitors were able to approach the house, look into the window and 'see' the interior with its furniture, fixtures, and fittings. They would then enter the house and walk past the space where the room appeared to exist. When viewed from this vantage point there was nothing there except an empty space. Artists have often questioned and researched the concepts of 'inside and outside', voyeurism, reality, normality, and 'existence', but few have had the tenacity to produce an installation with such visual and conceptual impact.

Twenty-First Century Art

Art holography has developed and matured over the past 50 years to become a viable and significant element in the contemporary visual arts. Critics are still asking 'is it art?' in the same way they used to worry about whether photography was art. While they consider this problem, practitioners in the medium are continuing to find ways to push past its technical and visual boundaries (Figure 16). They continue to collaborate with the scientific and research world and use holography as a medium to comment on life and society in the early twenty-first century.

> …I hope, that one day I will be able to give you, artists, something really powerful; panoramic holograms,

Introduction

Holography is well-known to most of us: there can be few who are not familiar with the white-light display hologram seen in exhibitions and shops and on credit cards. The impact of holography, though, spreads far and wide into areas as diverse as vibration analysis, image processing, holographic-optical elements, and optical computers. One aspect often overlooked is its suitability for high-precision imaging and accurate dimensional measurement. It is the unique ability of holography to recreate, from a flat photographic film, a three-dimensional image that is optically indistinguishable from the original which sets it apart from other imaging techniques. In particular, holography comes into its own when recording objects in a hazardous environment or where access is difficult, such as underwater or in nuclear fuel element inspection.

We describe here the use of holography for imaging, identification, and measurement of aquatic organisms. A detailed knowledge of the distribution and dynamics of marine and freshwater organisms and particles, such as plankton, is crucial to our understanding of such systems and how they affect our environment. Traditional methods of gathering *in situ* data on aquatic particles, such as net-collection and electronic counting or photography, are not usually suited to observing precise spatial relationships and can destroy the more delicate organisms. The overriding benefit of holography is that it permits nonintrusive and nondestructive observation and analysis of organisms in their natural environment, while preserving their relative spatial distribution. Holography also offers a permanent archive. The use of a short-duration pulsed laser is essential, in order to reduce the effects of vibration or movement in any of the optical components or objects being recorded. Consequently, the object scene is effectively 'frozen' at the recording instant, thereby allowing fast moving particles to be imaged. Compared to a photograph, a hologram captures vastly more data. Sequential holograms can record changes within the volume over a defined period of time and the wide recording dynamic range afforded by a hologram allows images to be captured that would otherwise be lost in noise.

Methodology of Holographic Recording and Replay

Of the many possible recording methods of holography two in particular, 'in-line' and 'off-axis', find use for high-resolution *in situ* imaging underwater. The concepts and fundamental principles outlined here are generally applicable wherever high-precision measurement is needed from a hologram.

In an in-line reference beam hologram (ILH), a single laser beam (Figure 1) is directed through the

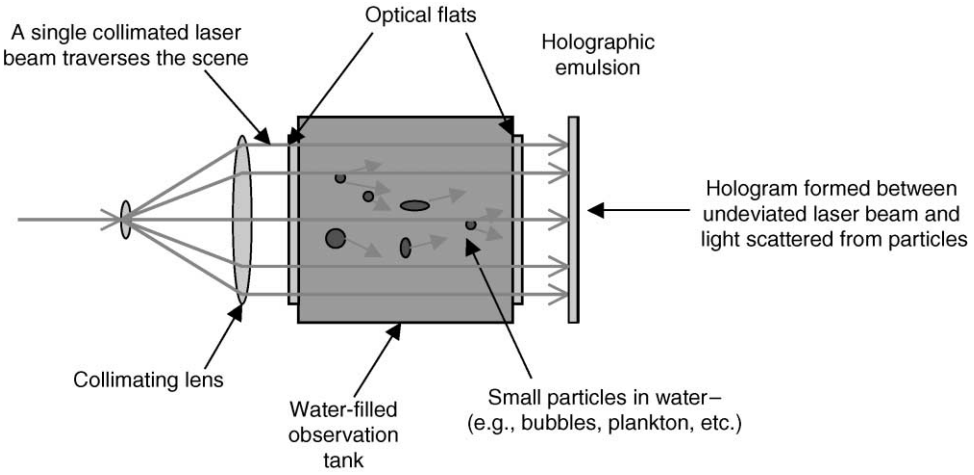

Figure 1 Recording an in-line hologram.

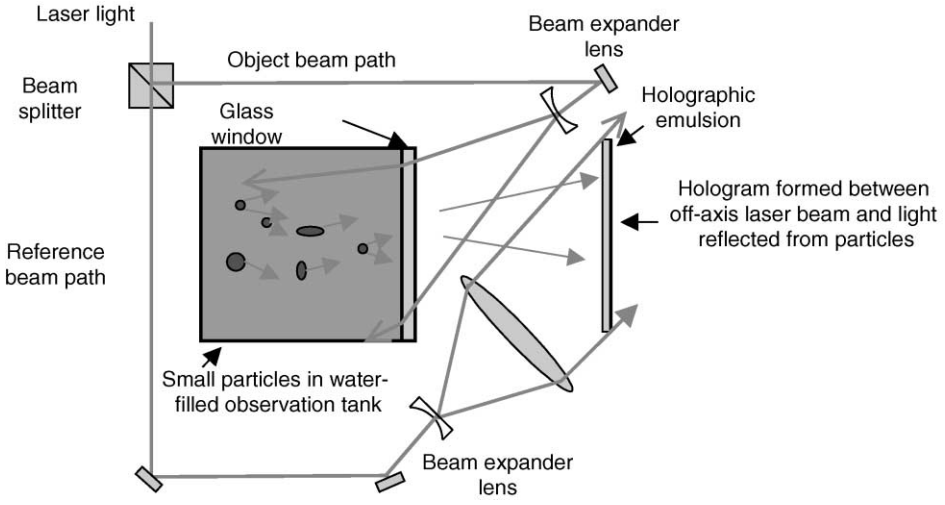

Figure 2 Recording an off-axis hologram.

sample volume towards the holographic plate and records the optical interference between light diffracted by the object and the undeviated portion of the illuminating beam. The subject volume is illuminated in transmission and the scene needs an overall transparency of about 80% so that speckle noise does not seriously degrade image quality. Particles down to around 5 μm dimension can be readily recorded and identified. The particular benefits of ILH are its geometric simplicity, minimization of laser coherence and energy requirements, and high resolution over a large depth of field.

For recording an off-axis reference beam hologram (OAH), a two beam geometry is utilized: one beam illuminates the scene and the other directly illuminates the holographic film at an oblique incidence angle (Figure 2). Interference occurs between diffuse light reflected from the scene and the angularly separated reference beam. On replay, the real and virtual images are similarly angularly separated which makes their interrogation easier. OAH is primarily applied to opaque subjects of large volume. Although there is no real upper limit to the size of particles that can be recorded (this is determined by available energy and coherence of the laser) the practical lower limit to the resolution that can be achieved is around 50 to 100 μm. The scene can be front, side or back illuminated (or all three combined) allowing high concentrations of large particles to be recorded, provided that they reflect sufficient light to the film, and allowing subject visibility to be optimized. OAH provides a more complete record than ILH, in the sense that it gives information on the surface

structure of the object, while ILH records only a silhouette.

Holograms are replayed or reconstructed in a variety of ways, depending on the recording parameters and subsequent processing of the recording medium. In scientific and engineering applications the requirements of high resolution and image fidelity demand that they are replayed with a laser, and viewed with some auxiliary optical system and (usually) a video camera. Depending on the orientation of the hologram, either the virtual image, which is apparently located behind the hologram and seen through it, or the real image, which is formed in space in front of the hologram, will be visible.

Considering first the off-axis hologram in the virtual image mode, the processed hologram is replaced in the position in which it was recorded and illuminated with an exact duplicate of the original reference wave, in terms of its wavelength, curvature, and beam angle. In this mode, which might be termed 'normal' viewing of an off-axis hologram, a virtual image (**Figure 3**) is observed as if viewing the scene through a window. Other than the colour, this image is almost optically indistinguishable from the original scene; it retains features such as parallax and three-dimensionality and does not suffer from perspective distortion or defocusing of the image.

For data extraction and measurement from a hologram, creation of the virtual image is not the best method of observation. Here the projected real image (**Figure 4**) is most useful. If we illuminate an off-axis hologram from behind, with a wave which is the exact conjugate of the original (i.e., one which possesses the same wavelength as the original but with the opposite direction and curvature), we generate an image that appears to float in the real space in front of the observer. Often a collimated reference beam is used in recording, since reconstruction is then a simple case of turning the hologram around. No lens is needed to form this image, and it is optically identical to the original wave that it is reversed left-to-right and back-to-front (pseudoscopic). Planar sections of the real image can be optically interrogated by directly projecting onto a video camera (often with the lens removed) which can be moved throughout the 3D volume. It is this 'optical sectioning' feature of a holographic recording that is so useful when nondestructive (noninvasive) evaluation must be made, at high resolution, of collections of objects which extend over a considerable depth.

A series of images taken from the real image of one hologram and captured on a video camera (**Figure 5**) illustrates how the viewing plane can be moved sequentially through the reconstruction to show firstly one marine organism and then another. The axial separation of the organisms is about 35 mm.

To replay an in-line hologram, it is also placed in a conjugate of the recording beam (**Figure 6**). The replayed hologram simultaneously forms two images, one virtual, the other real, which are located on the optic axis on opposite sides of the holographic plate. These images are co-axial, and located (for the typical case of collimated recording and replay beams) at equal distances in front of and behind the hologram plane. Although a true 3D real image is produced it has almost no parallax, and cannot easily be seen by the unaided eye. This image has inverted depth perspective and is seen in darkfield against the out-of-focus virtual image.

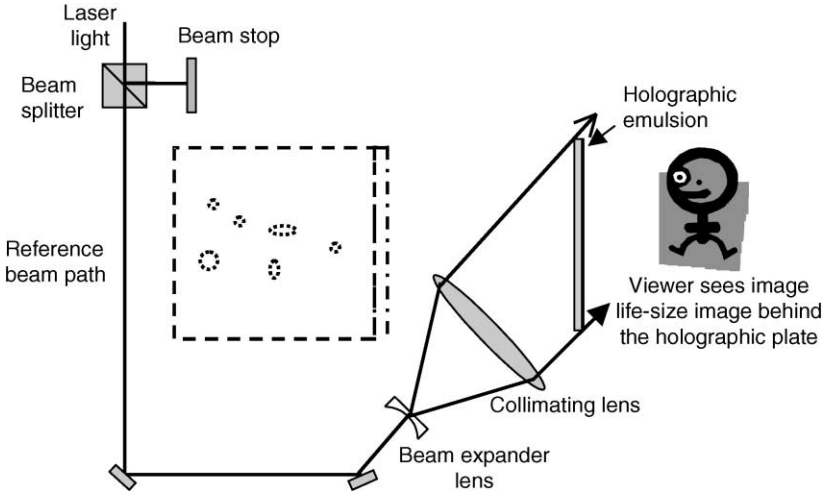

Figure 3 Replay of an off-axis hologram in virtual image mode.

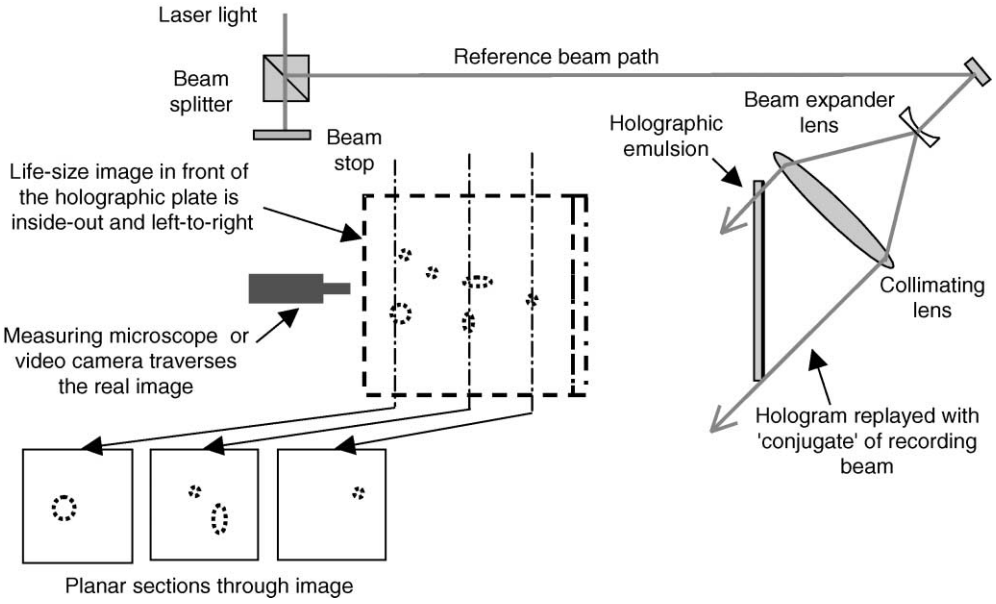

Figure 4 Replay of an off-axis hologram in real image mode.

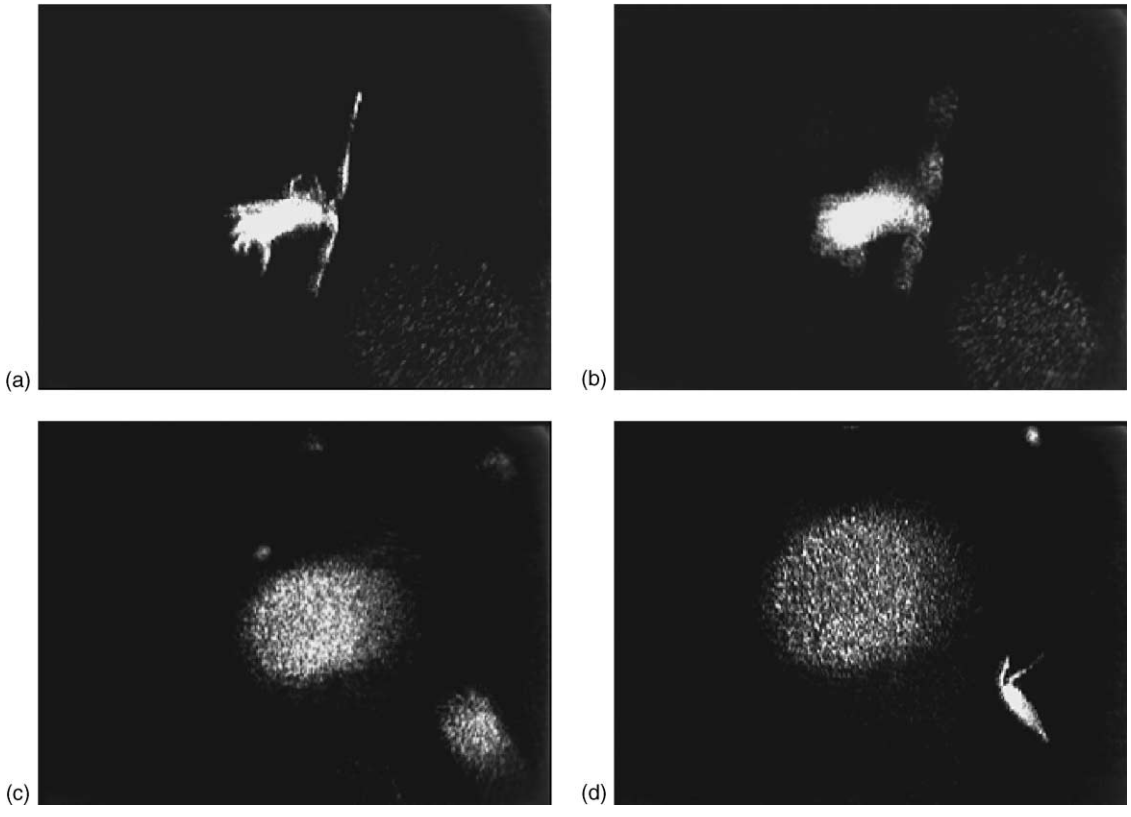

Figure 5 A series of images taken from a single hologram showing the concept of moving the viewing plane through the real image.

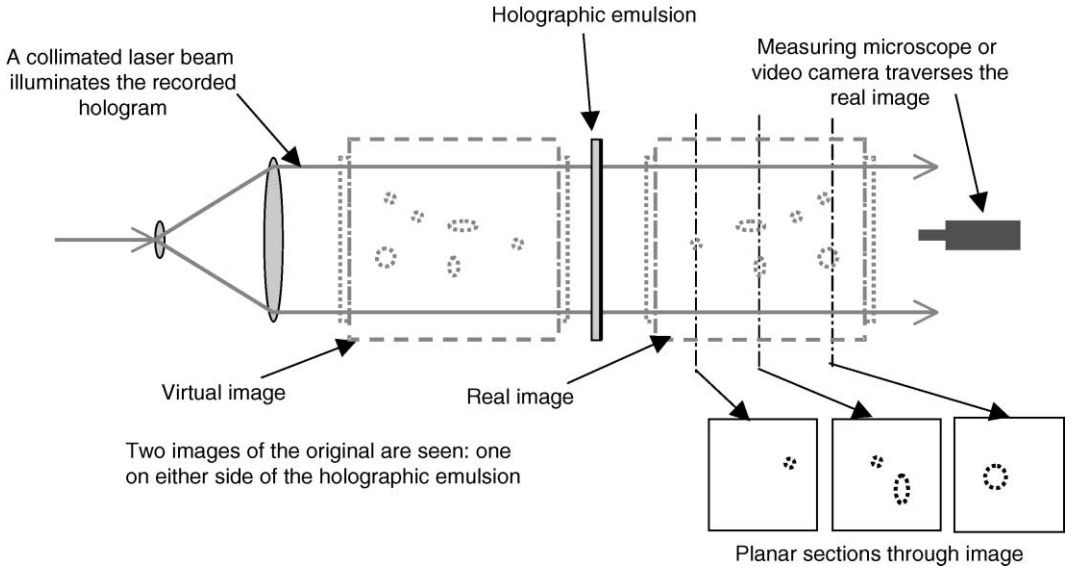

Figure 6 Replay of an in-line hologram.

Holographic Image Quality

In general, the usefulness of holography for accurate inspection and measurement is dependent on its ability to reproduce an image of the object which is low in optical aberrations and high in image resolving power. Regardless of whether or not the hologram is recorded underwater, high resolution, high contrast, and low noise are the dominant requirements, rather than image brightness. In practice, loss of resolution and image degradation can occur at any stage in the recording and replay of a hologram. All the primary monochromatic aberrations to be found in any optical system (spherical aberration, astigmatism, coma, distortion, and field curvature), may be present in the holographic image. The most significant factors affecting this are departure from conjugacy of the reconstruction beam; positional mismatch and misalignment between reference beam and film; degradation of the reconstruction beam due to poor optical quality of the film substrate or optical components; and, distortion of the fringe pattern recorded in the holographic film as a result of chemical processing. For precise and accurate reconstruction of the real image, the reconstruction reference beam should be the exact phase conjugate of that used in recording. Under these conditions, the lateral, longitudinal, and angular magnifications of the real image with all equal unity and aberrations will be reduced to a minimum.

Diffraction-limited resolution of a holographically produced real image, in the absence of all aberrations, is usually defined from the ability to distinguish two points in the image separated by a distance r. The resolution as defined in this way is dependent upon reconstruction wavelength, λ_c, the separation between hologram and reconstructed image, s, and the effective aperture, D, of the hologram:

$$r = 1.22s\lambda_c/D \qquad [1]$$

This relationship is well-known in imaging optics: it defines the ideal resolving power of a lens and is equally applicable to holography. In holography, though, the presence of speckle effects introduced by the coherence of the light and the finite aperture of the viewing system influence the resolving power. In practice, the minimum resolution is increased by a factor of two to three to take account of speckle. For off-axis holograms the choice of film size (effective aperture) has a considerable bearing on image resolution. Typically, for 100 mm diameter film the theoretical image resolution (neglecting speckle effects) is around 6 μm (150 lp/mm) with a 532 nm laser at a target distance of 1 m. For in-line holograms (with collimated illumination) the film size also defines the transverse dimensions of the volume recorded.

Wavelength matching between recording and reconstruction beams require that, if possible, the same type of laser be used in both replay and recording. Of course, this is not possible in field situations when the use of a pulsed laser is essential to ensure that the fringe pattern is not blurred by any movement in the system. In such applications, laboratory replay of the hologram may require the use of a tuneable laser to match wavelengths

precisely, although in practice an argon laser provides a useful selection of wavelengths. A mismatch between record and replay wavelengths will lead to distortion in the image, because longitudinal and lateral magnifications will no longer have the same value.

In contrast to off-axis holograms, the interference patterns on an in-line hologram are localized about the geometric shadow of the objects. The lack of a spatially separate reference beam leads to a requirement that there be a large fraction (>80%) of the beam unobscured. This limits the size of particles that can be recorded and sets an upper limit on the recordable concentration of particles (around 40 particles cm^{-3} for 20 μm diameter particles and a recorded depth of 1 m). There is also a need to balance the size of the particles with the object-to-hologram distance. The range of object size recordable on an in-line hologram has an upper limit set by the requirement to record in the far-field of the object, so that the conditions of Fraunhofer recording are satisfied:

$$z > d^2/\lambda \qquad [2]$$

where z is the object-to-film distance and d is the maximum dimension of the object to be recorded. In-line holograms are relatively easy to replay as the only requirement is to place the hologram normal to the replay beam. Following this criterion, the upper limit for good size measurement is about 2 to 3 mm particle size over a recording distance of a meter. Unlike off-axis holograms which are extremely sensitive to misalignment, the in-line geometry minimizes the effects of film rotation about its axes. A collimated recording beam is by far the easiest to duplicate upon replay. Small deviations from collimation can significantly affect conjugacy and hence resolution, introducing aberrations (mainly spherical) and a depth-dependent magnification (e.g., a cuboid replays as a trapezoidal prism).

In general, the interference field is captured on photographic emulsions; these may be laid on acetate or polyester film bases or on glass plates. If film is used, it is essential that it be held as flat as possible between thin flat glass plates or under vacuum, and should not be stretched or put under any strain during exposure. An in-line hologram does not require an extremely high-resolution recording medium. The fringe spacing is not as fine as the typical carrier fringe frequency used in off-axis holograms, and holograms can be made on conventional slow photographic emulsions. In practice, however, ultra-fine grained holographic film is almost always used since the intensity of the forward scattered light (a function of grain size) is then reduced: this is important in increasing the signal-to-noise ratio, as the replayed image is viewed against a background of the attenuated replay beam. Since the proportion of the illuminating beam that goes into the images is very low, this lack of angular separation requires that the average optical density of the hologram is high. The high optical density attenuates the undiffracted light, thus the image appears bright against a dark background, resulting in contrast reversal.

The exposed film is chemically processed to render the interference field permanent. This process is a crucial step in the holographic procedure, and especially critical for good off-axis holograms. Some of the factors, which have to be considered, include image brightness, image resolution, reconstruction wavelength, emulsion shrinkage, humidity, and noise level. It has been well established that for bright off-axis holograms on silver halide film, bleaching of the emulsion with its consequent conversion into a phase hologram is essential to maximize diffraction efficiency. Some forms of bleaching produce a nonuniform shrinkage of the emulsion which will give rise to astigmatism in the reconstructed image. Bleaching significantly increases the background noise levels of the hologram and introduces a high degree of variability into the result. In practice, the best repeatability will be obtained with amplitude processing if the low brightness can be tolerated.

Underwater Holography

When holography is extended to the inspection of underwater scenes, the hologram is recorded in water but the image is replayed, in the laboratory, in air. Because of the refractive index difference between recording and replay spaces, optical aberrations will be introduced into the reconstructed image, and will seriously impair the potential for precision measurement, unless some method of aberration reduction is incorporated. In ILH, only spherical aberration is significant since both reference and object beam angles are normal to the recording plane. However, in OAH the dominant aberrations are astigmatism and coma, which increase with the field angle of the subject in the reconstructed image. These limit resolution and introduce uncertainty in co-ordinate location, since the focal 'point' is now distributed over a finite region of image space. A key point here is an appreciation that the additional aberrations introduced are entirely due to the refractive index mismatch between object and image spaces and are unconnected with the holographic process itself: they are in essence the same distortions seen when looking into a fish-tank. Furthermore, the water

itself may be expected to influence the quality of the images produced. An increase in the overall turbidity of the water will adversely affect both in-line and off-axis techniques and would be expected to create a background noise that will reduce image fidelity.

Techniques, such as immersing the holographic plate in water during recording or direct replay back into water, have been used to minimize underwater aberrations, but such methods are generally impractical in the field. One practical solution, unique to holography, compensates the change of effective wavelength of light as it passes through water, by allowing a deliberate mismatch of recording and replay reference beams to balance the refractive index mismatch.

For holograms recorded and replayed in air, a usual prerequisite is that the reconstruction wavelength should remain unchanged from that used in recording. By noting the dependence of wavelength on the refractive index, we can apply the more general condition that it is the ratio λ/n that must remain constant. This relationship suggests that a hologram, immersed in water, and recorded at a wavelength λ_a will produce an aberration-free image in air when replayed at a reconstruction wavelength, λ_c, which is itself equivalent to the wavelength of light when passing through water, λ_w, i.e.:

$$\lambda_c = \lambda_w = \lambda_a n_a / n_w \qquad [3]$$

where n_a and n_w are the respective refractive indices of air and water. Thus, in principle, the aberrations may be completely eliminated by the introduction of an appropriate wavelength change between recording and replay. If a green (532 nm) laser is used in recording, the ideal replay wavelength is about 400 nm (i.e., 532 nm/1.33). However, no convenient laser lines exist at exactly this wavelength. Furthermore, complete correction assumes that the entire recording system be located in water. Since this is both impractical and undesirable, holograms are usually recorded with the holographic film in air behind a planar glass window. The additional glass and air paths affect the compensation of aberrations. However, third-order aberration theory shows that if the window-to-air path length ratio is appropriately chosen for a specific replay wavelength, then aberration balancing occurs and residual aberrations are reduced to a minimum over a wide range of field angles and object locations. For an air gap of 120 mm and a BK7 window of 30 mm thickness, a blue replay wavelength of 442 nm (HeCd laser) achieves a good performance over a full field angle of about 40°.

In most underwater applications the objects (or the camera) are in motion during the exposure. The effect of this motion is to blur out the finer fringes, and thus reduce resolution and contrast. In-plane motion is the most severe, and adopting the experimentally verified criterion that the maximum allowable motion is less than one-tenth of the minimum required fringe spacing of the smallest object, then for in-line holograms the maximum object motion must be less than one-tenth of the object's dimension. For particles of 10 μm dimension, and a typical Q-switched YAG laser pulse duration of 20 ns, a high transverse velocity of up to 50 m s^{-1} can be tolerated. Off-axis holograms are more demanding in their requirements and the maximum allowed velocity is reduced to about 3 m s^{-1}. This is, however, more than adequate for most field applications of the technique.

Underwater Holographic Cameras

The first-known use of holography for recording living marine plankton was by Knox in 1966, who recorded in-line holograms (ILH), using a short coherence length ruby laser, of a variety of living marine plankton species in a tank. However, to avoid problems with refractive index and wavelength changes, the holographic plate was immersed directly in water, which is completely impractical for field use. It was not until the late 1970s that quantitative data from replayed holograms of marine particles recorded *in situ* were obtained by Carder and his team. Small volumes (10 or 20 cm^3) were recorded using ILH and a low-power HeNe laser, which limited the technique to slowly moving objects. Later, Heflinger used the off-axis geometry with both pulsed argon-ion (514 nm) and pulsed xenon (535 nm) lasers to record plankton on 35 mm film. In order to compensate for the aberrations introduced by replaying the real image in air, the real image was projected back into the water tank using a conjugate beam from a continuous-wave argon laser. The sides of their tank were flexible so that the real image could be placed close to the exit window and viewed via an external microscope. Knox later developed a ship-borne in-line holographic camera which was deployed from the *RV Ellen B Scripps*. A pulsed xenon laser was used to record water volumes of up to 10^5 cm^3 to a water depth of 100 m.

It was not until the late 1990s that significant use of underwater holography for plankton recording came to the fore again. Joseph Katz at Johns Hopkins University, Baltimore, USA developed a camera based

around a ruby laser to record in-line holograms on rolls of film, in a 63 mm diameter sample volume that can be varied from 100 to 680 mm in length. The camera housing utilizes a two-tube design with one tube holding the laser and another containing film holder and power units. The recording volume is situated 890 mm above the camera to minimize disturbance to flow. The camera is designed as a 'Lagrangian drifter' to move with the water current and was successfully deployed in Chesapeake Bay, Baltimore, and Solomon's Island, Maryland. Holograms were recorded of various species of phytoplankton and zooplankton and represented a significant advance in the deployment of sub-sea holography.

From the early 1980s, a team led by Aberdeen University, Scotland, investigated the use of underwater holography for offshore applications. Primary interest was in inspection of subsea pipelines for corrosion and damage, and much of the work concentrated on an analysis of the optical aberrations introduced by recording in water and replaying in air and methods of compensating for such aberrations. However, this work was later adapted for holography of plankton and led to the consequent development of the HoloMar system. The HoloMar camera was the first to incorporate simultaneous ILH and OAH recording.

More recent developments have utilized digital or electronic recording of holograms in the in-line mode, and it is to be expected that much more use will be made of 'e-holography' in the future.

For field applications of holography, it is essential to record the holograms using a pulsed laser in order to create stable interference fringes. For subsea purposes, a laser with a wavelength in the blue-green region of the spectrum will match the oft-quoted peak transmission window of seawater. In practice, a frequency-doubled Nd-YAG laser with a wavelength of 532 nm is a good choice, although ruby lasers operating at 694 nm are also acceptable if transmission distance is not an issue. Usually OAH requires more energy and places stricter constraints on coherence properties than ILH. Beam quality is governed by quality of the optical components in the beam path and also by the output beam of the laser itself. Because off-axis holography uses diffuse front/side illumination, energies of up to several hundred millijoules are often required for large (up to a meter in diameter) poorly reflective objects, and coherence lengths of greater than a meter are needed to record large scene depths. To obtain a long coherence length, and thus enable large-volume objects to be recorded, it is necessary that the laser operate in a single longitudinal cavity mode so that the bandwidth of the laser line is kept small. To enable smooth even illumination of both subject and holographic emulsion, good spatial beam quality is needed. This usually dictates laser output beams with either a Gaussian (TEM_{00}) mode profile or a flat profile, and spatial filtering during beam expansion. Compared to off-axis holography, the demands placed upon lasers for ILH are minimal. The only essential requirement is for a good spatial mode structure. Energy requirements are moderate: as little as 10 mJ is enough since little light is lost during the passage of the beam through the recording volume. The laser coherence length can be quite short, and only depends on the

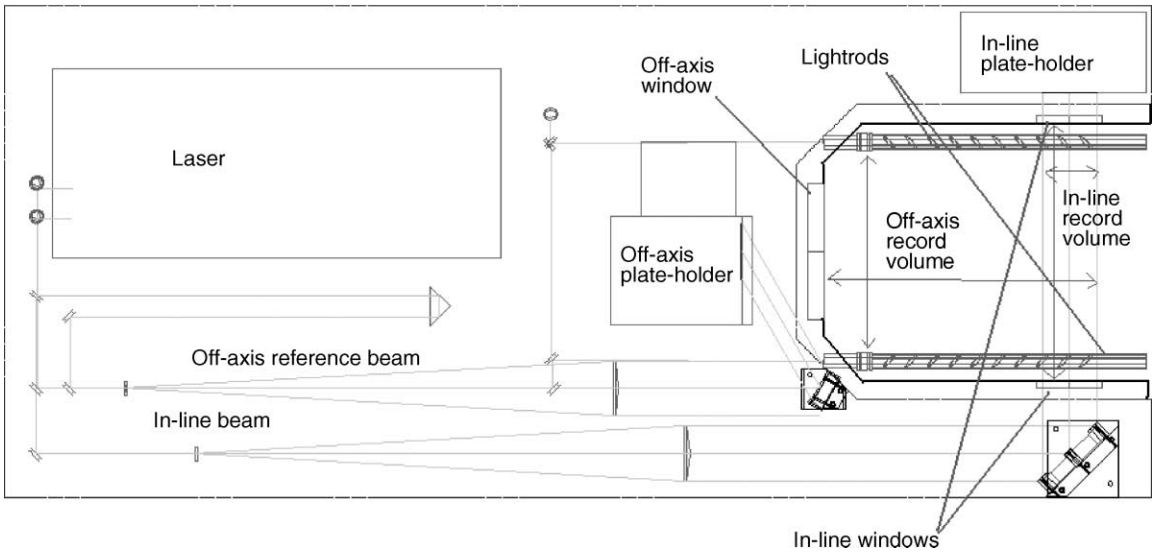

Figure 7 The HoloMar camera configuration showing the separate in-line and off-axis beam paths.

effective hologram area, thus lasers operating on more than one longitudinal mode are usually quite suitable.

The HoloMar System

The HoloMar system (shown diagrammatically in Figure 7) was developed to record simultaneous in-line and off-axis holograms of partially overlapping, but orthogonal, views of the water column. Although the recording views are orthogonal to each other, the arrangement provides an element of cross-correlation between holograms. It is designed around a Q-switched, frequency-doubled Nd-YAG laser with an output energy of 700 mJ in a single pulse of less than 10 ns duration and a coherence length in excess of 2 m. The laser output is split into two beams: one of 100 mJ and the other of 600 mJ energy. The 100 mJ beam is further split into two equal energy beams and expanded and collimated to a diameter of about 90 mm. One path forms the illuminating beam for the in-line mode and the other path forms the reference beam for the off-axis mode. The in-line path records a water column of 470 mm by 90 mm diameter (9,000 cm^3) at 400 mm from the front face of the housing, whereas the off-axis hologram records almost the entire volume (50,000 cm^3) delineated by the front window to the end of the arms that house the in-line system (see Figure 7). Three 'lightrods', encompassing hollow perspex tubes with 10 glass beam-splitter plates distributed equally along the length, positioned at 45° to the main axis, provide roughly even side illumination to the off-axis volume. The front face of the camera is shown in Figure 8; the lightrods are positioned on either side of the recording volume (two on one side, one on the other). The exit window for the in-line beam path and the off-axis window can also be seen.

Two motor-driven plate holders and transport mechanisms hold up to 20 plates for in-line and 24 for off-axis holograms. One pair of plates can be exposed every 10 seconds, or they can be exposed separately. The camera is remotely operated from the surface via a control console (PC). A network of micro-controllers serves as the backbone of the in-camera control system and communication between topside and camera modules is implemented using a Controller Area Network (CAN) bus via an umbilical cable. The entire camera is enclosed in a water-tight stainless steel housing of 1,000 mm diameter by 2,200 mm length. The prototype system is capable of either ship deployment or attachment to a fixed buoy and allows recording down to a water depth of 100 m.

The HoloMar camera is shown, in Figure 9, being lowered into Loch Etive, a sea loch on the west coast of Scotland, on its maiden dive. Figures 10 and 11 show holographic images of plankton recorded on this cruise. The first shows a view from a virtual

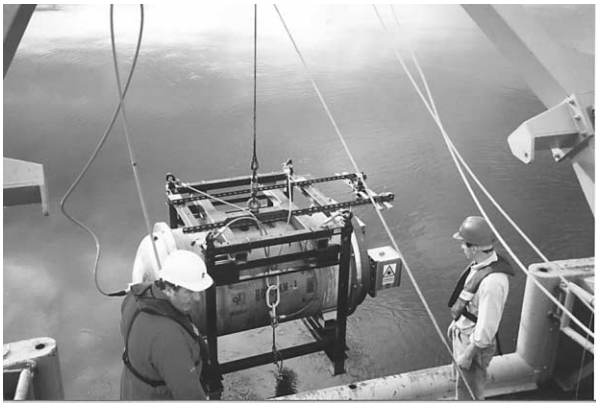

Figure 9 The HoloMar camera being lowered into Loch Etive, Scotland.

Figure 10 A photograph taken from a virtual image replay of an off-axis hologram recorded in Loch Etive.

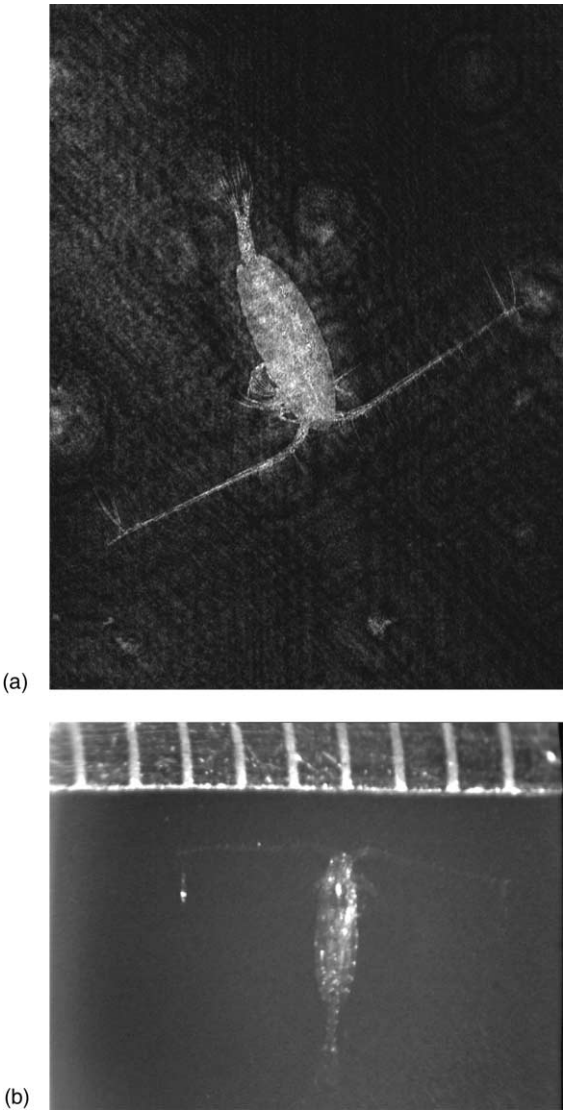

Figure 11 Images of calanoid copepods from (a) an in-line hologram recorded at 70 m depth and (b) an off-axis hologram recorded at 60 m depth, the millimeter scale is added at the replay stage. Each organism is approximately 4 mm long.

replay of an off-axis hologram at a wavelength of 514 nm: this is what a viewer would see when looking from the inside of the holocamera into the laser-illuminated water. Each bright dot signifies an object of interest; two fiducial wires can also be seen fixed diagonally across the arms at the end of the camera, some 300 mm from the off-axis window. In the lower left of the image a long 'string-like' object about 40 mm long is probably 'floc', the dead organic matter that forms the food-stuff of many zooplankton. Objects like this would be destroyed in net-collection. Figure 11 shows images taken from the real image projection of in-line and off-axis holograms. The holograms are replayed using a collimated beam at wavelengths of 514, 488, 457, or 442 nm, depending on location in the image volume. Some of the contrasting features between in-line and off-axis holograms are apparent: the in-line image shows clearly the outline of the organism with detail resolvable down to about 10 μm, whereas the off-axis hologram, although not achieving this resolution, reveals the body structure of the organism.

List of Units and Nomenclature

d	dimension of object to be recorded
D	effective aperture of hologram
n	refractive index
n_a	refractive index of air
n_w	refractive index of water
r	minimum resolvable separation between two points on the hologram
s	distance between hologram and image location
z	distance between hologram and object location
λ	wavelength
λ_a	in-air wavelength of recording beam
λ_c	reconstruction wavelength
λ_w	effective wavelength of recording beam in water

Holographic Recording Materials and Their Processing

Introduction

The first off-axis transmission holograms in the USA were recorded on Kodak 649F spectroscopic silver halide material (now discontinued). For the first reflection holograms, which were recorded in Russia, a very fine-grain emulsion (Lippmann emulsion) had to be prepared to resolve the fine interference pattern associated with such holograms. Since then various types of recording materials for holography have been developed and manufactured, including improved silver halide emulsions.

The following provides a brief description of the holographic recording process. For recording holograms and holographic optical elements (HOEs), dichromated gelatin, photopolymer materials, and photoresist materials are employed, in addition to silver halide materials. Existing holographic recording materials are described, as well as suitable processing methods to obtain high-quality holograms and HOEs.

Holographic Recording Materials

To produce a hologram, a micropattern, caused by interference between the object beam and the reference beam, is recorded in a light-sensitive high-resolution material. The quality of a holographic image depends on a number of factors, such as: the geometry and stability of the recording setup; the coherence of the laser light; the reference and object beam ratio; the type of hologram produced; the size of the object and its distance from the recording material; the recording material and the emulsion substrate used; the processing technique applied as well as the reconstruction conditions. The material must comply with certain requirements to be suitable for this purpose. The most important of these concerns the resolving power of the material. The recording material must be able to resolve the highest spatial frequencies of the interference pattern created by the maximal angle θ between the reference and the object beams in the recording setup (Figure 1).

If λ is the wavelength of the laser light used for the recording of a hologram and n the refractive index of the emulsion, then the closest separation d_e between the fringes in the interference pattern created by the angle θ between the reference and the object beams in the recording setup is

$$d_e = \frac{\lambda}{2n \sin(\theta/2)} \qquad [1]$$

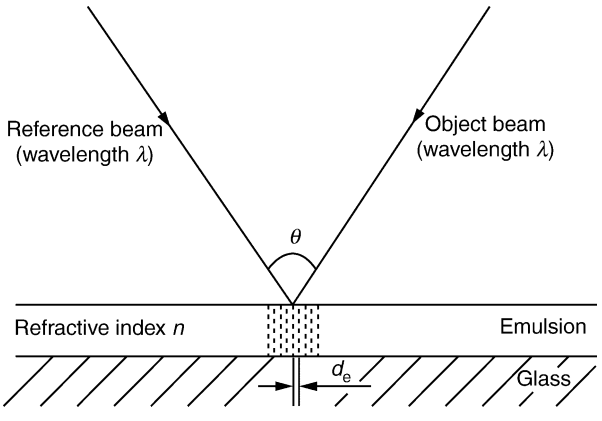

Figure 1 Demand on resolution for recording a hologram.

For high-quality holograms the resolution limit of the material must be higher than the minimum value obtained according to the above formula. For a reflection hologram recorded in blue light ($\lambda = 400\,\text{nm}$) with an angle of 180° between the beams, a minimum resolving power of 7600 lines $(\text{mm})^{-1}$ is required.

In holography, the resolution of the holographic image and the resolving power of the recording material are not directly related to the way in which they are in photography.

Equation [1] gives the minimum resolving power needed to record a hologram. The resolution of the image depends on the area (diameter D) of the recording material, the recording laser wavelength (λ), and the distance (L) between the recording material and the object (Figure 2).

Theoretically, the resolution of the holographic image is the diffraction-limited resolution that can be obtained when the information is collected over an aperture equal to the size of the recording holographic plate. In principle, the larger the holographic plate the better the resolution will be. To obtain high image resolution, it is important that the recorded interference fringes will not change or be distorted during processing. To prevent that from happening, a stable support for the emulsion (like a glass plate) is needed and the processing method applied must not affect the recorded fringe pattern in the emulsion. In coherent imaging systems laser speckles are present which may also have an effect upon image resolution.

There are two main types of holograms: amplitude and phase holograms. In a pure amplitude hologram only the absorption varies with the exposure (after processing), whereas in a pure phase hologram, either the refractive index or the emulsion thickness varies with the exposure. If the hologram is thin, $d \approx 0$, phase variations are then caused by surface relief variations only. If the hologram is thick and has a negligible surface relief ($\Delta d = 0$), phase variations are caused by index variations only. In many cases, the phase modulation in a hologram is a combination of the two different extreme types (a complex hologram).

For amplitude holograms, amplitude transmission T_a against exposure or log exposure is used (Figure 3). For a phase hologram, the corresponding curve is the phase shift against the log exposure relation (Figure 4).

One of the most important hologram characteristics is its diffraction efficiency η. It is defined as the diffracted intensity E_i of the wanted diffraction order of the hologram in relation to the incident

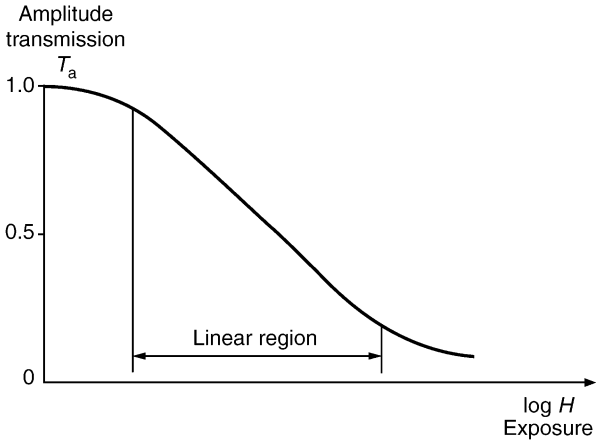

Figure 3 Amplitude transmission T_a versus the logarithm of exposure H used for the characterization of amplitude transmission holograms.

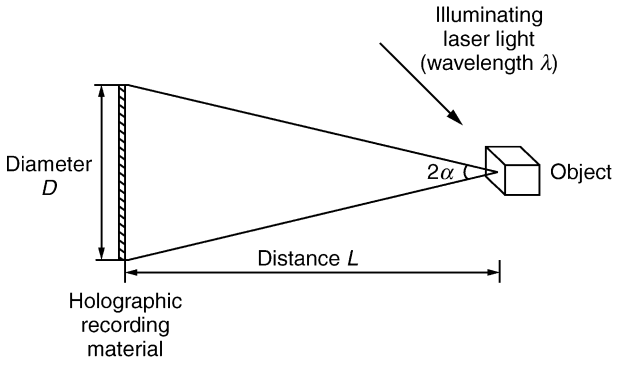

Figure 2 Resolution of a holographic image depends on the area (diameter D) of the recording material, the recording laser wavelength λ, and the distance L between the recording material and the object.

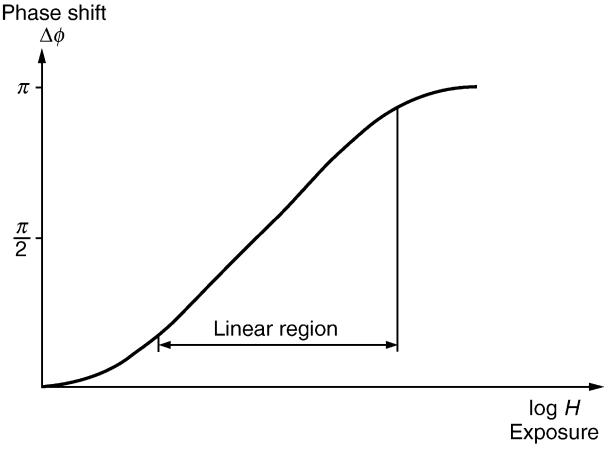

Figure 4 Phase shift $\Delta\phi$ versus the logarithm of exposure H used for the characterization of phase transmission holograms.

intensity of the reconstruction beam E_r : $\eta = E_i/E_r$. In the definition of η, the incidental light losses caused by surface reflection and base absorption should be subtracted, but are often ignored. Other important hologram characteristics are the signal-to-noise ratio (SNR) and the dynamic range of the recording material.

The resolution capability of an image reproduction process is normally described by the Modulation Transfer Function (MTF). Briefly, a test pattern containing a sinusoidal variation in illuminance combined with a continuous variation in spatial frequency along one direction is recorded. The modulation M of the pattern in the test target is

$$M = (H_{\mathrm{MAX}} - H_{\mathrm{MIN}})(\mathrm{H}_{MAX} + \mathrm{H}_{MIN})^{-1} \qquad [2]$$

where **H** is the exposure incident on the photographic material. When this pattern is recorded in the material, light scattering will take place in the emulsion, which will reduce the original contrast of the pattern. Therefore, the modulation of the pattern will be decreased, in particular at high spatial frequencies. The effective exposure modulation M' will then be

$$\mathrm{M}' = (H'_{\mathrm{MAX}} - H'_{\mathrm{MIN}})(H'_{\mathrm{MAX}} + H'_{\mathrm{MIN}})^{-1} \qquad [3]$$

where $\mathbf{H}'$ is exposure in the emulsion.

The original modulation M is constant and accurately known; it is also independent of the spatial frequency. After the tested emulsion has been processed, the corresponding 'exposed' modulation is obtained from the density variations. The ratio between modulation M' in the emulsion and modulation M of the incident exposure is called the modulation transfer factor, also called response

$$R = M(M')^{-1} \qquad [4]$$

If the response is plotted as the function of spatial frequency, this curve will then be the modulation transfer function of the material. The MTF for both a holographic emulsion and a conventional photographic emulsion are illustrated in Figure 5.

There are many ways of categorizing holograms but here we are mainly interested in definitions related to the recording material and its processing. One of the valid criteria is the thickness of the recording layer (as compared to the interference fringe spacing within the layer), i.e., the layer coated on the material substrate. Holograms can thus be classified into 'thin' or 'thick' (sometimes also called 'plane' or 'volume' holograms, respectively). To distinguish between the two types, the Q-parameter is normally used; it is defined in the following way:

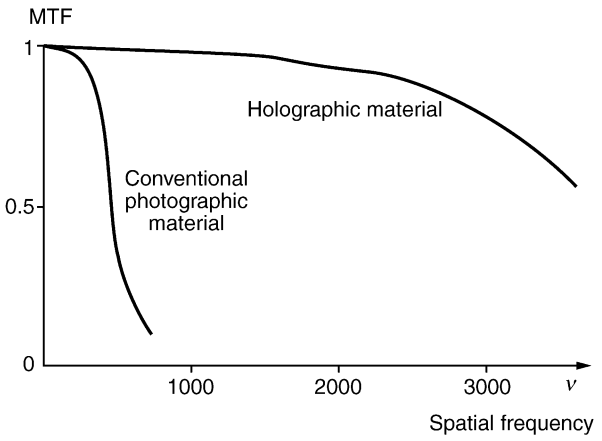

Figure 5 Graphical representation of the modulation transfer function (MTF) curves for both a conventional emulsion and a holographic emulsion are shown.

$$Q = 2\pi\lambda d(n\Lambda^2)^{-1} \qquad [5]$$

where λ is the wavelength of the illuminating light, d is the thickness of the layer, n is the refractive index of the emulsion, and Λ the spacing between the recorded fringes. A hologram is considered thick if $Q \geq 10$, and thin if $Q \leq 1$. Holograms with Q-values between 1 and 10 can be treated as either thin or thick.

Recording Materials

The most common holographic materials used for recording holograms are the following: silver halide emulsions; dichromated gelatin emulsions; photopolymer materials; photoresist materials; thermoplastic materials; bacteriorhodopsin; and photorefractive crystals.

The following materials can also be considered for holographic recordings, but not many practical applications have been reported so far: chalcogenide glasses; ferroelectric-photoconductors; liquid crystals; magneto-optic films; metal and organic dye ablative films; photochromic and photodichroic materials; photothermorefractive glass; and transparent electrophotographic films.

Sensitivity of Photographic and Holographic Materials

The time of exposure for a given material will depend on the sensitivity of the material used, as

well as on the intensity of the interference pattern. Some holographic materials must be processed after exposure in a specific way to obtain a hologram. The recorded intensity variations are converted during this processing step to local variations in optical density or refractive index and/or thickness of the recording layer.

Exposure H is defined as the incident intensity E times the time t of exposure of the recording material. If the intensity is constant during the whole exposure time, which is usually the case, then

$$H = Et \qquad [6]$$

Holographic materials are usually characterized using radiometric units. The radiometric equivalent of illuminance is irradiance. The unit of irradiance is $\mathrm{W(m)}^{-2}$ and the exposure will then be expressed in $\mathrm{J(m)}^{-2}$. The sensitivity of a holographic emulsion is most often expressed in $\mu\mathrm{J(cm)}^{-2}$ or $\mathrm{mJ(cm)}^{-2}$. Knowing the sensitivity of the material used and having measured the irradiance at the position of the holographic plate, the exposure time can be calculated using the above formula, i.e.,

$$\text{Exposure time} = \text{sensitivity/irradiance}$$

Holographic materials are sensitized in such a way that they are optimized for laser wavelengths commonly used in holography.

Silver Halide Materials

A silver halide recording photographic material is based on one type, or a combination of silver halide crystals embedded in a gelatin layer. The emulsion is coated on a flexible or stable substrate material. Silver-halide grain sizes vary from about 10 nanometers for the ultra-fine-grain holographic emulsions to a few micrometers for highly sensitive photographic emulsions (Table 1).

Silver salts are only sensitive to UV light, violet, and deep blue light. Therefore special sensitizers (dyes) must be added to the emulsion to make it sensitive to other parts of the spectrum. Orthochromatic emulsions are sensitive to green light. If the material has been sensitized to both green and red light, it is said to be panchromatic.

In the following, silver halide materials manufactured by photographic and holographic companies are described. The main difference between the new materials and the previous emulsions from Agfa, Ilford, etc., is that for the current silver halide emulsions, the grain sizes are smaller. The present holographic silver halide emulsion manufacturing process is more or less based on the Russian ultrafine-grain emulsion technology.

Table 1 Silver halide emulsion grain sizes

Type of emulsion	*Average grain diameter [nm]*
Ultra-fine-grain holographic emulsion	10–30
Fine-grain holographic emulsion	30–50
Fast holographic emulsion	50–100
Chlorobromide paper emulsion	200
Lithographic emulsion	200–350
Fine-grained photographic emulsion	350–700
Fast photographic emulsion	1000–2000
Fast medical X-ray emulsion	2500

Substrates for Holographic Emulsions

The material on which the emulsion is coated has a strong bearing on the final quality of the hologram. The best choice is often a glass plate as it is mechanically stable and optically inactive. High resolution imaging, hologram interferometry, holographic optical elements (HOEs) and spatial filters are a few examples where a very stable emulsion support is important. Mass produced holograms are mainly recorded on film substrates. However, the use of film has many advantages as compared to that of glass (breakage, weight, cost, size, etc.). Film substrates are used exclusively in the production of large-format holograms. Film substrates are of mainly two types: a polyester (polyethylene terephthalate); or a cellulose ester, commonly triacetate (cellulose triacetate) or acetate–butyrate. Polyester is mechanically more stable than triacetate film and it is also less sensitive to humidity. Because of the higher tensile strength, the polyester film can be made thinner than the triacetate film. On the other hand, polyester is birefringent, which can cause problems when recording holograms. In Table 2 most current commercial silver halide materials for holography are listed.

Processing of Silver Halide Emulsions

In silver halide emulsions a latent image is formed during exposure, which later is developed to a silver image. Processing (development, fixing, and bleaching) silver halide emulsions requires some expertise to obtain high-quality holograms. With the exception of DCG emulsions, other holographic materials are easier to process and more straightforward. Here it is not possible to describe all techniques employed and recipes used for silver halide processing. The reader is referred to the Further Reading section for more details.

Table 2 Commercial holographic recording materials

Material	*Thickness [μm]*	*Spectral sensitivity [nm]*	*Sensitivity [μJ (cm)$^{-2}$] at*				*Resolv. power [lp (mm)$^{-1}$]*	*Grain size [nm]*

The developing agent is the most important constituent in a holographic developer. In addition to the developing agent, a developer consists of the following components: a preservative (or antioxidant); a weak silver-solvent agent; an accelerator (or activator); a restrainer; and a solvent which is usually water. Employing a developer which contains a silver-solvent agent, solution-physical development

or semi-physical development can be performed. Such a developer is particularly suitable for processing the ultrafine-grain emulsions.

Holographic Developers

Silver halide materials for holography are all of the fine-grain type. Such materials require the application of special processing techniques to achieve the best possible results. For the processing of amplitude holograms a high-contrast developer is required, such as Kodak D-19. For holograms which are going to be bleached (phase holograms), developers based on ascorbic acid, hydroquinone, metol, pyrocatechol, or pyrogallol are frequently used. The following developers are recommended for the new silver halide materials: D-19; CW-C2; AAC; MAA-3; PAAP; and for pulsed laser recordings, the SM-6 developer. Colloidal development, employing a highly diluted developer which contains silver solvents, is recommended for the ultrafine-grain emulsions. Colloidal silver grains formed in the emulsion during such development are very small which means that very little absorption occurs. The method produces holograms with high diffraction efficiency combined with very low light scattering noise. The Russian GP-2 developer is recommended for colloidal development. Recipes for common holographic developers are found in Table 3.

Bleach Baths

Bleaching is used to convert a developed hologram (containing a silver image) into a phase hologram, to obtain a higher diffraction efficiency than is possible for amplitude holograms. During bleaching the silver image is converted into a water-soluble or an insoluble silver compound. Holographic bleaching techniques can be divided into three categories:

1. Conventional or direct (rehalogenating) bleaching;
2. Fixation-free rehalogenating bleaching;
3. Reversal (complementary) or solvent bleaching.

In conventional bleaching, the developed silver image is, after fixing, converted into a transparent silver halide compound, i.e., after the unexposed silver halide crystals have been removed. This method is not recommended for ultrafine-grain emulsions. Instead the fixation-free rehalogenating bleaching is preferred. The hologram is bleached directly after development, without fixing, leaving the unexposed silver halide crystals in the emulsion. A rehalogenating bleach bath consists of: an oxidizing agent; an alkali halide (often KBr); and a buffer. Among the rehalogenating bleaches, the following bleach baths work well: PBQ-bleach; Ferric EDTA; and the PBU-bleaches (PBU-amidol or the PBU-metol).

In reversal bleaching, the developed silver image is not fixed. Instead it is converted into a soluble silver complex which is removed from the emulsion during bleaching, leaving only the original unexposed silver halide grains in the emulsion. A reversal bleach bath consists of an oxidizing agent and a buffer. For ultrafine-grain silver halide emulsions, the reversal method is not recommended. The very small unexposed silver halide grains are also affected (partly dissolved) during reversal bleaching, resulting in low diffraction efficiency. For materials with larger grains, a more diluted version of the dichromate Kodak R-9 bleach can be

Commercial Silver Halide Emulsions

In Table 2 most of the current silver halide holographic emulsions are listed. The main manufacturer of holographic silver halide emulsions is the Micron branch of the SLAVICH Joint Stock Company photographic company located outside Moscow (2 pl. Mendeleeva, 152140 Pereslavl-Zalessky, Russia, www.slavich.com). Both film (triacetate) and glass plates are manufactured. Many different sizes are produced, including 115 cm by 10 m film rolls. Recommended holographic developers: CW-C2, SM-6. Many rehalogenating holographic bleach baths work well and, in particular, the PBU-type bleaches are recommended.

Colourholographic Ltd is a new company based in England (Braxted Park, Great Braxted, Witham CM8 3BX, England; www.colourholographic.com). The Colourholographic materials are based on the HRT emulsion, previously manufactured in Germany by Dr Birenheide. At the present time only glass plates are manufactured in England. Recommended processing solutions for the new HRT materials are a sodium-sulfite-free ascorbic acid–metol developer followed by a rehalogenating ferric EDTA or PBU bleaches. For reflection holograms, a pyrogallol developer and the ferric-EDTA bleach can be used.

Eastman Kodak's holographic materials are produced in America (343 State Street, Rochester, New York 14650, USA; www.kodak.com/go/PCB products). These plates are usually made to order only. Materials can be ordered with (marked -01) or without (marked -02) anti-halation layer. The 120 emulsion can be used for recording holograms using a pulsed ruby laser. Kodak recommends the developer Kodak D-19 for the processing.

FilmoTec is located in Germany (Chemie Park Bitterfeld-Wolfen, Röntgenstrasse, D-06766 Wolfen, Germany; www.filmotec.de). The company manufactures ORWO holographic emulsions which are coated only on triacetate film, 104 cm wide in 10 and 30 m lengths.

In France, M. Yves Gentet has started a small-scale emulsion manufacturing company: Atelier de Création d'Art en Holographie Yves Gentet (50, rue Dubourdieu, F-33800 Bordeaux, France; www.perso.wanadoo.fr/holographie) Monochromatic and panchromatic ultrafine-grain emulsions are produced called 'Ultimate'. Plates and film up to 60 cm by 80 cm are produced. An ascorbic acid–metol developer is recommended followed by a Ferric EDTA bleach. In addition, the Russian GP-2 developer can be used. Also a special developer can be ordered from the company.

Konica in Japan is manufacturing a green-sensitive emulsion for the use in the American holographic VOXEL 3D medical imaging system and, in addition, for the Japanese market only.

Dichromated Gelatin Materials

Dichromated gelatin (DCG) is an excellent recording material for volume phase holograms and HOEs. The grainless material has its highest sensitivity in the UV region, but extends into the blue and green parts of the spectrum. There are possibilities to sensitize the

emulsion in the red part of the spectrum as well. However, DCG is most often exposed with blue laser wavelengths. Depending on processing parameters, diffraction efficiency and bandwidth can be controlled. It is easy to obtain high diffraction efficiency combined with a large SNR.

During the exposure of a DCG emulsion to UV or blue light, the hexavalent chromium ion (Cr^{6+}) is photo-induced to trivalent chromium ion (Cr^{3+}) which causes cross-linking between neighboring gelatin molecules. The areas exposed to light are hardened and become less soluble than the unexposed areas. Developing consists of a water wash which removes the residual or unreacted chemical compounds. Dehydration of the swollen gelatin follows after the material has been immersed in isopropanol, which causes rapid shrinkage resulting in voids and cracks in the emulsion, thus creating a large refractive index modulation. The underlying mechanism is not completely clear because high modulation can also be caused by the binding of isopropanol molecules to chromium atoms at the cross-linked sites. The DCG material has a rather low sensitivity of about 100 mJ$(cm)^{-2}$. In many cases DCG plates are prepared by fixing an unexposed silver halide emulsion and then sensitizing it in a dichromate solution. It is also, for example, possible to make a 10 μm thick emulsion on a 8″ by 10″ glass plate using 1 g ammonium dichromate mixed with 3 g photographic grade gelatin in 25 ml deionized water. Then the emulsion is spin-coated on the glass substrate or the emulsion is applied by the doctor blade coating technique. Many HOE manufacturers prefer to produce their own emulsions but there are also commercial DCG emulsions available on the market.

Processing of DCG holograms are performed in graded alcohol (propanol) baths starting with water–propanol solutions of high water content and ending with pure propanol (cold or hot) baths. Depending on the wanted HOE characteristics, one has to carefully control the propanol/water mixtures as well as the temperature of the different baths. Cold baths produce better uniformity and lower noise. Warm baths can yield high index modulation but often with increased noise. The bandwidth can be controlled by the processing temperature and the ratio of propanol/water mixtures.

Commercial DCG Materials

Slavich in Russia is one manufacturer of presensitized dichromated plates for holography. The DCG emulsion is marked PFG-04. Plates up to a size of 30 by 40 cm can be ordered.

The FilmoTec DCG emulsions are only available on 190 μm triacetate film, 104 cm wide in 10 and 30 m lengths; emulsion thickness 6 or 20 μm. Note that the film needs to be sensitized in dichromate solution before recording. This means that the company only supplies large-format gelatin-coated film.

Holotec is a German-based company which offers presensitized DCG coated on both plates and film (Jülicher Strasse 191, D-52070 Aachen, Germany; www.holotec.de). The Holotec emulsion is the high-quality DCG emulsions developed by Professor Stojanoff in Aachen. The company can supply large-format DCG glass plates (m^2 size) or film (PET-Polyethylenterephtalat), pre-sensitized and ready to use.

Photopolymer Materials

Photopolymer materials have become popular for recording phase holograms and HOEs, in particular for mass production of holograms since some photopolymer materials only require dry processing techniques.

A photopolymer recording material, such as the DuPont material, consists of three parts: a photopolymerizable monomer; an initiator system (initiates polymerization upon exposure to light); and a polymer (the binder). First, an exposure is made to the information-carrying interference pattern. This exposure polymerizes a part of the monomer. Monomer concentration gradients, formed by variation in the amount of polymerization due to the variation in exposures, give rise to diffusion of monomer molecules from the regions of high concentration to the regions of lower concentration. The material is then exposed to regular light of uniform intensity until the remaining monomer is polymerized. A difference in the refractive index within the material is obtained. The DuPont material requires only a dry processing technique (exposure to UV light and a heat treatment) to obtain a hologram. The DuPont photopolymer materials have a coated film layer thickness of about 20 μm. The photopolymer film is generally coated in a 12.5″ width on a 14″ wide Mylar® polyester base which is .002″ thick. The film is protected with a .00092″ thick Mylar® polyester cover sheet.

The recording of a hologram on DuPont polymer is rather simple. The film has to be laminated to a piece of clean glass or attached to a glass plate using an index-matching liquid. Holograms can be recorded manually, but in order to produce large quantities of holograms, a special machine is required. For hologram replication a laser line scanning technique can provide the highest production rate.

The photopolymer material needs an exposure of about 10 mJ(cm)$^{-2}$.

After the exposure is finished, the film has to be exposed to strong white or UV light. DuPont recommends about 100 mJ(cm)$^{-2}$ exposure at 350–380 nm. After that, the hologram is put in an oven at a temperature of 120 °C for two hours in order to increase the brightness of the image. The process is simple and very suitable for machine processing using, for example, a baking scroll oven.

Commercial Pholymer Materials

Currently the only manufacturer of holographic photopolymer materials is E.I. du Pont de Nemours & Co. (DuPont Holographics, POB 80352, Wilmington, DE 19880, USA; www.dupont.com/holographics). In the past it was possible to obtain photopolymer materials from DuPont, but in 2002 the company changed its policy and today it is producing materials mainly for DuPont Holographics, but approved customers may still be able to buy material from DuPont. The reason for the restrictions is that many applications of mass-produced holograms are in the field of document security, where DuPont's photopolymers are used to produce optical variable devices (OVDs).

Photoresist Materials

Photoresist materials in holography are used for making masters for display and security holograms. The recorded relief image in the photoresist plate is then used to make the nickel shim needed as the tool for embossing holograms into plastic materials.

The exposure to actinic radiation produces changes in the photoresist layer that result in a solvency differentiation as a function of exposure. Processing is done with a suitable solvent dissolving either the unexposed or exposed regions, depending on whether the resist is of the negative or the positive type. For optical recording, positive photoresist (exposed resist removed during development) is preferred to the negative type because of the higher resolving power and low scatter. On the resulting surface, relief pattern particles of nickel are deposited by electrolysis to make a mold, which can then be used as an embossing tool. The photoresist process can be used for making transmission holograms only. If an embossed hologram is mirror-backed by using, for example, an aluminum coating process, it can be used in the reflection reconstruction mode as well. Photoresists are UV and deep-blue sensitive. The material is spincoated on glass substrates to obtain a thickness of between 0.5 and 2 μm, then it is baked at about 75 °C for 15 minutes. A typical photoresist for holography (e.g., Shipley Microposit 1350) has a sensitivity of about 10 mJ(cm)$^{-2}$. The most common laser wavelengths for recording photoresist holograms are the following wavelengths: 413 nm (Krypton-ion), 442 nm (Helium–Cadmium), and 458 nm (Argon-ion). At higher wavelengths, e.g., 488 nm, the sensitivity is rather low. Development of Shipley resist is performed in Shipley 303A developer, diluted 1 part developer + 5 parts de-ionized water. Normally only a 10 second development time is needed (under agitation). After that the plate has to be rinsed in de-ionized water for 2 minutes. The plate needs to be dried quickly with a high pressure steam of compressed nitrogen or dry, filtered compressed air.

Commercial Resist Materials

The main American manufacturer of photoresist is Shipley Co. (1457 Macarthur Rd., #101, Whitehall, PA 18052, USA). There are a few companies which make plates based on Shipley resist.

Towne Technologies, Inc. (6–10 Bell Ave., Somerville, NJ 08876, USA; www.townetech.com) produces spin-coated plates using Shipley resist (Shipley S-1800 series). Towne plates have a sublayer of iron oxide which enhances adhesion of the resist during electroplating operations. In addition, the sublayer eliminates unwanted backscatter from the glass substrate. The plates are developed in Shipley 303A developer.

Hoya Corporation (7-5 Naka-Ochiai 2-chome, Shinjuku-ku, Tokyo, Japan; www.hoya.co.jp) is a producer of mask blanks coated with 0.5 μm thick Shipley S-1800 resist (SLW plates). Different types of glass as well as quartz plates are produced. Hoya supply plates for holography, however, custom orders only.

Thermoplastic Materials

The holographic thermoplastic is a multilayer structure coated on glass or film. The substrate is first coated with a conducting layer, e.g., evaporated gold, then a photoconductor, e.g., poly-n-vinyl carbazole, PVK, that has been sensitized with, e.g., 2,4,7-trinitro-9-fluorenone (TNF), and on top of this layer a thermoplastic coating is deposited (usually a styrene-methacrylate material). The recording of a hologram starts with a uniform charging of the surface of the thermoplastic material using a corona charger. The charge is divided between the photoconductor and the thermoplastic layer. Exposure and the consequent photogeneration in the photoconductor cause charges of opposite signs to migrate to the interface with the thermoplastic layer and

the substrate. This will not change the charge, but only decrease the surface potential. Before the image can be developed, the material has to be recharged with the uniform corona charger. This step adds additional charges to the exposed areas, in proportion to the reduced potential which is also proportional to the exposure. The material is then heated to a softening temperature of the thermoplastic layer which will be deformed due to the electrostatic forces acting on it. The material is then cooled and the image is fixed as a relief surface pattern in the thermoplastic layer. The processing time after the exposure necessary to obtain the image is between ten seconds and half a minute. If the material is heated to a somewhat higher temperature, the pattern disappears and the image is erased. The thermoplastic material can now be used for the recording of another hologram, repeating the recording procedure. Such a cycling technique can be repeated hundreds of times, without any serious effect on the quality of the image. That, and the fast dry processing made such materials popular for the use in holographic cameras for nondestructive testing. The sensitivity is between 10 and 100 $\mu J(cm)^{-2}$ over the whole visible electromagnetic spectrum.

Commercial Thermoplastic Materials

In the past, several companies produced thermoplastic materials and recording equipment for holography. Since there is very little demand for such materials today, there is only one company which can deliver thermoplastic equipment for holography: Tavex America Inc. (14 Garden Road, Natick, MA 01760, USA; www.tavexamerica.com). Tavex America manufactures a thermoplastic camera, TCC-2 in which 40 mm by 40 mm plates are used. For obsolete systems, thermoplastic film can still be obtained from MD Diffusion in France (93 rue d'Adelshoffen, F67300 Schiltigheim, France).

Bacteriorhodopsin

Photochromic materials, a class to which bacteriorhodopsin (BR) belongs, have not been used much in holography. Photochromics are real-time recyclable materials which need no processing for development. They can easily be erased and reused over and over again. In holography the only successful material has been the BR film which was introduced only a few years ago. BR is a biomolecule with several applications in photonics, comprising a light-driven molecular proton pump with exceptional photoelectric and photochromic properties. BR is a photochromic protein, found in the photosynthetic system of a salt-marsh bacterium, termed purple membrane (PM), of the cell membrane of *Halobacterium salinarum*. BR thin films are made from polymer suspensions of the isolated purple membrane. Some of the desirable properties of BR films are real-time writing and erasing in microsecond time-scales, durability allowing millions of write/erase cycles without degradation, very high spatial resolution of 5000 $lp(mm)^{-1}$, reasonably good light sensitivity of approximately 10 $mJ(cm)^{-2}$, the encoding of both amplitude and phase patterns, and the use of visible laser light for writing and reading. The composition of the films may also be altered by chemical means to control the optical characteristics, and the BR molecules themselves may be mutagenically changed for performance optimization. Particular properties that can be enhanced in these ways are image lifetimes and the diffraction efficiency of holograms recorded in the films. One advantage of this material is that it is reversible. Therefore it has been considered to be used in holographic storage systems and for real-time holographic interferometry applications. BR film can be used for recording polarization holograms because of BR films inherent photo-inducable optical anisotropy. The material is also possible to expose with pulsed lasers, which makes it suitable for fast holographic recording.

The BR film works in the following way. When illuminated with green light, the BR molecule undergoes an absorption resulting in a maximum shift of about 160 nm towards the red and its color changes from purple to yellow. The yellow image can be erased by illuminating the BR material with blue light. The recording–erasing cycle can be repeated about a million times. Suitable BR-films for holography are obtained by embedding purple membranes into inert matrices like polyvinylalcohol or polyacrylamide. For hologram recording and erasure two photochemical conversions $B \rightarrow M$ (B-type holograms) and $M \rightarrow B$ (M-type holograms) can be employed. After excitation by light, BR cycles through a sequence of spectrally distinguishable intermediates and returns to the initial state. The time associated with this thermal relaxation process depends on several aspects, for example, type of BR (wildtype or variant), pH value of film-matrix, film-temperature, etc. For example, the M intermediate is populated from the B state (absorption spectrum peaked at 570 nm) by a green pumping beam and information is recorded with blue light, which initiates the photochemical $M \rightarrow B$ transition. The M state has its absorption peak at 410 nm. In BR variants in which the thermal relaxation of the M state has been prolonged, photocontrolled switching between these two states can be achieved. Only when

the pumping beam is incident upon the BR film can information be recorded with blue light. The pumping beam can be used as a readout beam for the recorded hologram.

Commercial BR Materials

A holographic camera based on a BR film is manufactured in Germany. The holographic system, FringeMaker-*plus*, developed at the University of Marburg is marketed by Munich Innovation Biomaterials (MIB) GmbH. (Hans-Meerwein-Str., D-35032 Marburg, Germany; www.mib-biotech.de). MIB is also a manufacturer of both wildtype and genetically modified BR film for holography and other scientific/technical applications. BR-films offered by MIB can be used in two different recording configurations: the transition from the initial B to M-state (induced with yellow light) serves as basis for optical data recording and processing (B-type recording); or the photochemically induced transition from M to B state (M-type recording). In the latter case, yellow light is used to control the population of the M-state and blue light is used to write the information. MIB offers BR-films with normal and slow thermal relaxation characteristics. Typical relaxation time ranges (RTR), after which the photochemically excited BR molecules have returned to the original state, are between 0.3 and 80 s. The BR film is sealed between two windows of high-quality optical glass. The BR film layer has a thickness of 30–100 μm, dependent on the optical density of the film. The diameter of the film device is 25 mm and the clear aperture is 19 mm.

Photorefractive Crystal Materials

Photorefractive crystals are electro-optic materials which are suitable for recording volume phase holograms in real-time. These crystals are important components in holographic storage systems and are seldom used in other holographic image applications. Holograms recorded in crystals, such as: lithium niobate ($LiNbO_3$); barium titanate ($BaTiO_3$); potassium tantalate niobate (KTN); barium sodium neobate (SBN); bismuth silicon oxide (BSO); and bismuth germanium oxide (BGO), consist of bulk space charge patterns. An interference pattern acting upon a crystal will generate a pattern of electronic charge carriers that are free to move. Carriers are moving to areas of low optical illumination where they get trapped. This effect will form patterns of net space charge, creating an electrical field pattern. As these crystals have strong electro-optic properties, the electrical field pattern will create a corresponding refractive index variation pattern, which means a phase hologram. These holograms can be immediately reconstructed with a laser beam differing from the beams creating the hologram. A hologram can also be erased and a new hologram can be recorded in the crystal. Holograms can be fixed by converting the charge patterns to the patterns of ions which are not sensitive to light. In some materials the hologram can be fixed by heating the crystal to above 100 °C based on thermally activated iconic conductivity. The resulting iconic is frozen upon cooling the crystal back to room temperature. More details about these materials and storage applications are found in the Further Reading.

Major Milestones

1948:	Essential concept for holographic recording by Dennis Gabor.
1960:	The first successful operation of a laser device by Theodore Maiman.
1962:	Off-axis technique of holography by Leith and Upatnieks.
1962:	Yu N Denisyuk suggested the idea of three-dimensional holograms based on thick photoemulsion layers. His holograms can be reconstructed in ordinary sunlight. These holograms are called Lippmann–Bragg holograms.
1964:	Leith and Upatnieks pointed out that a multicolor image can be produced by a hologram recorded with three suitably chosen wavelengths.
1969:	S A Benton invented 'Rainbow Holography' for display of holograms in white light. This was a vital step to make holography suitable for display applications.

Holography is the science of recording an entire optical wavefront, both amplitude and phase information, on appropriate recording material. The record is called a hologram. Unlike conventional photography, which records a three-dimensional scene in a two-dimensional format, holography records true three-dimensional information about the scene.

Holography was invented by Gabor in 1948 and his first paper introduced the essential concept for holographic recording – the reference beam. Holography is based on the interference between waves and, it provides us with a way of storing all the light information arriving at the film in such a way that it can be regenerated later.

The use of the reference beam is utilized because the physical detectors and recorders are sensitive only to light intensity. The phase is not recorded but is manifest only when two coherent waves of the same frequency are simultaneously present at the same location. In that case, the waves combine to form a single wave whose intensity depends not only on intensities of the two individual waves, but also on the phase difference between them. This is key to holography. The film record, or hologram, can be considered as a complicated diffraction grating. Holograms bear no resemblance to conventional photographs in that an image is not actually recorded. In fact, the interferometric fringes which are recorded on the recording material are not visible to an unaided eye because of extremely fine interfringe spacing (~ 0.5 micrometer). The fringes which are visible on the recording material are the result of dust particles in the optical system used to produce the hologram.

Gabor's original technique is now known as in-line holography. In this arrangement, the coherent light source as well as the object, which is a transparency containing small opaque details on a clear background, is located along the axis normal to the photographic plate. With such a system, an observer focusing on one image observes it superposed on the out-of-focus twin image as well as a strong coherent background. This constitutes the most serious problem of Gabor's original technique.

The first successful technique for separating the twin images was developed by Leith and Upatnieks in 1962. This is called the off-axis or side band technique of holography. We shall consider mainly the off-axis technique here.

Basic Holography Principle

Light from a laser or any light beam is characterized by spatial coherence (l_c) and temporal coherence (τ_c), which is discussed in all textbooks on optics. For typical laboratory hologram recording, the required degree of coherence of laser radiation is determined by the type of object and geometrical arrangement being used for the recording. The following condition must hold:

$$L \ll c\tau_c \qquad [1]$$

where τ_c is the coherence time, and L the maximum path length difference between the two waves chosen to record the hologram. To begin recording, two wavefronts are derived from the same laser source. One wavefront is used to illuminate the object and another is used as a reference wavefront. The wavefront derived by illuminating the object is superimposed with the reference wave and the interference pattern is recorded. These object and reference waves must:

- be coherent (derived from the same laser); and
- have a fixed relative phase at each point on the recording medium.

If the above conditions are not met, the fringes will move during the exposure and the holographic record will be smeared. Therefore, to record the hologram one should avoid air currents and vibrations. The recording medium must have sufficient resolution to record the fine details in the fringe pattern. This will be typically of the order of the wavelength. To create a three-dimensional image from the holographic process one then has to record and reconstruct the hologram. The object and reference waves are derived from the same laser.

Holograms record an interference pattern formed by interference of object and reference wavefronts, as explained above. We may mention here that for the two plane waves propagating at an angle θ between them, the spacing of the interference fringes is given by

$$\alpha = \frac{\lambda_0}{2\sin(\theta/2)} \qquad [2]$$

where λ_0 is the free space wavelength.

Processing of the hologram (developing, fixing, and washing of the recording material) yields a plate with alternating transparent and opaque parts, variation of refractive index, or variation of height corresponding to intensity variation in the fringe pattern. Such a plate can be regarded as a complicated diffraction grating. In this process, the hologram is illuminated with monochromatic, coherent light. The hologram diffracts this light into wavefronts which are essentially indistinguishable from the original waves which were diffracted from the object. These diffracted waves produce all the optical phenomena that can be produced by the original waves. They can be collected by a lens and brought into focus, thereby forming an image of the original object, even though the object has since been removed. If the reconstructed waves are intercepted by the eye of an observer, the effect is exactly as if the original waves were being observed; the observer sees what appears to be the original object in true three-dimensional form. As the observer changes his viewing position, the perspective of the image scene changes; parallactic effects are evident and the observer must refocus when the observation point is changed from a near to a distant object in the scene. Assuming that both the construction and reconstruction of the hologram are made with the same monochromatic light source, there is no visual test which can be made to distinguish between the real object and the reconstructed image of the object. It is as if the hologram were a window through which the apparent object is viewed.

Hologram of a Point Object

Consider a hologram recorded with a collimated reference wave normal to the recording plate and a point object inclined at a certain angle. If the hologram is illuminated once again with the same collimated reference wave, it reconstructs two images, one virtual true image and the other real image. However, the two images differ in one very important respect.

While the virtual image is located in the same position as the object and exhibits the same parallax properties, the real image is formed at the same distance from the hologram but in front of it. Corresponding points on the real and virtual images are located at equal distances from the plane of the hologram; the real image has the curious property that its depth is inverted. Such an image is not formed with a normal optical system; it is therefore called a pseudo image as opposed to a normal or orthoscopic image.

This depth inversion results in conflicting visual clues, which make viewing of the real image

psychologically unsatisfactory. Thus, if O_1 and O_2 are two elements in the object field, and if O_1 blocks the light scattered by O_2 at a certain angle, the hologram records information only on the element O_1 at this angle and records no information about this part of O_2. An observer viewing the real image from the corresponding direction then cannot see this part of O_2, which, contrary to normal experience, is obscured by O_1, even though O_2 is in front of O_1.

Production of an Orthoscopic Real Image

An orthoscopic real image of an object can be produced by recording two holograms in succession. In the first step, a hologram is recorded of the object with a collimated reference beam. When this hologram is illuminated once again with the collimated reference beam that was used to record it, it reconstructs two images of the object at unit magnification, one of them being an orthoscopic virtual image, while the other is a pseudoscopic real image. A second hologram is then recorded of this real image with a second collimated reference beam.

When the second hologram is illuminated with a collimated beam it reconstructs a pseudoscopic virtual image located in the same position as the real image formed by the second hologram is an orthoscopic image. Since a collimated reference beam is used throughout, the final real image is the same size as the original object and free from aberrations.

In addition to these characteristic linked intensities with the three-dimensional nature of the reconstruction, the holographic recording has several other properties. Each portion of the hologram can reproduce the entire image scene. If a smaller and smaller portion of the hologram is used for reconstruction, there is loss of image intensity and reconstruction. When a hologram is reversed, such as in contact printing processes, it will still reconstruct a positive image indistinguishable from the image produced by the original hologram.

Simple Mathematical Description of Holography

Let the object and reference waves be given by

$$U_o = O(x, y)e^{i\phi(x,y)} \qquad [3]$$

and

$$U_r = R\, e^{iky\sin\theta} \qquad [4]$$

U_r describes the reference (plane wave) propagating at angle θ to the z-axis.

The intensity at the hologram plane is

$$\begin{aligned} I &= |U_r + U_o|^2 \\ &= |U_r|^2 + |U_o|^2 + U_r^* U_o + U_r U_o^* \end{aligned} \qquad [5]$$

As can be seen from the above equation, the amplitude and phase of the wave are encoded as the amplitude and phase modulation of a set of interference fringes. The material used to record the patterns of interference fringes described above is assumed to provide linear mapping of the intensity incident during the reconstruction process into amplitude transmitted by or reflected from the recorded material. Usually both light detection and wavefront modulation are performed by photographic plate/film. We assume the amplitude transmission properties of the plate/film after processing to be described by

$$T = T_o - b(E - E_o) \qquad [6]$$

where the exposure E, at the film is $E = I\tau$; here τ is the exposure time. T_0 is the transmittance of the unexposed plate.

If the hologram is reilluminated by the reference wave, the transmitted wave amplitude will be

$$U_t = U_r(T_o - b\tau(|U_o|^2 + U_r^* U_o + U_r U_o^*)) \qquad [7]$$

The first term is reference wave times a constant. The second term is the reference wave modulated by $|U_o|^2 = O(x, y)^2$; it gives small-angle scattering about the reference wave direction. The third term is proportional to U_o. It is the same as the original object wave (note this is only so if the reconstruction wave is identical to the reference wave). The fourth term is

$$-b\tau U_r^2 U_0^* = -b\tau R^2\, e^{iky2\sin\theta} O(x, y)e^{-i\phi(x,y)} \qquad [8]$$

This is essentially a wave traveling in a direction $\sin^{-1}(2\sin\theta)$ to the z-axis, with the correct object amplitude modulation but its phase reversed in sign, producing a conjugate wave.

Types of Holograms

Primarily, the holograms are classified as thin and thick, based on the thickness of the recording medium. When the thickness of the recording medium is small compared with the average spacing of the interference fringes, the hologram can be treated as a thin hologram. Such holograms are characterized by

spatially varying complex amplitude transmittance:

$$\mathbf{t}(x, y) = [\mathbf{t}(x, y)]\exp[-i\phi(x, y)] \qquad [9]$$

Thin holograms can be further categorized as thin amplitude holograms or thin phase holograms. If amplitude transmittance of the hologram is such that $\phi(x, y)$ is constant while $\mathbf{t}(x, y)$ varies over the hologram, the hologram is termed an amplitude hologram. For a lossless phase hologram, $|\mathbf{t}(x, y)| = 1$, so that the complex amplitude transmittance is caused by variation in phase.

When the thickness of the hologram recording material is large compared to the fringe spacing of the interference fringes, the holograms may be considered as volume holograms. These may be treated as a three-dimensional system of layers corresponding to a periodic variation of absorption coefficient or refractive index, and the diffracted amplitude is at a maximum when Bragg's condition is satisfied. In general, the behavior of thin and thick holograms corresponds to Raman Nath and Bragg diffraction regimes. The distinctions between two regimes is made on the basis of a parameter Q, which is defined by the relation:

$$Q = \frac{2\pi\lambda_o d}{n_o \Lambda^2} \qquad [10]$$

where

Λ = spacing of fringe on hologram, measured normal to the surface;
d = thickness of recording medium;
n_o = mean refractive index of the medium; and
λ_o = wavelength of light.

Small values of Q ($Q < 1$) correspond to thin gratings, while large values of Q ($Q > 10$) correspond to volume gratings. For values of Q between 1 and 10, intermediate properties are exhibited. However, this criterion is not always adequate. The boundaries between the thin and thick holograms are given by the value of

$$P = \frac{\lambda_o^2}{\Lambda^2 n_o n_1} \qquad [11]$$

where P^{-2} is the relative power diffracted into higher orders, and $P < 1$ for thin holograms and $P > 10$ for thick holograms. For P having values between 1 and 10, the hologram may be thin or thick, depending on the other parameters involved.

Holograms can also be classified based on whether they are reconstructed in transmitted light or reflected light. For transmission holograms, during the recording stage, two interfering wavefronts make equal but opposite angles to the surfaces of recording medium and are incident on it from the same side. Reflection holograms reconstruct images in reflected light. They are recorded such that the interfering wavefronts are symmetrical with respect to the surface of the recording medium but are incident on it from opposite sides. When the angle between the interfering wavefronts is maximum (180°), the spacing between the fringe planes of the recording medium is minimum. Under such conditions, reflection holograms may have wavelength sensitivity high enough to be reconstructed, even with white light.

An important development in the field of holography was the invention of rainbow holograms by Benton in 1969. This provides a method for utilizing white light for illumination when viewing the holograms. The technique does so by minimizing the blur introduced by color dispersion in transmission holograms, at the price of giving up parallax information in one dimension.

Recording Materials

An ideal recording medium for holography should have a well matching spectral sensitivity corresponding to available laser wavelengths, linear transfer characteristics, high resolution, and low noise. It should also be either inexpensive or indefinitely recyclable. Toward achieving the above-mentioned properties, several materials have been studied, but none has been found so far that meets all the requirements. Materials investigated include: silver halide photographic emulsion; dichromated gelatin plates/films; silver halide sensitized gelatin plates/films; photo-resists; photo polymer systems; photochromics; photo thermoplastics; and ferro-electric crystals. Recently, the use of storage and processing capabilities of computers, together with CCD cameras, has been used for recording holograms.

Silver halide photographic emulsions are a commonly used recording material for holography, mainly because of relatively high sensitivity and easy availability. Manufacture, use, and processing of these emulsions have been well standardized. The need for wet processing and drying may constitute a major drawback. Dichromated gelatin can be considered an almost ideal recording material for volume phase holograms, as it has a large refractive index modulation capability, high resolution, low absorption and scattering.

Because of these features, dichromated gelatin has been extensively investigated. The most significant disadvantage is its comparatively low sensitivity. Pennington *et al.* developed an alternative technique, which combines the advantage of silver halide emulsions (high sensitivity) with that of dichromated

gelatin (low absorption scattering and high stability). It involves exposing silver halide photographic emulsion and then processing it, so as to obtain a volume phase hologram consisting solely of hardened gelatin.

Thin phase holograms can be recorded on photoresists, which are light-sensitive organic films yielding relief image after exposure and development. They offer advantages of easy replication using thermoplastics but are slow in response and undergo nonlinear effects at diffraction efficiency greater than ~0.05. Shipley AZ-1350 is a widely used photoresist, with maximum sensitivity in the ultraviolet, dropping rapidly for longer wavelengths towards the blue.

Photopolymers are being keenly investigated because they offer advantages such as ease of handling, low cost, and real-time recording for the application of holography and nonlinear optics. However, they have low sensitivity and short shelf life.

Thin phase surface relief holograms can be recorded in a thin layer of thermoplastics. These materials have a reasonably high sensitivity over the whole visible spectrum, fairly high diffraction efficiency, and do not require wet processing. Their application in holographic interferometry, optical information processing, and in making compact holographic devices has been widely reported.

Photorefractive crystals such as $Bi_{12}SiO_{20}$, $LiNbO_3$, $Bi_{12}GeO_{20}$, $BaTiO_3$, $LiTaO_3$, etc., as recording materials, offer high-angular sensitivity and provide capability to read and write volume holographic data in real time. Besides the materials discussed here, several other materials have been investigated for recording holograms; these include photocromics, elastomere devices, magneto-optic materials, etc.

Application of Holography

Holography can be constructed not only with the light waves of lasers, but also with sound waves, microwaves, and other waves in the electromagnetic spectrum of radiation. Holograms made with ultraviolet light or X-rays can record images of objects/particles smaller than the wavelength of visible light, e.g., atoms or molecules. Acoustical holography uses sound waves to see through solid objects. Holography has a vast scope of practical applications, which have been classified into two major categories:

1. applications requiring three-dimensional images for visual perception; and
2. applications in which holography is used as a measuring tool.

The unique ability of holography – to record and reconstruct both electromagnetic and sound waves – makes it a valuable tool for education, science, industry, and business. Below are some of the important applications:

1. Holographic interferometry (HI) is one of the most powerful measuring tools. In HI, two states of an object, i.e., initial and deformed state are recorded on the same photographic plate. After reconstruction of the light wave corresponding to two states of an object, interferences and deformations are displayed in terms of the interference pattern. The change of distance of one tenth of a micron, or lower, can be resolved. HI provides scientists/engineers with crucial data for design of critical machine parts of power-generating equipment, in the aircraft industry, automobile industry, and nuclear installations (say, for example, in the design of containers used to transport nuclear materials, improve the design of aircraft wings and turbine blades, etc.). Presently, HI is being widely used in mechanical engineering, acoustics, and aerodynamics, for nondestructive testing, to investigate oscillation in diaphragms and flow around various objects, respectively.
2. Microwave holography can detect objects deep within spaces, by recording the radio waves they emit.
3. Another important application of holography is the design of optical elements, which possess special properties. A holographic recording of a concave mirror behaves in much the same way as the mirror itself, i.e., it can focus the light. In some cases chromatism can be introduced in the design of elements so that a location of the point, where the beams are focused, depends on the wavelength. This can be achieved by accurately choosing the recording arrangement of the focusing elements, these elements are, in fact, diffraction gratings. These can have low noise levels, freedom from astigmatism, and have other useful properties. Holographic optical elements have found applications in supermarket scanners to read barcodes, headup displays in fighter aircraft to observe critical cockpit instruments, etc.
4. A telephone credit card used in Europe and other developed countries has embossed surface holograms which carry a monetary value. When the card is inserted into the telephone, a card reader discerns the amount due and deducts the appropriate amount to cover the cost of the call.

5. Holography is having applications in analog and digital computers, offering remarkable opportunities to realize various logical operators, devices for identifying images based on matched filtering, and in computer memory units. The basic advantage of holographic memory is that a relatively large volume of information can be stored and that there are a limited number of ways to change the record. The arrival of the first prototype of optical computers, which use holograms as storage material for data, could have a dramatic impact on the holographic market. The yet-to-be-unveiled optical computers will be able to deliver trillions of bits of information faster than the current generation of computers.
6. Optical tweezers are going to become an important tool for the study of micro-organisms/bacteria, etc.
7. Holograms can be used to locate and retrieve information without knowing its location in the storage medium, only needing to know some of its content.
8. The links between computer science and holography are now well-established and are developing, with at least two aspects making computer-generated holograms extremely interesting. First, such holograms enable us to obtain visual 3-dimensional reconstructions of imagined objects. For example, one can reconstruct three dimensions of a model of an object still in the design stage. Second, computer-generated holograms can be used to reconstruct lightwaves with specified wave fronts. This means specially computed and manufactured holograms may function as optical elements that transform the incident light wave into desired wavefronts.
9. Another important applications of holography is its utilization to compensate for the distortion that occurs when viewing objects through optically heterogeneous mediums. It can be achieved based on the principle of beam reversal by the hologram.
10. Finally, let us consider the application of holography to art. The development of holography gives very effective ways of creating qualitative three-dimensional images. Thus, a new independent area of holographic creative work representational/artistic holography has appeared. The art of holographic depiction has developed along two major routes. The first is creation of the view hologram, used as holograms of natural objects that are to be displayed in exhibitions and museums; these are also known as artistic holograms. Portrait holography is also classified under this category. The progress in portrait holography is hampered partly because of imperfection of pulsed lasers and partly because of the deterioration of photographic material when exposed to pulsed electromagnetic radiation.

The principle behind the creation of elusion by using composite holograms is also very convincing for the display of objects. To synthesize the composite holograms, the photographs of various aspects of a scene are printed onto the photographic plate. The synthesis techniques for preparing the composite hologram are very complicated, while the images created by holograms are still far from perfect. However, there is no doubt that composite holography opens holography up as an artistic technique. Recently rainbow holography has been very popular to display such objects.

Color Holography

H I Bjelkhagen, De Montfort University, Leicester, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Since the appearance of the first laser-recorded monochromatic holograms in the 1960s, the possibilities of recording full-color high-quality holograms have now become a reality. Over many years holographic techniques have been created to produce holograms with different colors, referred to as pseudo- or multicolor holograms. For example, in the field of display holography, it is common to make multiple-exposed reflection holograms using a single-wavelength laser and emulsion thickness manipulation to obtain an image with different colors. In this way many beautiful pseudocolor holograms have been made by artists. Applying Benton's rainbow hologram technique (for example, the one used for embossing holograms on credit cards), it has been possible to record transmission holograms as well as mass-produce embossed holograms with 'natural' colors. However, a rainbow hologram has a very limited viewing position from which a correct color image can be seen.

This article will acquaint the reader with the topic of color holography (full-color or true-color holography). This describes a holographic technique to obtain a color 3D image of an object where the color rendition is as close as possible to the color of the real object. A brief review of the development of color holography, the current status and the prospects of this new 3D imaging technique, are presented. Also included are recording techniques using three lasers providing red, green and blue (RGB) laser light as well as computer-generating techniques for producing full parallax 3D color images.

The Development of Color Holography

In theory, the first methods for recording color holograms were established in the early 1960s. Already Leith and Upatnieks (1964) proposed multicolor wavefront reconstruction in one of their first papers on holography. The early methods concerned mainly transmission holograms recorded with three different wavelengths from a laser or lasers, combined with different reference directions to avoid cross-talk. Such a color hologram was then reconstructed (displayed) by using the original laser wavelengths from the corresponding reference directions. However, the complicated and expensive reconstruction setup prevented this technique from becoming popular. More suitable for holographic color recording is reflection holography, which can be reconstructed and viewed in ordinary white light.

Most likely, the three-beam transmission technique might eventually become equally applicable, provided inexpensive multicolor semiconductor lasers become widely available. Such RGB lasers can be used to display a very realistic, deep, and sharp holographic image of, for example, a room.

Relatively few improvements in color holography were made during the 1960s and 1970s. Not until the end of the 1970s did a few examples of color holograms appear. During the 1980s, new and improved techniques were introduced. A review of various transmission and reflection techniques for color holography was published by Hariharan (1983). From 1990 until today, many high-quality color holograms have been recorded, mainly due to the introduction of new and improved panchromatic recording materials. On the market are ultra-fine-grain silver halide emulsions (manufactured by Slavich in Russia) as well as photopolymer materials (manufactured by E. I. du Pont de Nemours & Co. in the USA).

Color reflection holography presents no problems with regard to the geometry of the recording setup, but the final result is highly dependent on the recording material used and the processing techniques applied. There are some problems associated with recording color holograms in general and specifically in silver halide emulsions:

- Scattering occurring in the blue part of the spectrum typical of many holographic coarse-grain silver halide emulsions makes them unsuitable for the recording of color holograms.

- Multiple storage of interference patterns in a single emulsion reduces the diffraction efficiency of each individual recording. The diffraction efficiency of a three-color recording in a single-layer emulsion is lower than a single wavelength recording in the same emulsion.
- During wet processing, emulsion shrinkage frequently occurs, causing a wavelength shift. White-light-illuminated reflection holograms normally show an increased bandwidth upon reconstruction, thus affecting the color rendition.
- The fourth problem, related to some extent to the recording material itself, is the selection of appropriate laser wavelengths and their combination in order to obtain the best possible color rendition of the object.

In the beginning, when no suitable panchromatic emulsion existed, the sandwich technique was used to make color reflection holograms. Two plates were sandwiched together, in which, for example, two different types of recording materials were used. The most successful demonstration of the sandwich recording technique was made by Kubota (1986) in Japan. He used a dichromated gelatin (DCG) plate for the green (515 nm) and the blue (488 nm) components, and an Agfa 8E75 silver halide plate for the red (633 nm) component of the image. Kubota's sandwich color hologram of a Japanese doll recorded in 1986, demonstrated the potential of high-quality color holography for the first time. Color holograms have also been recorded in red-sensitized DCG materials.

Extensive work in the field of reflection color holography was performed by Hubel and Solymar (1991). Primarily they employed Ilford silver halide materials for the recording of color holograms applying the sandwich technique.

Very important is the research on recording materials by Usanov and Shevtsov (1990) in Russia. Their work is based on the formation of a microcavity structure in gelatin, by applying a special processing technique to silver halide emulsions. Such holograms recorded in a silver halide emulsion have a high diffraction efficiency and exhibit a typical DCG hologram quality.

Not until panchromatic ultra-fine-grain silver halide emulsions were introduced in Russia in the early 1990s, was it possible to record high-quality color holograms in a single emulsion layer as demonstrated by the present author. Although it is now possible to produce color holograms, they need to be displayed correctly. An important improvement would be to find an edge-illuminating technique to make color holograms easier to display. The display problem still remains the main obstacle preventing color holograms, as well as monochrome holograms, being more widely used.

Recording of Color Holograms

Currently, most transmission color holograms are of the rainbow type. Large-format holographic stereograms made from color-separated movie or video recordings have been produced. There are also some examples of embossed holograms in which a correct color image is reproduced. In order to generate a true color rainbow hologram, a special setup is required in which the direction of the reference beam can be changed in between the recordings of the color-separated RGB primary images. However, as already mentioned, holographic color images of the rainbow type can reconstruct a correct color image only along a horizontal line in front of the film or plate and, thus, of less interest for serious color holography applications. Reflection holography can offer full parallax, large field of view 3D color images where the colors do not change when observed from different directions.

Silver Halide Materials

To be able to record high-quality color reflection holograms it is necessary to use extremely low light-scattering recording materials. This means, for example, the use of ultra-fine-grain silver halide emulsions (grain size about 10 nm). Currently, the only producer of a commercial holographic panchromatic ultra-fine-grain silver halide material is the Micron branch of the Slavich photographic company located outside Moscow. The PFG-03c emulsion comes in standard sizes from 63 mm × 63 mm format up to 300 mm × 406 mm glass plates and is also available on film. Some characteristics of the Slavich material are presented in Table 1.

By using suitable processing chemistry for the PFG-03c emulsion it has been possible to obtain high-quality color holograms. These holograms are recorded in a single-layer emulsion, which greatly simplifies the recording process as compared with many earlier techniques. The aforesaid single-layer technique is described below.

Table 1 Characteristics of the Slavich panchromatic emulsion

Silver halide material	PFG-03C
Emulsion thickness	7 μm
Grain size	12–20 nm
Resolution	~10,000 lp(mm)$^{-1}$
Blue sensitivity	~1.0–1.5 × 10^{-3} J(cm)$^{-2}$
Green sensitivity	~1.2–1.6 × 10^{-3} J(cm)$^{-2}$
Red sensitivity	~0.8–1.2 × 10^{-3} J(cm)$^{-2}$
Color sensitivity peaked at	633 nm and 530 nm

Photopolymer Materials

The color holography photopolymer material from DuPont is another alternative recording material for color holograms. In particular, this type of material is suitable for mass production of color holograms. Although, being less sensitive than the ultra-fine-grain silver halide emulsion, it has special advantages of easy handling and dry processing (only UV-curing and baking). The DuPont color photopolymer material has a coated film layer thickness of about 20 μm. The photopolymer film is generally coated in a 12.5-inch width on a 14-inch wide Mylar® polyester base which is 0.002-inch thick. The film is protected with a 0.00092-inch thick Mylar® polyester cover sheet. However, the panchromatic polymer material is only supplied to specially selected and approved hologram producers. The reason for this is that some applications of color holograms are in the field of document security where optically variable devices (OVDs) are produced.

The recording of a color hologram on DuPont polymer is simple. The film has to be laminated to a piece of clean glass or attached to a glass plate using an index-matching liquid. To obtain the right color balance, the RGB sensitivity depends on the particular material, but typically red sensitivity is lower than green and blue sensitivities. It is difficult to obtain high red-sensitivity of photopolymer materials. Simultaneous exposure is the best recording technique for photopolymer materials. Holograms can be recorded manually, but in order to produce large quantities of holograms, a special machine is required. For hologram replication the scanning technique can provide the highest production rate. In this case, three scanning laser lines are needed, which can be adjusted in such a way that all three simultaneously can scan the film. The color photopolymer material needs an overall exposure of about 10 $mJ(cm)^{-2}$.

After the exposure is finished, the film has to be exposed to strong white or UV light. DuPont recommends about 100 $mJ(cm)^{-2}$ exposure at 350–380 nm. After that, the hologram is put in an oven at a temperature of 120 °C for two hours in order to increase the brightness of the image.

Laser Wavelengths for Color Holograms

The problem of choosing optimal primary laser wavelengths for color holography is illustrated in the 1976 CIE chromaticity diagram (Figure 1) which indicates suitable laser wavelengths for color holograms.

It may seem that the main aim of choosing the recording wavelengths for color holograms would be to cover as large an area of the chromaticity diagram as possible. However, there are many other

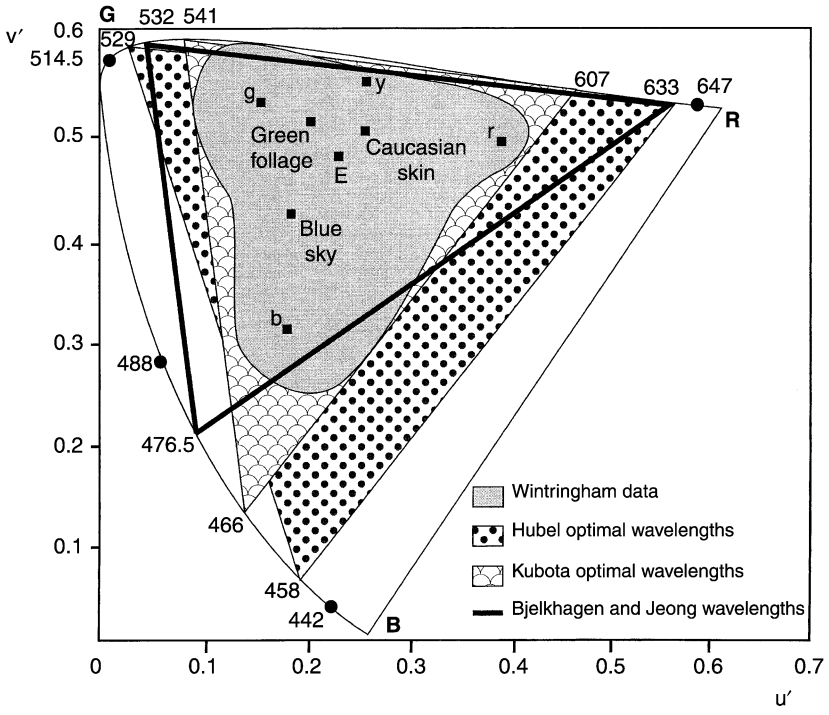

Figure 1 The 1976 CIE uniform scales chromaticity diagram shows the gamut of surface colors and positions of common laser wavelengths. Optimal color-recording laser wavelengths are also indicated.

considerations that must be taken into account when choosing the wavelengths for color holograms. One of these important considerations is the question of whether three wavelengths are really sufficient for color holography. The wavelength selection problem for color holography has been treated in several papers, for example by Peercy and Hesselink (1994).

Hubel and Solymar (1991) provided a definition of color recording in holography:

> A holographic technique is said to reproduce 'true' colors if the average vector length of a standard set of colored surfaces is less than 0.015 chromaticity coordinate units, and the gamut area obtained by these surfaces is within 40% of the reference gamut. Average vector length and gamut area should both be computed using a suitable white light standard reference illuminant.

An important factor to bear in mind when working with silver halide materials is that a slightly longer blue wavelength than the optimal one might give higher-quality holograms (better signal-to-noise ratio) because of reduced Rayleigh scattering during the recording. Another important factor to consider is the reflectivity of the object at primary spectral wavelengths. It has been shown that the reflectivity of an object at three wavelength bands, peaked at 450, 540, and 610 nm, has an important bearing on color reconstruction. These wavelengths can also be considered optimal for the recording of color holograms even though the laser lines are very narrow-band. A triangle larger than necessary can be considered in order to compensate for color desaturation (color shifting towards white) that takes place when reconstructing color reflection holograms in white light. According to Hubel's color rendering analysis, the optimal wavelengths are 464, 527, and 606 nm for the sandwich silver halide recording technique. If the calculations are performed to maximize the gamut area instead, the following set of wavelengths is obtained: 456, 532, and 624 nm. However, when approached from a different viewpoint, the optimal trio of wavelengths based on the reconstructing light source of 3400 K, a 6 μm thick emulsion with a refractive index of 1.63 and an angle of 30° between the object and the reference beam the following wavelengths were obtained: 466.0, 540.9, and 606.6 nm. Peercy and Hesselink (1994) discussed wavelength selection by investigating the sampling nature of the holographic process. During the recording of a color hologram the chosen wavelengths point-sample the surface-reflectance functions of the object. This sampling on color perception can be investigated by the tristimulus value of points in the reconstructed hologram which is mathematically equivalent to integral approximations for the tristimulus integrals. Peercy and Hesselink used both Gaussian quadrature and Riemann summation for the approximation of the tristimulus integrals. In the first case they found the wavelengths to be 437, 547, and 665 nm. In the second case the wavelengths were 475, 550, and 625 nm. According to Peercy and Hesselink, the sampling approach indicates that three monochromatic sources are almost always insufficient to preserve all of the object's spectral information accurately. They claim that four or five laser wavelengths are required.

Only further experiments will show how many wavelengths are necessary and which combination is the best for practical purposes. Another factor that may influence the choice of the recording wavelengths is the availability of cw lasers currently in use in holographic recording, for example, argon ion, krypton ion, diode-pumped solid state (DPSS) frequency-doubled Nd:YAG, helium neon, and helium cadmium lasers (Table 2).

The recent progress in DPSS laser technology has made available both red and blue DPSS lasers. These lasers are air-cooled, small, and each laser requires less than a hundred watts of electric power to operate. Usually, a set of three DPSS lasers will be the best choice of cw lasers for color holography in the future.

Setup for Recording Color Holograms

A typical reflection hologram recording setup is illustrated in Figure 2.

Table 2 Wavelengths from cw lasers

Wavelength [nm]	*Laser type*	*Single line power [mW]*
442	Helium cadmium	<100
457	DPSS blue	<500
458	Argon ion	<500
468	Krypton ion	<250
476	Krypton ion	<500
477	Argon ion	<500
488	Argon ion	<2000
497	Argon ion	<500
502	Argon ion	<400
514	Argon ion	<5000
521	Krypton ion	<100
529	Argon ion	<600
531	Krypton ion	<250
532	DPSS green	<3000
543	Green neon	<10
568	Krypton ion	<100
633	Helium neon	<80
647	Krypton ion	<2000
656	DPSS red	<1000

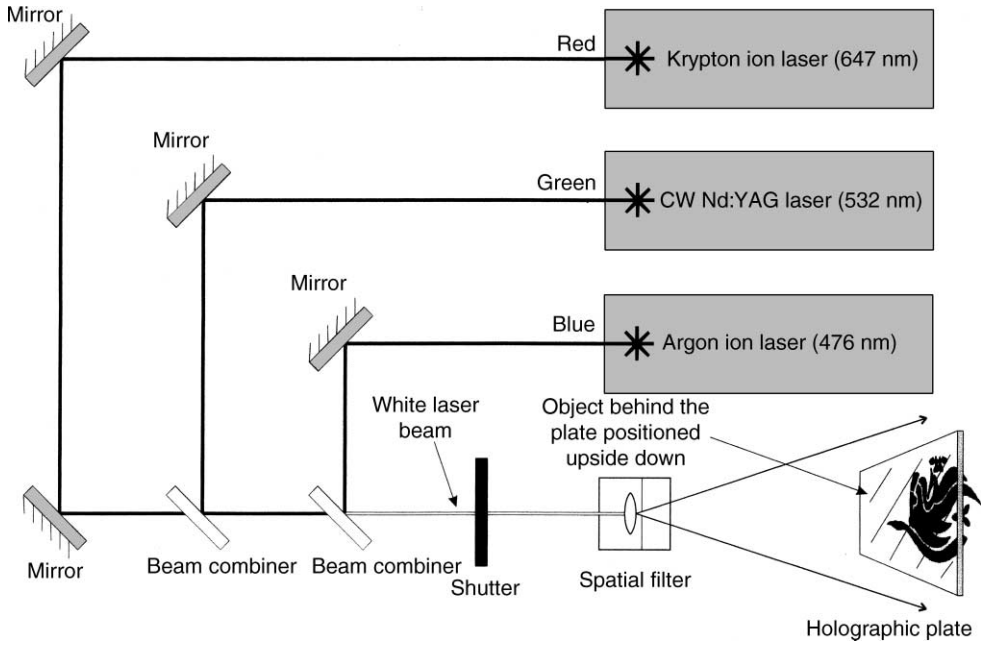

Figure 2 The setup for recording color reflection holograms.

The different laser beams necessary for the exposure of the object pass through the same beam expander and spatial filter. A single-beam Denisyuk arrangement is used, i.e., the object is illuminated through a recording holographic plate. The light reflected from the object constitutes the object beam of the hologram. The reference beam is formed by the three expanded laser beams. This 'white' laser beam illuminates both the holographic plate and the object itself through the plate. Each of the three primary laser wavelengths forms its individual interference pattern in the emulsion, all of which are recorded simultaneously during the exposure. In this way, three holographic images (a red, a green, and a blue image) are superimposed upon one another in the emulsion.

Three laser wavelengths are employed for the recording: 476 nm, provided by an argon ion laser, 532 nm, provided by a cw frequency-doubled Nd:YAG laser, and 647 nm, provided by a krypton laser. Two dichroic filters are used for the combining of the three laser beams. The 'white' laser beam goes through a spatial filter, illuminating the object through the holographic plate.

By using the dichroic filter beam combination technique, it is possible to perform simultaneous exposure recording, which makes it possible to control independently the RGB ratio and the overall exposure energy in the emulsion. The RGB ratio can be varied by individually changing the output power of the lasers, while the overall exposure energy is controlled solely by the exposure time. The overall energy density for exposure is about 3 $mJ(cm)^{-2}$.

In the initial experiments performed by the author in 1993, a specially designed test object consisting of the 1931 CIE chromaticity diagram, a rainbow ribbon cable, pure yellow dots, and a cloisonné elephant, was used for the color balance adjustments and exposure tests. Later, another test target was employed – the Macbeth ColorChecker® chart, which was used for color rendering tests.

Color reflection holograms can also be produced using copying techniques so that projected real images can be obtained, however, normally associated with a restricted field of view. For many display purposes, the very large field of view obtainable in a Denisyuk color hologram is often more attractive.

Processing of Color Holograms

The dry processing of color holograms recorded on photopolymer materials has already been described. The process is simple and very suitable for machine processing using, for example, a baking scroll oven. The processing of silver halide emulsions is more difficult and critical. The Slavich emulsion is rather soft, and it is important to harden the emulsion before the development and bleaching takes place. Emulsion shrinkage and other emulsion distortions caused by the active solutions used for the processing must be avoided. In particular, when recording master color holograms intended for photopolymer replication, shrinkage control is extremely important. The processing steps are summarized in Table 3.

Table 3 Color holography processing steps

1.	Tanning in a formaldehyde solution	6 min
2.	Short rinse	5 s
3.	Development in the CWC2 developer	3 min
4.	Wash	5 min
5.	Bleaching in the PBU-amidol bleach	~5 min
6.	Wash	10 min
7.	Soaking in acetic acid bath (printout prevention)	1 min
8.	Short rinse	1 min
9.	Washing in distilled water with wetting agent added	1 min
10.	Air drying	

It is very important to employ a suitable bleach bath to convert the developed silver hologram into a phase hologram. The bleach must create an almost stain-free clear emulsion so as not to affect the color image. In addition, no emulsion shrinkage can be permitted, as it would change the colors of the image. Washing and drying must also be done so that no shrinkage occurs. Finally, to prevent any potential emulsion thickness variation by humidity variations, the emulsion needs to be protected by a glass plate sealed onto the hologram plate.

Evaluation of Color Holograms

Recorded color holograms of the two test targets are presented here. The illuminating spotlight to reconstruct the recorded color holograms was a 12-Volt 50-Watt halogen lamp. This type of spotlight is suitable for displaying color holograms. The selection of a suitable lamp for the reconstruction of color holograms is much more important than the selection of lamps for monochrome hologram display. The color balance for the recording of a color hologram must be adjusted to the type of spotlight that is going to be used for the display of the finished hologram. Figure 3 shows a typical normalized spectrum obtained from a white area of the color test target hologram.

This means that the diffraction efficiency of each color component is obtained assuming a flat spectrum of the illuminating source. One should note the high diffraction efficiency in blue, needed to compensate for the low blue light emission of the halogen spotlight. The noise level, mainly in the blue part of the spectrum, is visible and low. The three peaks are exactly at the recording wavelengths; i.e., 647, 532, and 476 nm.

In Table 4 some results of the Macbeth ColorChecker® investigation are presented. The 1931 CIE x and y coordinates are measured at both the actual target and the holographic image of the target. The measured fields are indicated in the table by color and the corresponding field number.

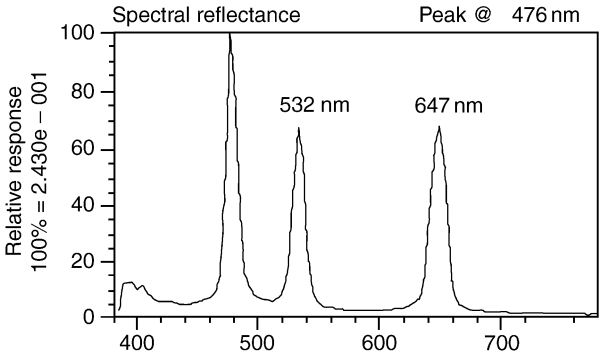

Figure 3 Normalized spectrum from a white area of a color test target hologram.

Color reproductions of two color holograms by the author are presented. A photograph of the 100 mm by 120 mm hologram of the CIE test object is shown in Figure 4. Featured in Figure 5 is a 200 mm by 250 mm hologram of a large Russian egg.

Computer-Generated Color Holograms

Today it is not possible to obtain a computer-generated hologram (CGH) with the same high information content as the laser-recorded ones of real objects. What may become possible in the future is a technique to compute and record the interference pattern that is stored in a Denisyuk color hologram which, upon illumination, can produce an image like the laser-recorded ones of real objects. Therefore, the best compromise is to use holographic stereograms which can provide high-quality computer-generated images. A holographic stereogram is created by using a series of 2D photographic images or 2D images displayed on a LCD screen from which the hologram is recorded. In order to obtain a high-quality holographic image with a large field of view, many 2D images are needed. As mentioned earlier, some color CGHs of the rainbow transmission type have been produced. However, image color changes as a function of viewer position in that type of hologram, making them less attractive than computer-generated reflection holograms. Over the last few years there has been rapid progress in color CGHs of the reflection type. Remarkable results have been achieved by Klug *et al.* (1997) at Zebra Imaging Inc. A new technique, to record very large full-parallax color reflection CGHs, has been developed. Color holograms can be produced, having both vertical and horizontal parallax, with a 100° field of view. The generation of a holographic hardcopy of either digitized images or computer graphics models is based on the following technique. The 'object'

sub-beam is directed through a sequence of digital images on a liquid-crystal screen. Each resulting exposure, about two millimeters square, is called a 'hogel'. The full-color hogels are the holographic building blocks of a finished CGH image. In an automated step-and-repeat process, 9×10^4 hogels are formed on a flat square tile of DuPont panchromatic photopolymer film by simultaneous RGB laser exposures. The 60 cm by 60 cm tile itself is the finished hologram, or to obtain larger holograms, the 3D image is made in 60 cm by 60 cm tiled increments. So far, the largest image created was of Ford's P2000 Prodigy concept car in which ten such holograms tiled together made up the large color reflection hologram (1.2 m by 3 m) which is reproduced in Figure 6.

This technique has opened the door to real 3D computer graphics. However, generating such a large hologram is a very time-consuming process. The Ford P2000 hologram took almost two weeks (300 hours) to produce, since each individual panel requires a 24-hour recording time.

The Future of Color Holography

The manufacturing of large-format color reflection holograms is now possible. Mass production of color holograms on photopolymer materials has started in Japan. Although good color rendition can be obtained, some problems remain to be solved, such

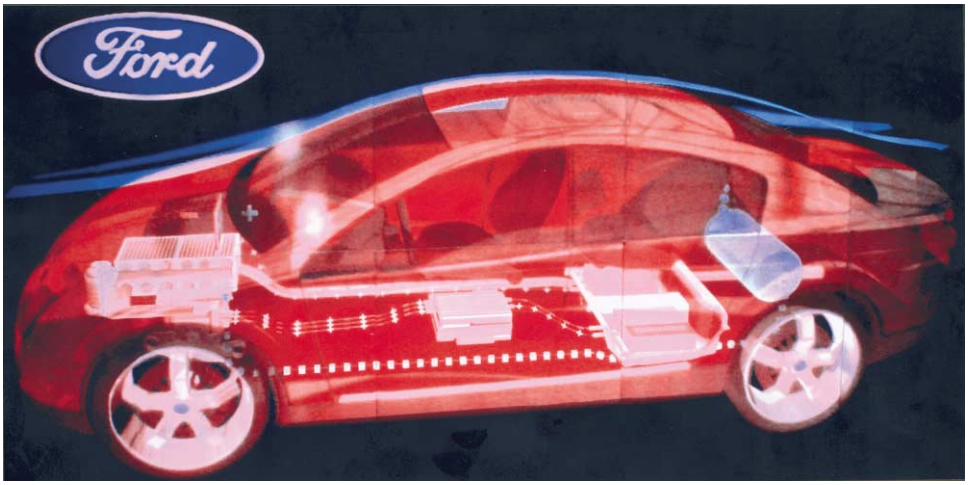

Figure 6 Computer-generated color hologram of Ford's P2000 Prodigy concept car. A ten tile full parallax Mosaic hologram produced by Zebra Imaging, Inc., size 1.2 m by 3 m.

as desaturation, image resolution, signal-to-noise ratio and dynamic range. Other limitations concerning holographic color recording include the fact that some colors we see are the result of fluorescence, which cannot be recorded in a hologram. There are some differences in the recorded colors in one of the test charts shown here. However, color rendition is a very subjective matter. Different ways of rendition may be preferable for different applications, and different people may have different color preferences.

At the present time, research on processing color reflection holograms recorded on ultra-fine-grain materials is still in progress. Work is carried out on microcavity structure holograms in order to produce low-noise reflection holograms with high diffraction efficiency. For producing large quantities of color holograms, the holographic photopolymer materials are most suitable and will be further improved in the future.

Another important field of research is the development of a three-wavelength pulsed laser. Employing such a laser, dynamic events, as well as portraits, can be recorded in a holographic form. Currently, research work is in progress at the French German Research Institute ISL, Saint Louis, France, as well as at the Geola company in Lithuania.

The virtual color image behind a color holographic plate represents the most realistic image of an object that can be obtained today. The extensive field of view adds to the illusion of beholding a real object rather than an image of it. The wavefront reconstruction process recreates accurately the three-wavelength light scattered off the object during the recording of the color hologram. This 3D imaging technique has many obvious applications, in particular, in displaying unique and expensive artifacts. There are also many potential commercial applications of this new feature of holographic imaging, provided that the display problem can be solved using some sort of integrated lighting.

Today, it is technologically possible to record and replay acoustical waves with very high fidelity. Hopefully, holographic techniques will be able to offer the same possibility in the field of optical waves, wavefront storage, and reconstruction. Further development of computer-generated holographic images will make it possible to display extremely realistic full-parallax 3D color images of nonexisting objects, which could be applied in various spheres, for example, in product prototyping, as well as in other applications in 3D visualization and three-dimensional art. Eventually it will become possible to generate true-holographic 3D color images in real-time, as computers become faster and possess greater storage capacity. However, the most important issue is the development of extremely high-resolution electronic display devices which are necessary for electronic holographic real-time imaging.

Introduction

A hologram is a tool for shaping the amplitude and the phase of a light wave. Shaping the amplitude distribution is easy, one way is by a photographic plate, another way is by binary pixels as used in 'halftone printing'. The phase distribution can be shaped by RE-fraction on a thin film of variable thickness, or by DIF-fraction on a diffraction grating that has been deliberately distorted.

Both kinds of holograms can be manufactured based on a computer design, the refractive version being called a 'kinoform', and the diffractive version being known as a computer-generated hologram (CGH). We will explain the fundamentals of computer holography with emphasis on the 'Fourier–CGH', and will also highlight the large variety of applications.

From the Classical Hologram to the Computer-Generated Hologram: CGH

Holography is a method to form images, consisting of two steps: recording and reconstruction. In the recording step, some interference fringes are recorded on a photographic plate (Figure 1a). The two interfering waves originate from the object and from a reference light source. After being developed by the usual photo-chemical treatment the photographic plate is called a hologram. In the reconstruction step, the hologram acts as a diffracting object that is illuminated by a replica of the reference light. Due to diffraction, the light behind the hologram is split into three parts (Figure 1b). One part proceeds to the observer who perceives a virtual object where the genuine object had been originally during the recording step.

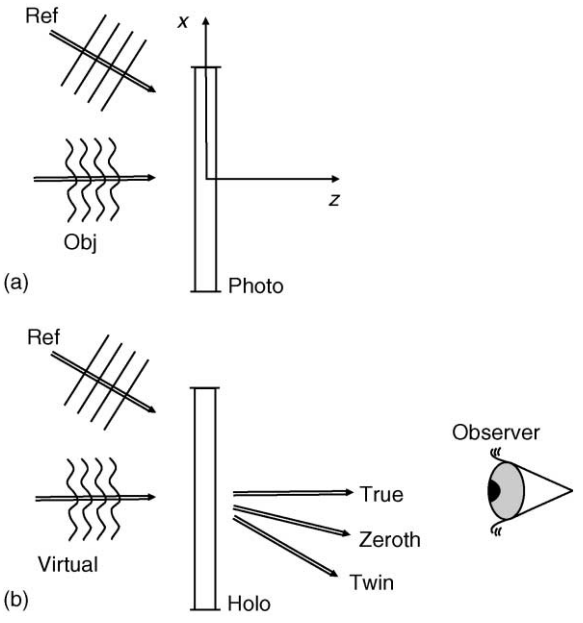

Figure 1 Holographic image formation in two steps: (a) recording the hologram, (b) reconstructing the object wave.

This was a brief description of 'classical-holography'. In 'computer holography' the first step, recording, is synthetic. In other words, the propagation of the light from the object to the photographic plate is simulated digitally. The simulation includes the addition of the object wave to the reference wave and the subsequent modulus square process, which describes the transition from the two complex amplitudes to the hologram irradiance:

$$|u_0(x) + u_R(x)|^2 = I_H(x) \qquad [1]$$

The amplitude transmittance of the hologram is

$$T_H(x) = c_0 + c_1 I_H(x) = c_1 u_0 u_R^* + \cdots \qquad [2]$$

The coefficients c_0 and c_1 represent the photochemical development. In the reconstruction process (Figure 1b) the transmittance T_H is illuminated by the reference beam. Hence, we get

$$u_R(x) T_H(x) = c_1 u_0(x) |u_R(x)|^2 + \cdots \qquad [3]$$

If the reference intensity $|u_R(x)|^2$ is constant, this term represents a reconstruction of the object wave $u_0(x)$. The omitted parts in eqns [2] and [3] describe those beams that are ignored by the observer (Figure 1b). The hologram transmittance $T_H(x)$ is an analog signal:

$$0 \le T_H \le 1 \qquad [4]$$

Before the 1960s, when computer holograms were invented, the available plotters could produce only binary transmittance patterns. Hence, it was necessary to replace the analog transmission $T_H(x)$ by a binary transmission $B_H(x)$, which is possible without loss of image quality. In addition, binary computer holograms have better light efficiency and a better signal-to-noise ratio. They are also more robust when being copied or printed.

Another advantage of a CGH is that the object does not have to exist in reality, which is important for some applications. The genuine object may be difficult to manufacture or, if it is three-dimensional, difficult to illuminate. The CGH may be used to implement an algorithm for optical image processing. In that case, the term 'object' becomes somewhat fictitious. We will discuss more about applications, towards the end of this article.

From a Diffraction Grating to a Fourier CGH

Now we will explain, in some detail, the 'Fourier type' CGH. Fourier holograms are more popular than two other types: 'image-plane' CGHs and 'Fresnel-type' CGHs. The Fresnel-type will be treated in the section on 'software' because of some interest in 3-D holograms. Certain hardware issues will also be described.

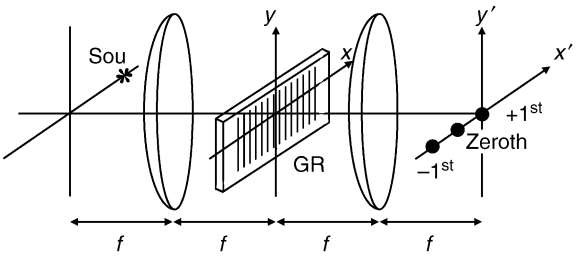

Figure 2 Grating diffraction, but with an off-axis source.

The explanation of Fourier CGHs begins with grating diffraction (Figure 2). The only uncommon feature in Figure 2 is the off-axis location of the source. It is arranged such that the plus-first diffraction order will hit the center of the output plane.

We will now convert a simple Ronchi grating (Figure 3a) into a Fourier CGH. The Ronchi grating transmittance can be expressed as the Fourier series:

$$G(x) = \sum_{(m)} C_m \exp\left(\frac{2\pi i m x}{D}\right); \quad C_0 = \frac{1}{2};$$

$$C_m = \frac{\sin(\pi m/2)}{\pi m} \qquad [5]$$

Now we shift the grating bars by an amount PD. Then we modify the width from $D/2$ to WD, as shown in Figure 3b. The Fourier coefficients are now

$$C_m = \frac{\exp(2\pi i m P)\sin(\pi m W)}{\pi m} \qquad [6]$$

The C_{+1} coefficient is responsible for the complex amplitude at the center of the readout plane:

$$C_{+1} = \frac{\exp(2\pi i P)\sin(\pi W)}{\pi} \qquad [7]$$

We are able now to control the beam magnitude, $A = (\frac{1}{\pi})\sin(\pi W)$, by the relative bar width W and the phase $\phi = 2\pi P$ by the relative bar shift P. This particular kind of phase shift is known as 'detour phase'.

So far, the light that ends up at the center of the exit plane, leaves the grating as a plane wave with a wave vector parallel to the optical axis. Now we distort the grating on purpose (Figure 3c):

$$W \to W(x, y); \qquad P \to P(x, y) \qquad [8]$$

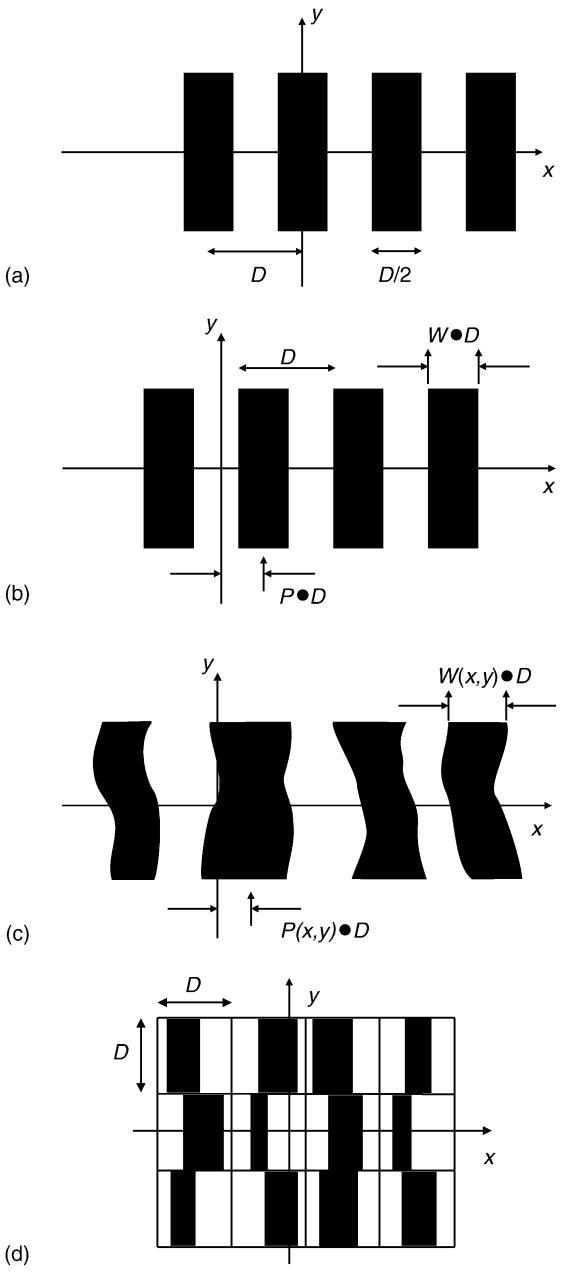

Figure 3 Modifying a grating into a hologram in 3 steps: (a) Ronchi grating, (b) Modified width and location of the grating bars, (c) Distorted grating bars, (d) as in **Figure 3c**, but now discrete distortions.

These distortions should be mild enough that the plus-first order light behind the distorted grating can be described by the complex amplitude:

$$\left(\frac{1}{\pi}\right)\sin[\pi W(x,y)]\,\exp[2\pi i P(x,y)] = u_{\mathrm{H}}(x,y) \qquad [9]$$

This is a generalization of eqn [7]. The phase $2\pi P(x,y)$ covers the range from $-\pi$ to $+\pi/2$ if the shift is bounded by $|P| \le \frac{1}{2}$. That is enough to cover the range of complex amplitudes within the circle of $|u_{\mathrm{H}}| \le \frac{1}{\pi}$. We will return shortly to the condition 'mild-enough distortions' in the context of **Figure 4**.

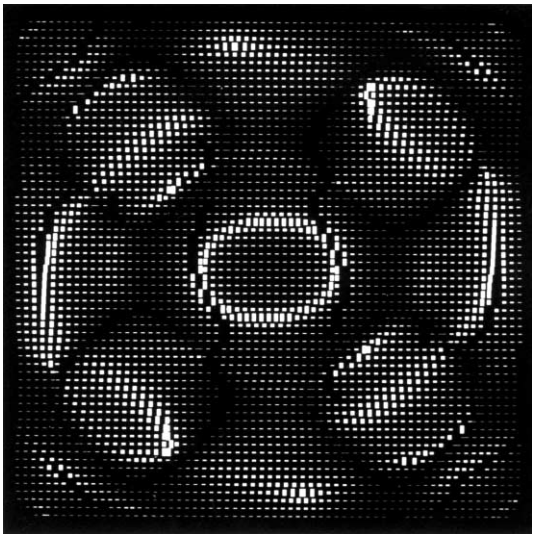

Figure 4 CGH with 64 × 64 cells.

Most plotters move their pens only in the x-direction and y-direction and printers place dots on a grid. Therefore it is convenient to replace the continuous (x, y) variations of W and P by piecewise constant variations, as in **Figure 3d**. That restriction turns out to be acceptable, as demonstrated by the first computer holograms. The theoretical proof involves the sampling theorem.

Recall that the light propagation through a 2-f system (**Figure 2**, between grating and output plane) can be described by a Fourier transformation:

$$\int\int u_{\mathrm{H}}(x,y)\,\exp\left[\frac{-2\pi i(xx' + yy')}{\lambda f}\right]\mathrm{d}x\,\mathrm{d}y = \tilde{u}_{\mathrm{H}}\left(\frac{x'}{\lambda f}, \frac{y'}{\lambda f}\right) \qquad [10]$$

Suppose now that we wish to see a particular image: $v(x', y')$. Hence, we request that

$$v(x', y') = \tilde{u}_{\mathrm{H}}\left(\frac{x'}{\lambda f}, \frac{y'}{\lambda f}\right)\mathrm{RECT}\left(\frac{x'}{\lambda f}\right) \qquad [11]$$

The RECT function indicates that only the PLUS first diffraction order is of interest. As a consequence we have to select the grating distortions $W(x, y)$ and $P(x, y)$ such that the hologram $u_{\mathrm{H}}(x, y)$ is the

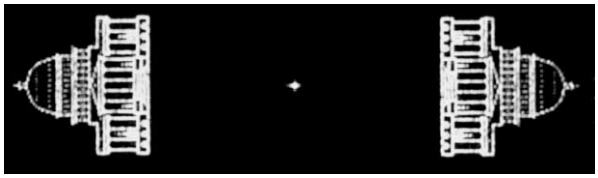

Figure 5 A reconstruction from a 1024 × 1024 CGH. The real image and the symmetrical twin image appear. The zeroth-order is blocked.

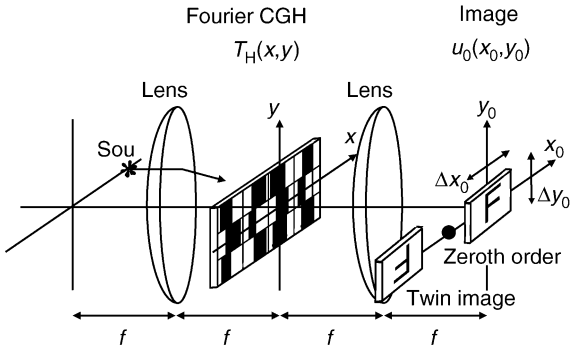

Figure 6 Reconstruction setup for a Fourier CGH.

Fourier transform of $v(x', y')$:

$$u_H(x,y) = \int\int v(x',y') \exp\left[\frac{2\pi i(xx'+yy')}{\lambda f}\right] dx'\,dy' \qquad [12]$$

The condition 'mild enough distortions' has been treated in the literature. There is not enough space here to present that part of the CGH theory. But we show an actual CGH with 64 × 64 cells (Figure 4). This CGH is no longer a grating, but, it shows enough resemblance to our heuristic derivation. Hence, the CGH theory appears to be trustworthy. A CGH looks less regular if the image $v(x', y')$ contains a random phase that simulates a diffuser. The diffuser spreads light across the CGH and so levels out unacceptably large fluctuations in the amplitude.

With 512 × 512 or 1024 × 1024 cells in a CGH one can obtain an image of the quality seen in Figure 5. The reconstruction setup is shown in Figure 6, here with the letter F as the image.

About Some CGH Algorithms

The computational effort for getting the desired hologram amplitude of a Fourier hologram u_H is reasonable due to the powerful FFT algorithm. However, to use it the data must be discrete. In other words, the CGH consists of cells, centered at $x_m = mD$, $y_n = nD$ as shown in Figure 3d. The questions now are: 'What is the proper cell size D?' and 'How many cells are needed?' The answers to those questions depend on the parameters of the image. If the zero order (see Figure 6) should be at the distance Δx_0, then the quasi-grating period D should obey:

$$\frac{\lambda f}{D} \geq \Delta x_0 \qquad [13]$$

And if the size of an image pixel should be as fine as δx_0, the size Δx_H of the hologram should obey:

$$\frac{\lambda f}{\Delta x_H} \leq \delta x_0 \qquad [14]$$

This condition is plausible because the finite size Δx_H of the hologram acts like a resolution-limiting aperture. The combination of eqns [13] and [14] yields

$$\frac{\Delta x_0}{\delta x_0} \leq \frac{\Delta x_H}{D} \qquad [15]$$

This means that the number of image pixels $\Delta x_0/\delta x_0$ is bounded by the number of CGH cells $\Delta x_H/D$. The generalization to two dimensions is straightforward. Again, Fourier CGHs benefit from the fact that the light propagation from the virtual object to the hologram plane can be described by a Fourier transformation. Hence, the FFT can be used.

And now we move to the synthesis of a Fresnel hologram. A Fresnel hologram is recorded at a finite distance z from the object. Hence, we have to simulate the wave propagation in free space from the object (at $z = 0$) to the hologram at a distance z. This free space propagation can be described (in the paraxial approximation) as a convolution of object and quasi-spherical wave:

$$u_0(x) \rightarrow \int_{-\infty}^{\infty} u_0(x') \exp\left[\frac{-i\pi(x-x')^2}{\lambda z}\right] dx' = u(x,z) \qquad [16]$$

In the Fourier domain the corresponding operation is:

$$\tilde{u}_0(\mu) \rightarrow \tilde{u}_0(\mu) \exp[-i\pi\lambda z\mu^2] = \tilde{u}(\mu,z) \qquad [17]$$

The indirect execution of eqn [16], based on eqn [17], is easy: a Fourier transformation of the object converts $u_0(x)$ into $\tilde{u}_0(\mu)$, which is then multiplied by the quadratic phase factor, yielding $\tilde{u}(\mu,z)$. An inverse Fourier transformation produces $u(x,z)$. The two Fourier transformations consist typically of $4N \log N$ multiply/add operations. N is the number of pixels: image size Δx_0, divided by the pixel size δx_0.

In the case of a rectangular object $u_0(x, y)$, the number of pixels is $\Delta x_0 \Delta y_0 / \delta x_0 \delta y_0$.

Now to describe the algorithmic effort for computing the convolution, the $u_0(x)$ has N pixels, and, the lateral size of the exponential is essentially $M = z/\delta z$, where δz represents 'depth of focus'. M describes the lateral size of the diffraction cone, measured in pixel size units δx_0, and the convolution involves MN multiply/adds. A comparison of these two algorithms is dictated by the ratio

$$\frac{M}{4 \log N} \qquad [18]$$

The direct convolution is preferable if the distance z is fairly small. The integration limits of eqn [16] depend on the oscillating phase $\pi x^2/\lambda z$. Effectively, nothing is contributed to this integral, when this phase varies by more than 2π over the length, δx_0, of an object pixel. Note that the pixel size of $u(x, z)$ does not change with the distance z, because the bandwidth $\Delta\mu(z) = \Delta\mu_0$ is z-independent. This is so because the power spectrum is z-invariant:

$$|\tilde{u}(\mu, z)|^2 = |\tilde{u}_0(\mu)|^2 \qquad [19]$$

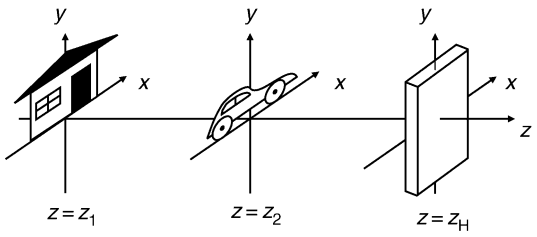

Figure 7 Synthesis of a hologram for a three-dimensional object.

It is easy to proceed from here to the CGH synthesis of a 3-D object. One starts with an object detail $u_1(x)$ at z_1, for example, the house as in Figure 7. Then, one propagates to the next object detail at z_2. This second detail may act as a multiplication (transmission) and as addition (source elements). This process is repeated as the wave moves towards the plane of the hologram. There, a reference wave has to be added, as in the Fourier case.

A very powerful algorithm for the CGH synthesis is 'IFTA' (iterative Fourier transform algorithm). Suppose, we want to design a Fourier CGH, which looks like a person and whose reconstructed image shows the signature of that person (Figure 8a,b). In other words, the two intensities

$$|u_H(x, y)|^2 \text{ and } |\tilde{u}_H(\mu, \nu)|^2 \qquad [20]$$

are determined. But, the phase distributions of u_H and $\tilde{u}_H$ are still at our disposal. The IFTA algorithm will yield those phases in many cases at the expense of ten, hundred or more Fourier transformations.

The IFTA algorithm is sometimes called 'Fourier Ping-Pong' because it bounces back and forth between the (x, y) and the (μ, ν) domain. The amplitudes $|u_H|$ and $|u_0|$ are enforced at every opportunity. But the associated phases are free to vary and to converge, eventually. If so, u_H and u_0 are completely known. The IFTA will not always converge, for example not if

$$|u_H(x, y)| = \delta(x, y) \text{ and } |\tilde{u}_H(\mu, \nu)| = \delta(\mu, \nu) \qquad [21]$$

But the chances are fairly good if both amplitudes are often close to one and seldom near zero.

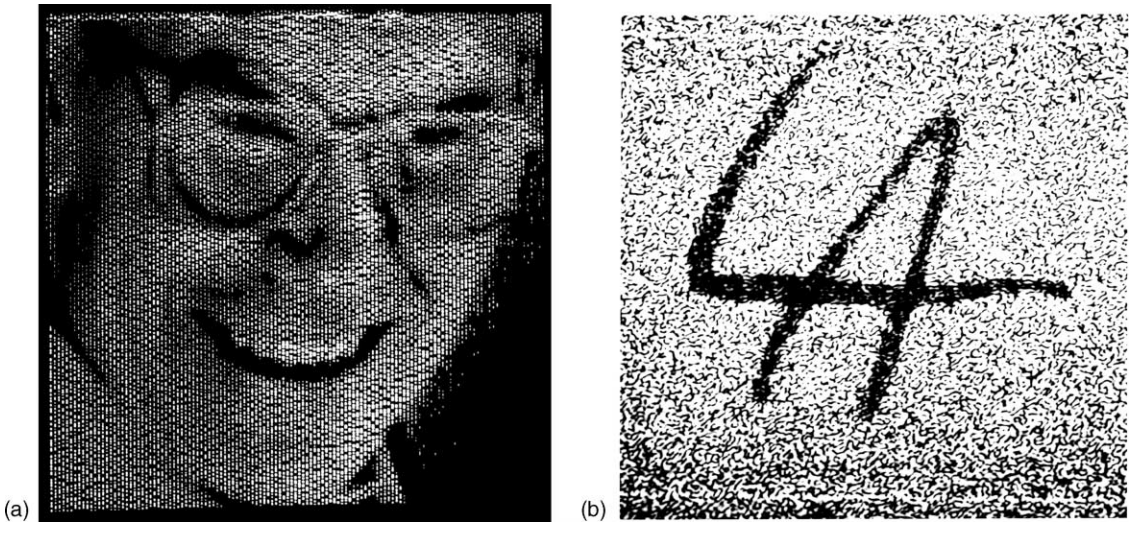

Figure 8 IFTA-CGH: (a) The Fourier CGH. (b) The optical reconstruction thereof. (Courtesy of H.O. Bartelt.)

Finally, an image plane CGH is trivial from an algorithmic point of view. The simulated propagation from object plane to image plane is usually an identity, apart from the finite bandwidth of the image-forming system. Nevertheless, image plane holograms can be quite useful, for example for interferometric testing of a nonspherical mirror of an astronomical telescope. The CGH is laid out to provide a wavefront that is suitable for an interferometric 'null test'. The CGH serves as a 'synthetic prototype'.

A fourth kind of CGH, to be named near-field CGH may emerge. It operates in the near-field and it employs evanescent waves as they occur, if object details are comparable in size with, or even smaller than, the wavelength. Conceivable topics are 'super resolution' and 'sub-lambda lithography'. Fundamentals and history of classical evanescent holography are reported in the Further Reading.

Some Hardware Aspects

We now describe some hardware aspects of the CGHs. Remembering the CGH cell structure in Figure 3d, we saw the amplitude encoded as relative width W (eqn [6]). Instead of the width, one may use the relative height $H \leq 1$ as the amplitude parameter. More efficient, but more difficult to manufacture are saw tooth-shaped hologram cells. The saw tooth prism may be approximated by a phase stair, which is possible with today's lithographic technology. The corresponding theory is called phase quantization.

Some CGH Applications

Some applications had been mentioned already before, e.g., 3-D display (see Figure 7). The data volume can be very high, hence, shortcuts such as eliminating the vertical perspective, are necessary. The largest CGHs for visual light are used for testing astronomical telescopes by means of interferometry. The IFTA algorithm has been used, among other things, for designing a CGH which acts as an optimal diffuser. Speckles and light efficiency are the critical issues in diffuser design. Another project, that also benefits from IFTA, is beam shaping. That is a broad topic with aims at, for example, homogenizing the output of laser, beam structuring for welding, cutting, and scanning.

A CGH can also be used as a spatial filter for image processing. For example, an input image may be Hilbert-transformed in the setup shown in Figure 9a. The filter (Figure 9b) is a grating, of which one sideband is shifted by one-half of the grating period. Such a geometric shift generates the π-phase shift that is needed for the Hilbert transformation. The same setup can also be used to implement Zernike's phase contrast. Now the grating is distorted such that the zero-frequency region at the optical axis is reduced in amplitude by (typically) a factor of 0.2. In addition, the phase is shifted by $\pi/2$ due to a fringe shift of a quarter period (Figure 10a). In the image plane one can see an ordinary image on-axis, and two phase-contrast images in the plus-minus first diffraction orders. One of them has positive phase contrast, the

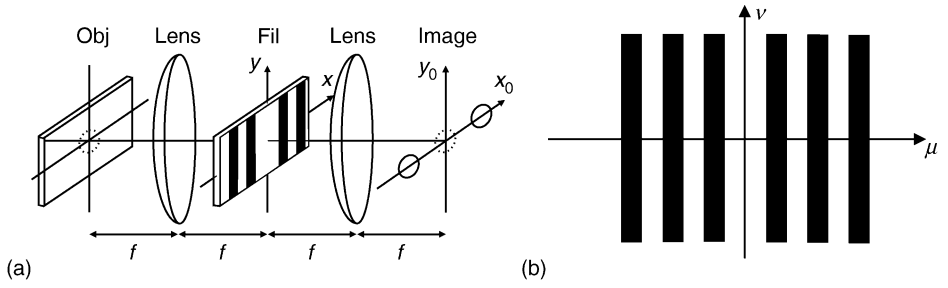

Figure 9 (a) Hilbert setup. (b) Hilbert filter.

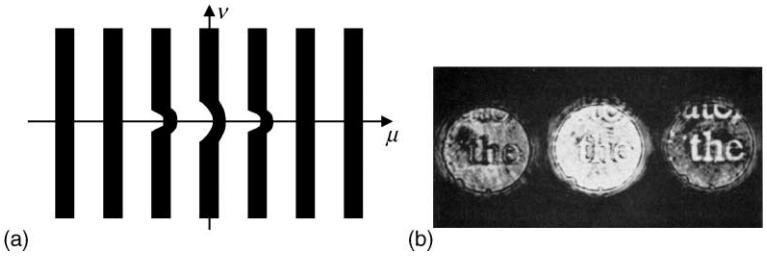

Figure 10 (a) Phase contrast filter. (b) Phase contrast output.

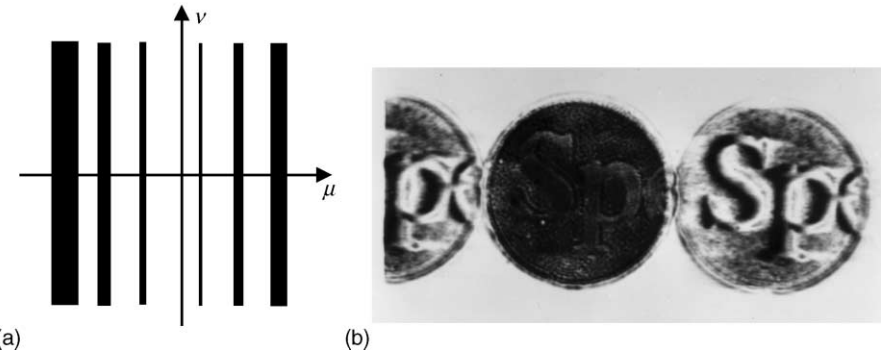

Figure 11 (a) Differentiation filter. (b) Differentiation output.

other one has negative phase contrast (Figure 10b). Another simple spatial filter (Figure 11a) produces a derivative of the input $u(x, y) : \partial u(x, y)/\partial x$ (Figure 11b). Equations [22]–[24] explain this differential filtering experiment.

$$u(x, y) \rightarrow \frac{\partial u(x, y)}{\partial x} = v(x, y) \qquad [22]$$

$$\tilde{u}(\mu, \nu) \rightarrow 2\pi i\mu \cdot \tilde{u}(\mu, \nu) = \tilde{v}(\mu, \nu) \qquad [23]$$

$$\tilde{p}(\mu, \nu) = 2\pi|\mu| \cdot \left\{ \begin{matrix} +i(\mu > 0) \\ -i(\mu > 0) \end{matrix} \right\} \qquad [24]$$

The phase portion of the filter (Figure 11a) is the same as for the Hilbert filter, but, the filter amplitude now enhances the higher frequencies. The object used for getting the results of Figure 10b and 11b was a phase-only object: a bleached photograph.

A very famous spatial filtering experiment is 'matched filtering', which can be used for pattern recognition. The original matched filters were classical Fourier holograms of the target pattern. Computer hologram's can do the same job, even with spatially incoherent objects, this work being initiated by Katyl.

Fourier holograms are also attractive for data storage, due to their robustness against local defects. However, a local error in the Fourier domain spreads out all over the image domain. The computed hologram has an advantage over classical holograms because of the freedom to incorporate any error detection and correction codes for reducing the bit error rate even further.

One of the most recent advances is in matched filtering with totally incoherent light. This step allows moving spatial filtering out of the well-guarded laboratory into hostile outdoor environments.

Finally, a word about terminology; several terms are used in place of 'CGH': synthetic hologram, digital hologram, holographic optical element (HOE), diffractive optical element (DOE) or digital optical element.

CGHs have also been made for other waves, such as acoustical waves, ocean waves, and microwaves. Digital antenna steering represents a case of computer holography.

Introduction

The sinusoidal nature of light, its ability to interfere, and the precise knowledge of its wavelength make it possible to measure several metrological quantities, such as distances and displacements, with high accuracy. However, the high frequency of light results in the difficulty that the primary quantity to be measured, i.e., the phase of the light wave, cannot be observed directly. All quadratic sensors (CCD, CMOS, photo plates) are only able to record intensities. Therefore, one makes use of a trick: the transformation of phase changes into recordable intensity changes as the basic principle of interferometry and holography. Holography provides the possibility to record and to reconstruct the complete information of optical wave fields. Numerous potential applications such as 3D-imaging of natural objects, fabrication of diffractive optical elements, and interferometric investigation of complex technical components become possible. Further progress has been made by recording holograms directly with electronic targets and not in photographic emulsions. In this way the independent numerical reconstruction of phase and intensity can be accomplished by the computer. One important consequence is that interferometric techniques, such as 3D-displacement analysis and 3D-contouring, can be implemented easily and with high flexibility. Furthermore, digitally recorded holograms can be transmitted via telecommunication networks and optically reconstructed at any desired place using an appropriate spatial light modulator. Consequently, the complete optical information of complex objects can be transported between different places with high velocity. This opens the possibility to compare nominal identical but physically different objects (master sample comparison) available at different locations with interferometric sensitivity. We call this remote metrology.

Direct Phase Reconstruction by Digital Holography

In digital speckle pattern interferometry (DSPI), the object is focused onto the target of an electronic sensor. Thus, an image plane hologram is formed as a result of the interference with an inline reference wave. In contrast with DSPI, a digital hologram is recorded without imaging. The target records the superposition of the reference and the object wave in the near-field region – a so-called Fresnel hologram. The basic optical setup in digital holography for recording holograms is the same as in conventional holography (**Figure 1a**). A laser beam is divided into two coherent beams, one illuminating the object and forming the object wave, the other entering the target directly and forming the reference wave. On this basis, very compact solutions are possible. **Figure 1b** shows a holographic camera where the interferometer, containing a beamsplitter and some wavefront shaping components, is mounted in front of the camera target.

For a description of the principle of digital Fresnel holography, we use a simplified version of the optical setup **(Figure 2a)**. The object is modeled by a plane rough surface that is located in the (x, y)-plane and illuminated by laser light. The scattered wavefield forms the object wave $u(x, y)$. The target of an electronic sensor (e.g., a CCD or a CMOS) used for recording the hologram is located in the (ξ, η)-plane at the distance d from the object. Following the basic principles of holography, the hologram $h(\xi, \eta)$ originates from the interference of the object wave $u(\xi, \eta)$ and the reference wave $r(\xi, \eta)$

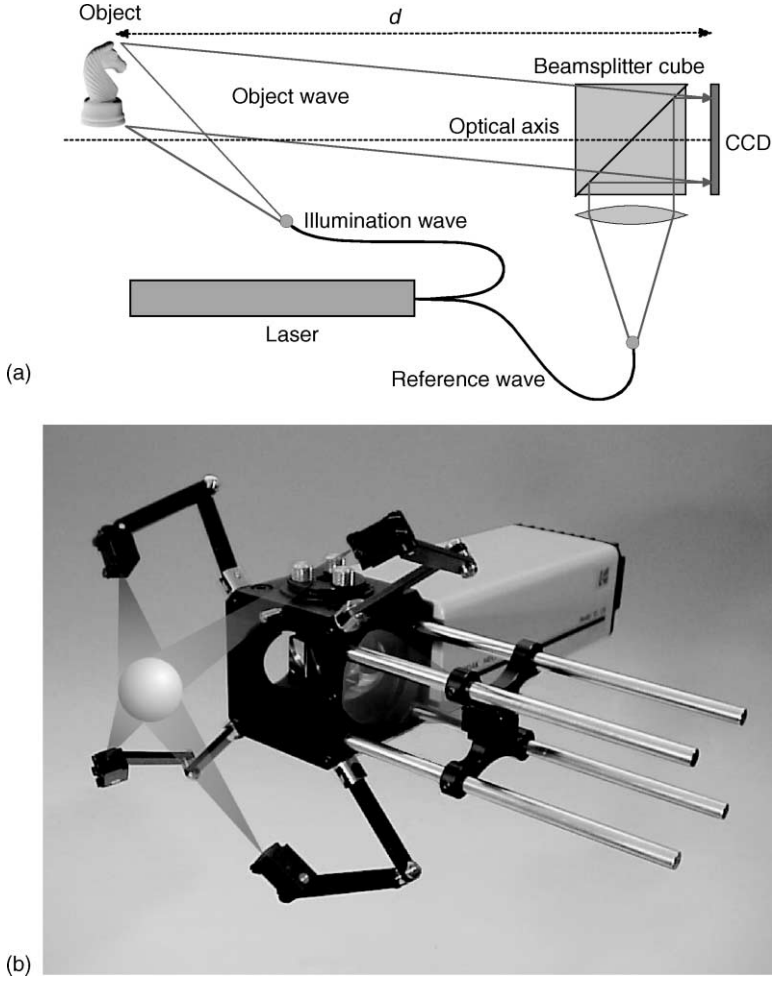

Figure 1 Setup for recording digital holograms. (a) Schematic setup for recording a digital hologram onto a CCD target. (b) Implementation of a holographic camera by mounting a compact holographic interferometer in front of a CCD-target (4 illumination directions are used). Reproduced from Seebacher S, Osten W, Baumbach Th and Jüptner W (2001) The determination of material parameters of microcomponents using digital holography. *Optics and Lasers in Engineering* 36(2): 103–126, copyright © 2001, with permission from Elsevier.

in the (ξ, η)-plane:

$$h(\xi,\eta) = |u(\xi,\eta) + r(\xi,\eta)|^2 = rr^* + ru^* + ur^* + uu^* \quad [1]$$

The transformation of the intensity distribution into a gray value distribution, that is stored in the image memory of the computer, is considered by the characteristic function t of the sensor. This function is generally only approximately linear:

$$T = t[h(\xi,\eta)] \quad [2]$$

Because the sensor has a limited spatial resolution, the spatial frequencies of the interference fringes in the hologram plane – the so-called micro-interferences – have to be considered. The fringe spacing g and the spatial frequency f_x, respectively, are determined by the angle β between the object and the reference wave (Figure 2b):

$$g = \frac{1}{f_x} = \frac{\lambda}{2\sin(\beta/2)} \quad [3]$$

with λ as the wavelength. If we assume that the discrete sensor has a pixel pitch (distance between adjacent pixels) $\Delta\xi$, the sampling theorem requires at least two pixels per fringe for a correct reconstruction of the periodic function:

$$2\Delta\xi < \frac{1}{f_x} \quad [4]$$

Consequently, we obtain for small angles β:

$$\beta < \frac{\lambda}{2\Delta\xi} \quad [5]$$

Modern high-resolution CCD or CMOS chips have a pitch, $\Delta\xi$, of about 4 μm. In this case, a maximum angle between the reference and the

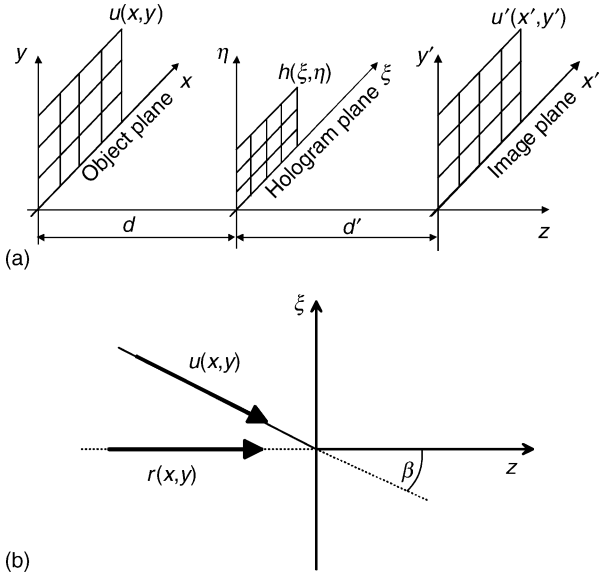

Figure 2 Geometry for recording and reconstruction of digital holograms. (a) Schematic setup for Fresnel holography. (b) Interference between the object and reference wave in the hologram plane.

object wave of only 4° is acceptable. The practical consequence of the restricted angle resolution in digital holography is a limitation of the effective object size that can be stored holographically by an electronic sensor. However, this is only a technical handicap. Larger objects can be placed at a sufficient distance from the hologram, or reduced optically by imaging with a negative lens.

The reconstruction is done by illuminating the hologram with a so-called reconstruction wave $c(\xi, \eta)$:

$$u'(x', y') = t[h(\xi, \eta)]c(\xi, \eta) \qquad [6]$$

The hologram, $t[h(\xi, \eta)]$, diffracts the wave, $c(\xi, \eta)$, in such a way that images of the object wave are reconstructed. Usually four terms are reconstructed if the wave, $u'(x', y')$, propagates in space. An assumed linear characteristic function, $t(h) = \alpha h + t_0$, delivers:

$$u' = Tc = t(h)c \qquad [7]$$

and

$$u' = \alpha\lfloor cu^2 + cr^2 + cur^* + cru^* \rfloor + ct_0 \qquad [8]$$

with two relevant image terms, $[cur^*]$ and $[cru^*]$. The appearance of the image terms depends on the concrete shape of the reconstruction wave. Usually the reference wave, $c = r$, or its conjugated version, $c = r^*$, is applied. In the case of the conjugated reference wave, a direct or real image will be reconstructed due to a converging image wave that can be imaged on a screen at the location of the original object.

However, in digital holography the reconstruction of the object wave in the image plane, $u'(x', y')$, is done by numerical simulation of the physical process, as shown in Figure 3a. The reconstruction wave with a well-known shape equal to the reference wave, $r(\xi, \eta)$, propagates through the hologram, $h(\xi, \eta)$. Following the Huygens principle, each point, $P(\xi, \eta)$, on the hologram, acts as the origin of a spherical elementary wave. The intensity of these elementary waves is modulated by the transparency, $h(\xi, \eta)$. In a given distance, $d' = d$, from the hologram, a sharp real image of the object can be reconstructed as the superposition of all elementary waves. For the reconstruction of a virtual image, $d' = -d$ is used.

Consequently, the calculation of the wavefield, $u'(x', y')$, in the image plane starts with the pointwise multiplication of the stored and transformed intensity values, $t[h(\xi, \eta)]$, with a numerical model of the reference wave, $r(\xi, \eta)$. If the hologram is assumed to be uniformly illuminated by a normally incident, monochromatic plane wave of amplitude 1 the reference wave can be modeled by $r(\xi, \eta) = 1$. After the multiplication the resulting field in the hologram plane is propagated in free space. In the distance, d', the diffracted field, $u'(x', y')$, can be found by solving the well-known Rayleigh–Sommerfeld diffraction formula, that is also known as the

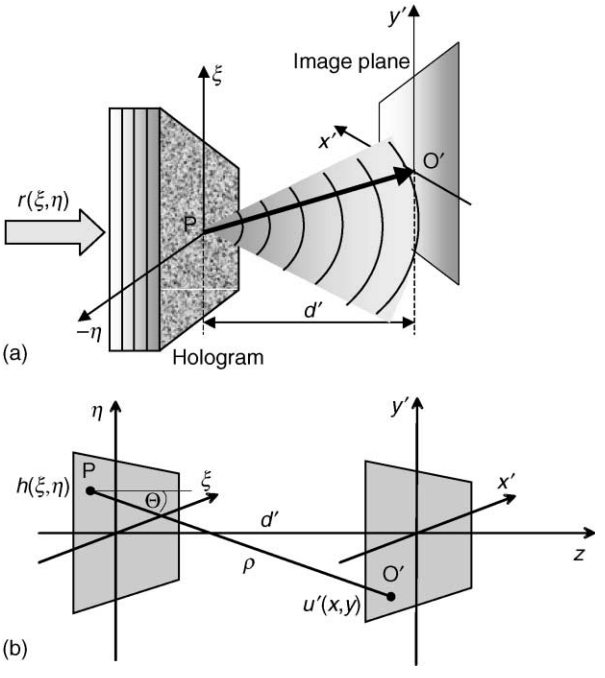

Figure 3 Reconstruction of digital holograms. (a) Principle of wave front reconstruction. (b) Light propagation by diffraction (Huygens–Fresnel principle).

Huygens–Fresnel principle:

$$u'(x',y') = \frac{1}{i\lambda}\int\int_{-\infty\cdots\infty} t[h(\xi,\eta)]r(\xi,\eta) \times \frac{\exp(ik\rho)}{\rho}\cos\theta\,d\xi\,d\eta \quad [9]$$

with

$$\rho(\xi-x',\eta-y') = \sqrt{d'^2+(\xi-x')^2+(\eta-y')^2} \quad [10]$$

as the distance between a point $O'(x',y',z=d')$ in the image plane and a point $P(\xi,\eta,z=0)$ in the hologram plane, and

$$k = \frac{2\pi}{\lambda} \quad [11]$$

as the wave number. The obliquity factor, $\cos\theta$, represents the cosine of the angle between the outward normal and the vector joining P to O′. This term is given as:

$$\cos\theta = \frac{d'}{\rho} \quad [12]$$

and therefore the Huygens–Fresnel principle can be rewritten:

$$u'(x',y') = \frac{d'}{i\lambda}\int\int_{-\infty\cdots\infty} t[h(\xi,\eta)]r(\xi,\eta)\frac{\exp(ik\rho)}{\rho^2}d\xi d\eta \quad [13]$$

This numerical reconstruction delivers the complex amplitude of the wavefront. Consequently, the phase distribution, $\phi(x',y')$, and the intensity, $I(x',y')$, can be calculated directly from the reconstructed complex function, $u'(x',y')$:

$$\phi(x',y') = \arctan\frac{\mathrm{Im}|u'(x',y')|}{\mathrm{Re}|u'(x',y')|} \qquad [-\pi,\pi] \quad [14]$$

$$I(x',y') = u'(x',y')u'^{*}(x',y') \quad [15]$$

The direct approach to the phase yields several advantages for imaging and metrology applications that are discussed later.

Reconstruction Principles in Digital Holography

Different numerical reconstruction principles have been investigated: the Fresnel approximation, the convolution approach, the lens-less Fourier approach, the phase shifting approach, and the phase-retrieval approach. In this section the main techniques are briefly described.

The Fresnel Approximation

If the distance, d, between the object and hologram plane, and equivalently, $d' = d$, between the hologram and image plane, is large compared to $(\xi - x')$ and $(\eta - y')$, then the denominator of eqn [13] can be replaced by d'^2 and the parameter ρ in the numerator can be approximated by a binomial expansion for the square root (10) where only the first two terms are considered:

$$\rho \approx d'\left[1 + \frac{(\xi-x')^2}{2d'^2} + \frac{(\eta-x')^2}{2d'^2}\right] \quad [16]$$

The resulting expression for the field at (x', y') becomes

$$u'(x',y') = \frac{\exp(ikd')}{i\lambda d'}\int\int_{-\infty\cdots\infty} t[h(\xi,\eta)]r(\xi,\eta) \times \exp\left[\frac{ik}{2d'}\{(\xi-x')^2+(\eta-y')^2\}d\xi\,d\eta\right] \quad [17]$$

Equation [17] is a convolution integral that can be expressed as

$$u'(x',y) = \int\int_{-\infty\cdots\infty} t[h(\xi,\eta)]r(\xi,\eta)H \times (\xi-x',\eta-y')d\xi\,d\eta \quad [18]$$

with the convolution kernel:

$$H(x',y') = \frac{\exp(ikd')}{i\lambda d'}\exp\left[\frac{ik}{2d'}(x'^2+y'^2)\right] \quad [19]$$

Another notation of eqn [17] is found if the term $\exp[(ik/2d')(x'^2+y'^2)]$ is taken out of the integral:

$$u'(x',y') = \frac{\exp(ikd')}{i\lambda d'}\exp\left[i\frac{k}{2d'}(x'^2+y'^2)\right]\int\int_{-\infty\cdots\infty} \times\left\{t[h(\xi,\eta)]r(\xi,\eta)\exp\left[i\frac{k}{2d'}(\xi^2+\eta^2)\right]\right\} \times\exp\left[-i\frac{2\pi}{\lambda d'}(\xi x'+\eta y')\right]d\xi\,d\eta \quad [20]$$

or

$$u'(x',y') = \frac{\exp(ikd')}{i\lambda d'}\exp\left[i\frac{k}{2d'}(x'^2+y'^2)\right] \times \mathrm{FT}_{\lambda d'}\left\{t[h(\xi,\eta)]r(\xi,\eta)\exp\left[i\frac{k}{2d'}(\xi^2+\eta^2)\right]\right\} \quad [21]$$

where $\mathrm{FT}_{\lambda d'}$ indicates the 2-dimensional Fourier transform that has been modified by a factor $1/(\lambda d')$. Equation [21] makes clear that the diffracted

wavefront consists of the Fourier transform (FT) of the digitally stored hologram, $t[h(\xi,\eta)]$, multiplied by the reference wave, $r(\xi,\eta)$, and the chirp function, $\exp\{(i\pi/\lambda d')(\xi^2+\eta^2)\}$. This Fourier transform is scaled by the constant factor, $1/(id'\lambda)$, and a phase factor that is independent of the processed hologram.

The discrete sampling in digital processing requires the transformation of the infinite continuous integral in eqn [20] into a finite discrete sum. This results in the finite Fresnel transform:

$$u'(m,n) = \sum_{j=0}^{M-1}\sum_{l=0}^{N-1} t[h(j\Delta\xi, l\Delta\eta)]r(j\Delta\xi, l\Delta\eta) \times \exp\left[\frac{i\pi}{d'\lambda}(j^2\Delta\xi^2 + l^2\Delta\eta^2)\right] \times \exp\left\{-i2\pi\left(\frac{jm}{M}+\frac{ln}{N}\right)\right\} \quad [22]$$

where constants and pure phase factors preceding the sums have been omitted. The main parameters are the pixel number $M \times N$ and the pixel pitches $\Delta\xi$ and $\Delta\eta$ in the two directions, which are defined by the used sensor chip.

The discrete phase distribution, $\phi(m,n)$, of the wavefront and the discrete intensity distribution, $I(m,n)$, on the rectangular grid of $M \times N$ sample points can be calculated from the reconstructed complex function, $u'(m,n)$, by using eqns [14] and [15], respectively. The wrapped phase distribution is computed directly without the need of additional temporal or spatial phase modulation such as phase shifting or spatial heterodyning.

For interferometric applications with respect to displacement and shape measurement the phase difference, $\delta(m,n)$, of two reconstructed wave fields, $u'_1(m,n)$ and $u'_2(m,n)$, needs to be calculated. The algorithm can be reduced to the following equation:

$$\delta(m,n) = \phi_1(m,n) - \phi_2(m,n) \quad [23]$$

Figure 4 shows the principle of displacement measurement by digital holography. Besides the investigation of surface displacements in the region of the wavelength, digital holography can be applied advantageously for the measurement of the shape of complex objects. In Figure 5, a turbine blade was investigated with the 2-wavelength contouring method. Both, the digitally reconstructed mod 2π-phase and its demodulated version after-phase unwrapping, are presented. Phase unwrapping is necessary in digital holography, since the fringe-counting problem still remains. However, there are some efficient approaches to overcome the difficulties of this process.

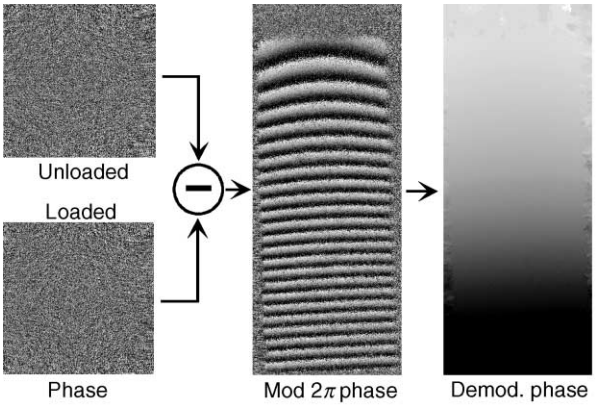

Figure 4 The principle of digital holographic interferometry demonstrated on an example of a loaded small beam. The interference phase is the result of the subtraction of the two phases which correspond to the digital holograms of both object states.

Following eqn [22] the pixel spacing in the reconstructed image is

$$\Delta x' = \frac{d'\lambda}{M\Delta\xi} \quad \text{and} \quad \Delta y' = \frac{d'\lambda}{N\Delta\eta} \quad [24]$$

Additional to the real image, a blurred virtual image and a bright dc-term, the zero-order diffracted field, is reconstructed. This term can effectively be eliminated by preprocessing the stored hologram or the different terms can be separated by using the off-axis instead of the in-line technique. However, the spatial separation between the object and the reference field requires a sufficient space-bandwidth product of the used CCD-chip, as discussed in the section on direct phase reconstruction above.

Numerical Reconstruction by the Convolution Approach

In the section above, we have already mentioned that the connection between the image term, $u'(x',y')$, and the product, $t[h(\xi,\eta)]r(\xi,\eta)$, can be described by a linear space-invariant system. The diffraction formula [17] is a superposition integral with the impulse response:

$$H(x'-\xi, y'-\eta) = \frac{\exp(ikd')}{i\lambda d'} \times \exp\left[\frac{ik}{2d'}\{(\xi-x')^2 + (\eta-y')^2\}\right] \quad [25]$$

A linear space-invariant system is characterized by a transfer function G, that can be calculated as the

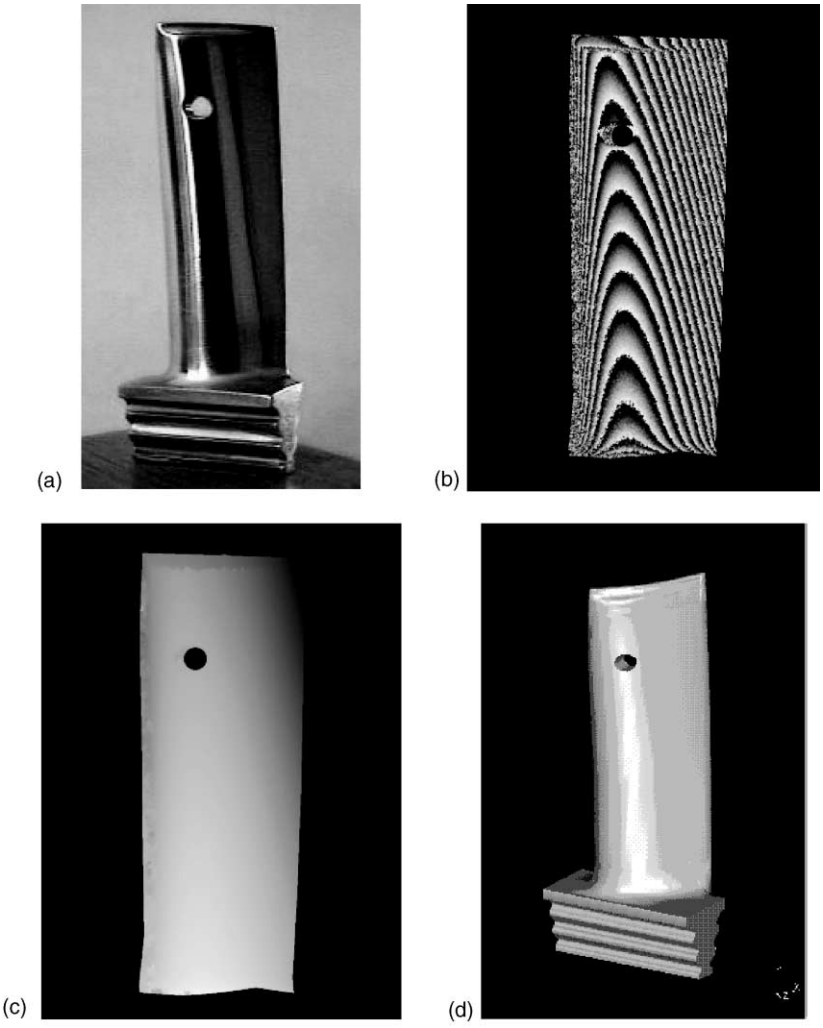

Figure 5 Phase reconstruction by digital holographic interferometry on an example of 2-wavelength contouring of a turbine blade. (a) Image of the turbine blade. (b) Mod-2π phase distribution. (c) Unwrapped phase distribution. (d) CAD reconstruction of the turbine blade.

Fourier-transform of the impulse response:

$$G(f_x, f_y) = \mathrm{FT}\{H(\xi, \eta, x', y')\} \qquad [26]$$

with the spatial frequencies f_x and f_y. Consequently, the convolution theorem can be applied, which states that the Fourier transform of the convolution, $t[h(\xi, \eta)]r(\xi, \eta)$, with H is the product of the individual Fourier transforms, $\mathrm{FT}\{t[h(\xi, \eta)]r(\xi, \eta)\}$ and $\mathrm{FT}\{H\}$. Thus $u'(x', y')$ can be calculated by the inverse Fourier transform of the product of the Fourier-transformed convolution partners:

$$u'(x', y') = \mathrm{FT}^{-1}\{\mathrm{FT}[t(h)r]\mathrm{FT}[H]\} \qquad [27]$$

$$u'(x', y') = [t(h)r] \otimes H \qquad [28]$$

with $\otimes$ as the convolution symbol. The computing effort is comparatively high: two complex multiplications and three Fourier transforms. The main difference to the Fresnel transform is the different pixel size in the reconstructed field:

$$\Delta x' = \Delta\xi \qquad \text{and} \qquad \Delta y' = \Delta\eta \qquad [29]$$

Numerical Reconstruction by the Lensless Fourier Approach

We have already mentioned that the limited spatial resolution of the sensor restricts the angle resolution of the digital hologram. The sampling theorem requires that the angle between the object beam and the reference beam at any point of the electronic sensor be limited in such a way that the

microinterference spacing is larger than double the pixel size. In general, the angle between the reference beam and the object beam varies over the sensor's surface, and so does the maximum spatial frequency. Thus, for most holographic setups, the full spatial bandwidth of the sensor cannot be used. However, it is important to use the entire spatial bandwidth of the sensor because the lateral resolution of the reconstructed image depends on a complete evaluation of the entire information obtained from the sensor.

Even if the speed of digital signal processing is increasing rapidly, algorithms should be as simple and as fast to compute as possible. For the Fresnel approach and the convolution approach, several fast Fourier transforms and complex multiplications are necessary. Therefore, a more effective approach, such as the subsequently described algorithm, seems promising.

The lensless Fourier approach is the fastest and most suitable algorithm for small objects. The corresponding setup is shown in Figure 6. It allows us to choose the lateral resolution in a range from a few microns to hundreds of microns without any additional optics. Each point, (ξ, η), on the hologram is again considered as a source point of a spherical elementary wavefront (Huygen's principle). The intensity of these elementary waves is modulated by $t[h(\xi, \eta)]$ – the amplitude transmission of the hologram. The reconstruction algorithm for lensless Fourier holography is based on the Fresnel reconstruction. Here again, $u(x, y)$ is the object wave in the object plane, $h(\xi, \eta)$ the hologram, $r(\xi, \eta)$ the reference wave in the hologram plane, and $u'(x', y')$ the reconstructed wavefield.

For the specific setup of lensless Fourier holography, a spherical reference wave is used with an origin at the same distance from the sensor as the object itself. In the case that $d' = -d$, $x = x'$, and $y = y'$, both virtual images are reconstructed and the reconstruction algorithm then reads:

$$u'(x', y') = \frac{\exp(\mathrm{i}kd)}{\mathrm{i}\lambda d} \mathrm{e}^{-\mathrm{i}\frac{k}{2d}(x^2+y^2)} \times \mathrm{FT}_{\lambda d'}\left\{t[h(\xi, \eta)] \cdot r(\xi, \eta) \cdot \mathrm{e}^{-\mathrm{i}\frac{k}{2d}(\xi^2+\eta^2)}\right\} \quad [30]$$

with $\mathrm{FT}_{\lambda d}$ as the 2-dimensional Fourier transformation which has been scaled by a factor $1/\lambda d$. In this recording configuration, the effect of the spherical phase factor associated with the Fresnel diffraction pattern of the object is eliminated by the use of a spherical reference wave, $r(\xi, \eta)$, with the same average curvature:

$$r(x, y) = \text{const.} \times \exp\left(\mathrm{i}\frac{\pi}{\lambda d}(\xi^2 + \eta^2)\right) \quad [31]$$

This results in a more simple reconstruction algorithm which can be described by

$$u'(x', y') = \text{const.} \times \exp\left(-\mathrm{i}\frac{\pi}{\lambda d}(x^2 + y^2)\right) \times \mathrm{FT}_{\lambda d}\{h(\xi, \eta)\} \quad [32]$$

Besides the simpler and faster reconstruction algorithm (only one Fourier transformation has to be computed), the Fourier algorithm uses the full space-bandwidth product (SBP) of the sensor chip because it adapts the curvature of the reference wave to the curvature of the object wave.

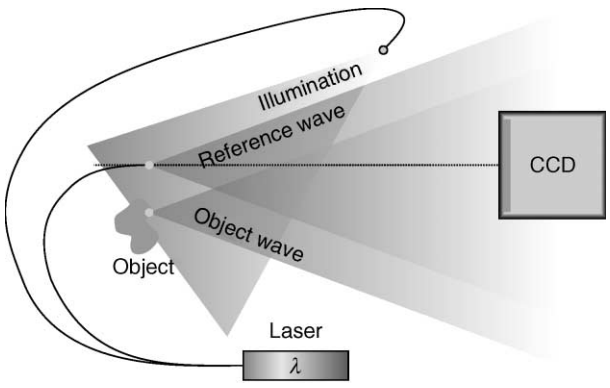

Figure 6 Scheme of a setup for digital lensless Fourier holography of diffusely reflecting objects.

Influences of Discretization

For the estimation of the lateral resolution in digital holography, three different effects related to discretization have to be considered: averaging, sampling, and the limited sensor size. We assume a quadratic sensor with $N \times M$ pixels of the size $\Delta\xi \times \Delta\xi$. Each pixel has a light-sensitive region with a side length $\gamma\Delta\xi = \Delta\xi_{\mathrm{eff}}$. γ^2 is the so-called fill factor $(0 \leq \gamma \leq 1)$, that indicates the active area of the pixel. The sensor averages the incident light which has to be considered because of possible intensity fluctuations over this area. The continuous expression for the intensity $I(\xi, \eta) = t[h(\xi, \eta)]$, registered by the sensor, has to be integrated over the light-sensitive area. This can be expressed mathematically by the convolution of the incident intensity $I(\xi, \eta)$, with a rectangle function:

$$I^1(\xi, \eta) \propto I \otimes \mathrm{rect}_{\Delta\xi_{\mathrm{eff}} \cdot \Delta\xi_{\mathrm{eff}}} \quad [33]$$

The discrete sampling of the light field is modeled by the multiplication of the continuous assumed hologram with the 2-dimensional comb-function:

$$I^2(\xi, \eta) \propto I^1(\xi, \eta) \times \mathrm{comb}_{\Delta\xi.\Delta\xi} \qquad [34]$$

Finally, the limited sensor size requires that the comb-function has to be truncated at the borders of the sensor. This is considered by the multiplication with a 2-dimensional rect-function of the size $N \times \Delta\xi$:

$$I^3(\xi, \eta) \propto I^2 \times \mathrm{rect}_{N\Delta\xi N.\Delta\xi} \qquad [35]$$

The consequences are amplitude distortions, aliasing and speckling that have to be considered in the reconstruction procedure.

Advantages of Digital Holography

Besides the electronic processing and the direct access to the phase, some further advantages recommend digital holography for several applications such as metrology and microscopy:

- The availability of the independently reconstructed phase distributions of each individual state of the object and interferometer, respectively, offers the possibility to record a series of digital holograms with increased load amplitude. In the evaluation process, the convenient states can be compared interferometrically. Furthermore, a series of digital holograms with increasing load can be applied to unwrap the mod 2π-phase temporally. In this method, the total object deformation is subdivided into many measurement steps, in which the phase differences are smaller than 2π. By adding up those intermediate results, the total phase change can be obtained without any further unwrapping. This is an important feature, since it is essential to have an unwrapped phase to be able to calculate the real deformation data from the phase map. Figure 7 shows an example of such a measurement. The left image shows the wrapped deformation phase for a clamped coin which was loaded with heat. The right image shows the temporal unwrapped phase which has been obtained by dividing the total deformation into 85 submeasurements. Thus, the displacement of the object can be observed almost in real time during the loading process.
- The independent recording and reconstruction of all states also gives a new degree of freedom for optical shape measurement. In the case of multiwavelength contouring, each hologram can be stored and reconstructed independently with its corresponding wavelength. This results in a drastic decrease of aberrations and makes it possible to use larger wavelength differences for the generation of shorter synthetic wavelengths.
- Because all states of the inspected object can be stored and evaluated independently, only seven digital holograms are necessary to measure the 3D-displacement field and shape of an object under test: one hologram for each illumination direction before and after the loading, respectively, and one hologram with a different wavelength (or a different source-point of illumination) which can interfere with one of the other holograms to perform two-wavelength-contouring (or two-source-point-contouring) for shape measurement. If four illumination directions are used, nine holograms are necessary.
- The direct access to all components of the wavefield makes it possible to correct wavefront aberrations effectively by computer.
- The digital hologram containing all information of the wavefront can be transmitted via the internet to any location and can be reconstructed digitally by computer or as an analogue version by a spatial light modulator. Consequently, remote access to wavefronts, that are generated at distant places, is possible.
- Finally, the possibility to miniaturize complex holographic sensor setups and to use this method for remote comparative interferometry, makes digital holography a versatile tool for the solution of numerous inspection and measurement problems.

Introduction

The development of holographic interferometry has redefined our perception of optical interferometry. The unique property of holographic interferometry to bring a wavefront, generated at some earlier time, stored in a hologram and released at a later time, to interfere with a comparison wavefront, has made possible the interferometric comparison of a rough surface, which is subject to stress, with its normal state. Assuming the surface deformations to be very small, the interference of the two speckled wavefronts forms a set of interference fringes that are indicative of the amount of displacement and deformation undergone by the diffuse object.

Holographic interferometry is an important and exciting area of research and development. It has established itself as a highly promising noninvasive technique in the field of optical metrology. Techniques within its folds for the measurement of static and dynamic displacements, topographic contours, and flow fields have been developed and demonstrated with success in a wide range of problems. Significant and extensive contributions to the development of holographic interferometry have been realized both from the theoretical and experimental perspectives. A wide range of procedures have been developed which make it not only possible to measure surface displacements and deformations of engineering structures to an accuracy of a fraction of a micrometer but also to detect material flaws and inhomogeneities having escaped the manufacturing process. The methodology of quantitative analysis of holographic interferograms has undergone extensive development during the last decade. This article provides a brief review of the holographic techniques with emphasis placed on bringing out its relevance in experimental mechanics and nondestructive testing. The series of books given in the Further Reading section at the end of this article treat the field in detail.

Basic Methods in Holographic Interferometry

The ability of holography to store a wavefront and release it for reconstruction at a later time offers access to the possibility to compare wavefronts, which have albeit existed at different times. There are several schemes that have been established to obtain the interferometric comparison of the wavefronts.

Double-Exposure Holographic Interferometry

In frozen form of wavefront comparison, two holograms of the object are recorded on a photographic plate. The first hologram is made with the object in its initial, unstressed state and the second hologram is recorded with the object in its final, stressed state. Upon reconstruction, the hologram releases the two stored wavefronts, one corresponding to the object in its unstressed state and the other corresponding to the object in its stressed state (Figure 1). The virtual image is overlaid by a set of

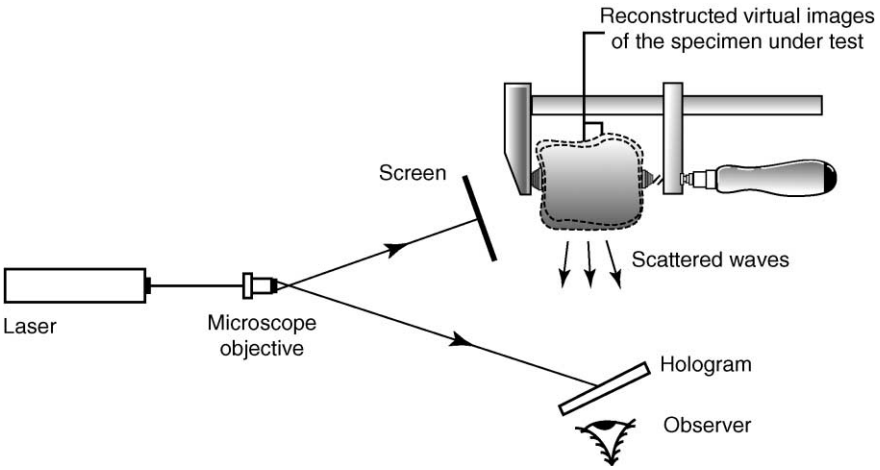

Figure 1 Layout for observing a double exposure holographic interferogram.

bright and dark interference fringes, which are due to the displacement of the object between the two exposures.

The fringe pattern is permanently stored on the holographic plate. The interference fringes denote the loci of points that have undergone an equal change of optical path between the light source and the observer. The image intensity of the holographic interferogram is

$$I(x, y) = I_0(x, y)\{1 + V(x, y)\cos(\varphi(x, y) - \varphi'(x, y))\} \quad [1]$$

where $I_0(x, y)$ is the background intensity, $V(x, y)$ is the fringe contrast, and φ and φ' are the phases of the waves from the object in its initial and deformed states, respectively.

A bright fringe is produced whenever

$$\varphi(x, y) - \varphi'(x, y) = 2n\pi \qquad n = 0, 1, 2, \ldots \quad [2]$$

where n is the fringe number. The wave scattered by a rough surface shows rapid variations of phase, which have little correlation across the wavefront. The phase difference varies randomly over the ray directions contained within the aperture of the viewing system, which would normally prevent the observation of fringes with large aperture optics near such points. However, a surface may exist at a distance from the object at which the value of phase difference is stationary over the cone of ray pairs defined by the viewing aperture. Interference fringes are localized in the region where the variation in phase difference is minimum over the range of viewing directions. This approach has been widely used to compute fringe localization for any object displacement and for any arbitrary illumination and observation geometry.

Real-Time Holographic Interferometry

A hologram is made of an arbitrarily shaped rough surface. After development, the hologram is placed back in exactly the same position. Upon reconstruction, the hologram produces the original wavefront. A person looking through the hologram sees a superposition of the original object and its reconstructed image (Figure 2). The object wave interferes with the reconstructed wave to produce a dark field due to destructive interference. If the object is now slightly deformed, interference fringes are produced which are related to the change in shape of the object. A dark fringe is produced, whenever:

$$\varphi(x, y) - \varphi'(x, y) = 2n\pi \qquad n = 0, 1, 2, \ldots \quad [3]$$

The method is very useful for determining the direction of the object displacement, and for compensating on the interferogram the influence of the rigid body motion of the object when subjected to a stress field.

The optical setup for real-time holography uses an immersion tank, which is mounted on a universal stage and contains the photographic plate. The holographic plate is followed by a vidicon camera, which visualizes the interferograms directly onto the TV monitor screen connected to a video-recording tape to memorize the information. The use of thermoplastic plates as recording material has gained in importance in recent years for implementing real-time and double exposure holographic interferometry setups, as it can be processed rapidly *in situ* using electrical and thermal processing.

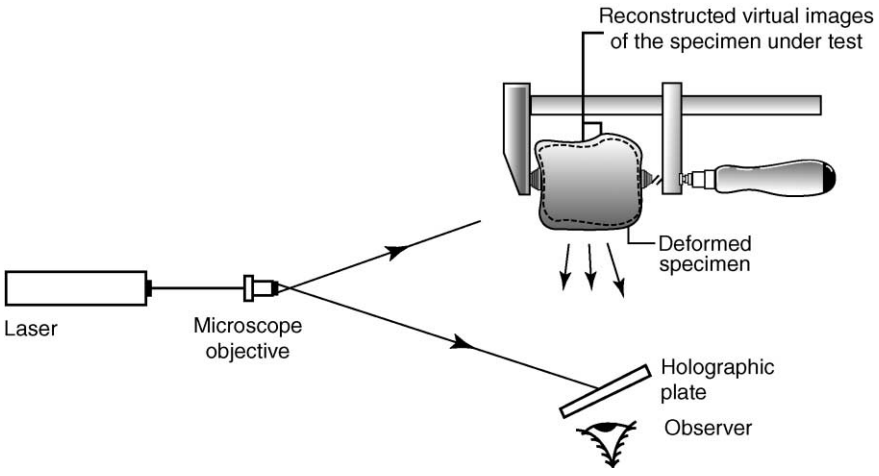

Figure 2 Layout for observing a holographic interferogram in real-time.

The plate is also cost-effective as it is erasable and reusable at least several hundred times. In thermoplastic recording the information is recorded as a thickness variation corresponding to a charge intensity pattern deposited on the thermoplastic layer. Self-developing or photorefractive crystals are other interesting alternatives to the use of film as the recording medium.

Digital Holographic Interferometry

The method consists of recording two holograms corresponding to undeformed and deformed states of an object using a CCD camera. These images are stored in a digital image processing system. The two holograms are then reconstructed separately by numerical methods from the digitaly stored holograms. The advantage of digital holography is that it allows for computing both the intensity and the phase of a holographically stored wavefront during the numerical reconstruction. The contours of constant optical phase change, due to deformation, are obtained by subtracting the reconstructed phases of the undeformed from the deformed object wavefield.

A hologram can be recorded on a CCD as long as the sampling theorem is fulfilled; that is to say, each period of the spatial variation of the hologram intensity is sampled by at least two pixels of the CCD array. The condition imposes a limit on the angle that the object beam can make with the reference beam, which must necessarily be small given that the resolution of CCDs is relatively low. The applications of the method are thus limited mainly by the pixel size in CCD array. The maximum spatial frequency $f_{\max}$ that must be resolved by the recording medium is determined by the maximum angle $\Delta\theta_{\max}$ between the reference and the object wave:

$$f_{\max} = \frac{2}{\lambda}\sin\frac{\Delta\theta_{\max}}{2} \qquad [4]$$

where λ is the wavelength of the laser source. Since the CCD cameras have resolutions of around 100 lines/mm, the maximum angle between the object and reference waves is limited to a few degrees.

Calculation of Phase Change on Object Loading

A diffusely reflecting object is deformed such that a point P on the surface moves to P′ as shown in Figure 3. In double-exposure or real-time holographic interferometry the two wavefronts related to the states of a surface before and after deformation are reconstructed simultaneously and compared. The change of optical path length due to displacement d is

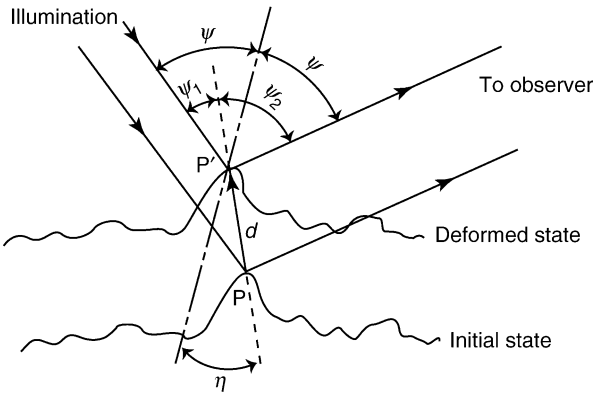

Figure 3 Calculation of the change in optical phase due to surface displacement.

$$\Delta\varphi = \frac{2\pi d}{\lambda}(\cos\psi_1 + \cos\psi_2) \qquad [5]$$

where ψ_1 and ψ_2 are the angles which the illumination and observation waves make with respect to the direction of displacement; eqn [5] can be written in the form:

$$\Delta\varphi = \frac{2\pi d}{\lambda}\cos\eta\cos\psi \qquad [6]$$

where ψ is the angle of bisection between the incident and viewing directions, and η is the angle which the bisector makes with the direction of displacement. The term $d\cos\eta$ being the resolved part of the displacement PP′ in the direction of the bisector, implies that the fringe pattern provides the measure of the displacement component along the bisector of the angle between the incident and viewing directions.

Digital Phase Measurement

The last decade has seen a rapid development of techniques for the automatic and precise reconstruction of phases from fringe patterns. These are based on the concepts of fringe tracking, Fourier transform, carrier frequency, and phase shift interferometry. Quantitative measurement of wavefront phase, for example, can be obtained in a few seconds using phase shift interferometry. With this technique one records a series of holograms by introducing artificially known steps of phase differences in the interference image in eqn [1]:

$$I_i(x,y) = I_0(x,y)\{1 + V(x,y)\cos(\Delta\varphi(x,y) + \Delta\psi_i)\};\quad i = 0,1,2,\ldots \qquad [7]$$

where $\Delta\psi_i$ is the phase shift which is produced, for example, by shifting the phase of the reference wave. A minimum of three intensity patterns is required to calculate the phase at each point on the object surface. Known phase shifts are commonly introduced using a piezoelectric transducer, which serves to shorten or elongate the reference beam path by a fraction of wavelength; the phase-shifter is placed in one arm of the interferometer. Numerous phase shifting techniques have been developed and which can be incorporated to holographic interferometry to generate a phase map, $\Delta\varphi(x, y)$, corresponding to the object displacement. The calculated phase $\Delta\varphi(x, y)$ is independent of the terms $I_0(x, y)$ and $V(x, y)$, and considerably reduces the dependence of the accuracy of measurements on the fringe quality.

The introduction of phase shift interferometry not only provides accurate phase measurements but also eliminates the problem of phase sign ambiguity of the interference fringes. Dynamic phase shifting techniques allow for producing time sequences of deformation maps for studying objects subjected to time-varying loads. The concept is based on considering the normal phase variations caused by a dynamic phenomenon as equivalent to the phase shifting that is introduced in a holographic interferometer in order to perform the phase evaluation task. This method extends the possibility of applying the method to continuous deformation measurements.

Basic Interferometers for Static Displacement Measurement

Equation [6] shows that observation along a single direction yields information only about the resolved part of the surface displacement in one particular direction. The approach to measuring three-dimensional vector displacement would be to record holograms from three different directions in order to obtain three independent resolved components of displacement. The computation of the resulting system of equations would then allow for determining the complete displacement vector.

Out-of-Plane Displacement Component Measurement

The out-of-plane component of displacement is usually measured by illuminating and viewing the object surface in a near normal direction. The fringe equation corresponding to the line of sight displacement component is given by

$$w = \frac{n\lambda}{2} \qquad [8]$$

where w is the out-of-plane component of displacement. An example of a fringe pattern depicting the out-of-plane displacements in a rectangular aluminum plate, clamped along the edges and drawn out at the center by means of a bolt, subjected to three-point loading, is shown in Figure 4.

In-Plane Displacement Component Measurement

The in-plane component of displacement can be measured by illuminating the object along two directions symmetric to the surface normal and observing along a common direction. This is schematized in Figure 5. The in-plane displacements, in a direction containing the two beams, are mapped as a moiré between the interferograms due to each illumination beam. The moiré appears as a family of fringes:

$$u = \frac{n\lambda}{2\sin\theta_e} \qquad [9]$$

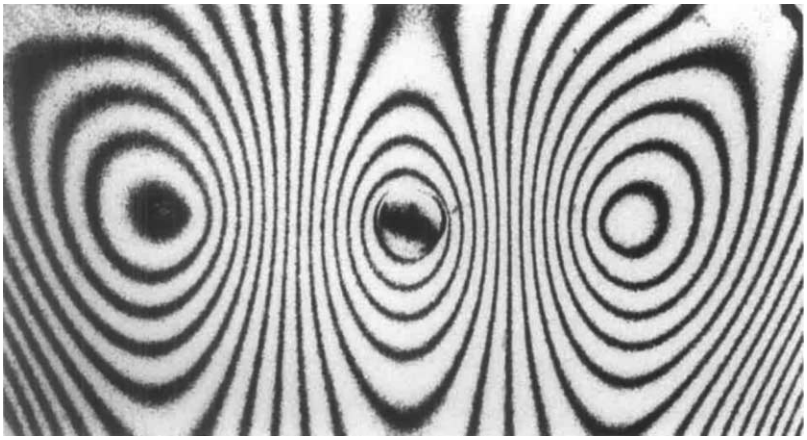

Figure 4 Example of interferogram corresponding to the whole field distribution of out-of-plane component of displacement, w, on an aluminum plate subjected to three-point bending.

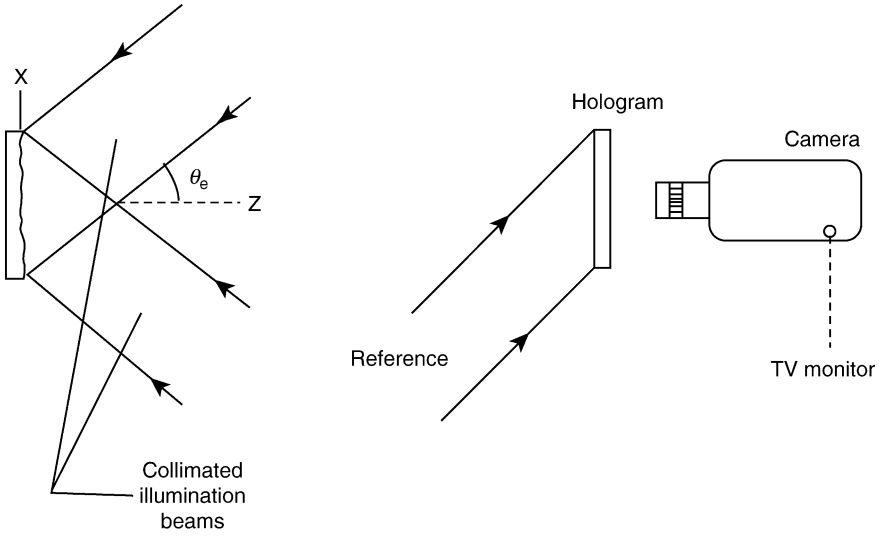

Figure 5 Schematic of the geometrical configuration for measuring the in-plane component of displacement, *u*.

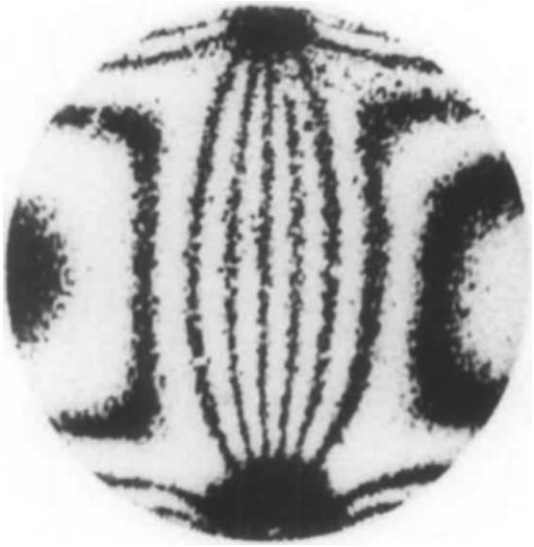

Figure 6 Fringe contours showing the in-plane displacement response of a disk under diametral compression.

where u is the displacement component in the x-direction and θ_e is the angle which the illumination beams make with the surface normal. Figure 6 shows the u pattern corresponding to a disk under diametral compression. The moiré pattern is obtained after optically filtering the interference image.

Comparative Holographic Interferometry

Another technique of significant interest in non-destructive testing is comparative holography that provides the contours of path variations related to the difference in displacements or shapes of two objects. The method provides information about the resolved part of the difference in displacement vector along the direction bisecting the illumination and observation rays. In the case of illumination and observation normal to the object surface, the fringe equation becomes

$$\Delta w = \frac{n\lambda}{2} \qquad [10]$$

where Δw is the difference in displacement component along z direction. The technique provides a tool to compare the mechanical responses of two nominally identical specimens subjected to the same loading and also the shapes of two nominally identical specimens. These features are useful in detecting anomalies in a test specimen with respect to the flaw-free master specimen. One such example is shown in Figure 7a, which displays the presence of a defect in a test specimen. In this case two plates, one flaw-free and the other with a flaw, are subjected to identical loadings. The fringe map in Figure 7b is related to the difference in displacements of test and master specimens subjected to unequal loadings. The presence of flaws is detected in both interferograms.

Basic Interferometers for Dynamic Displacement Measurement

Another important application of holographic interferometry is in the study of the resonant modes of vibration of an object.

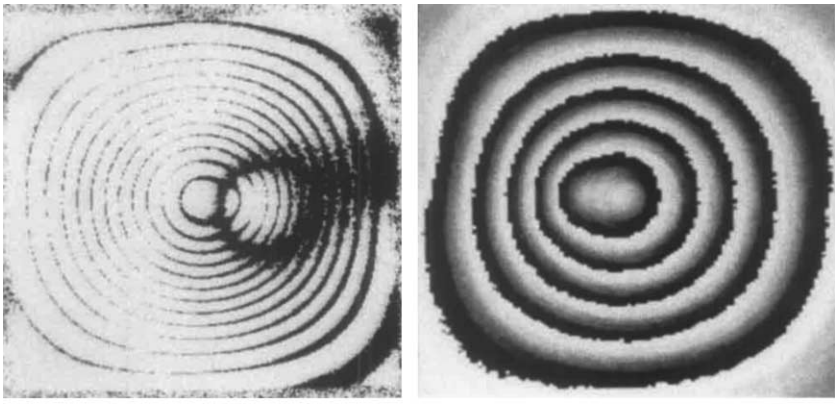

Figure 7 Comparative holography reveals the presence of defects in aluminum plates using (a) identical and (b) unequal loadings.

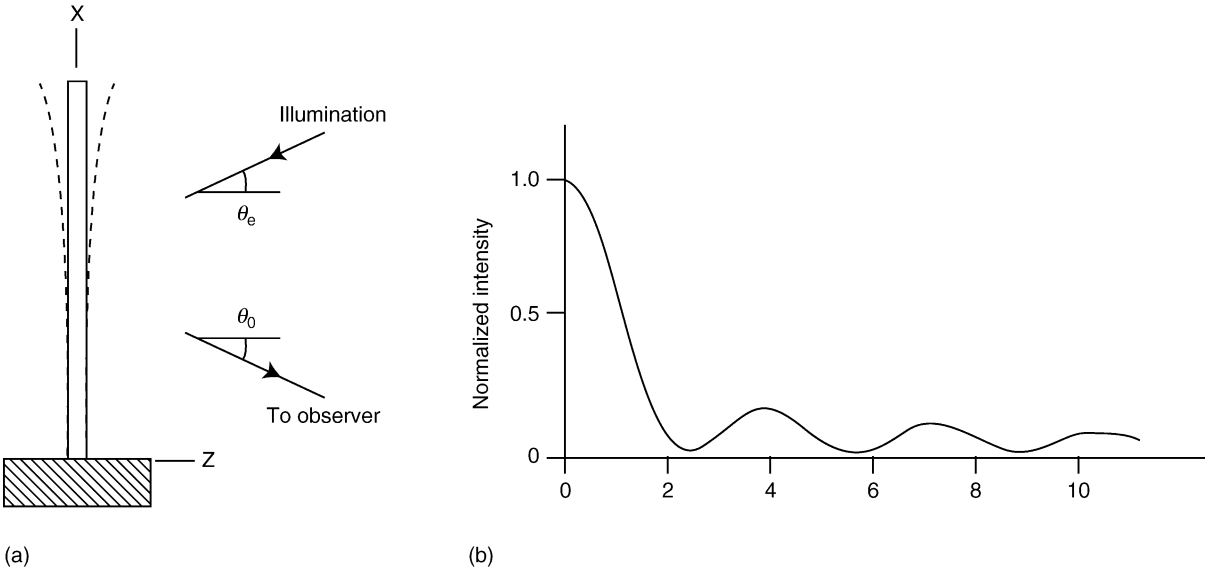

Figure 8 (a) Schematic of the geometrical configuration of a vibrating cantilever beam; (b) plot of fringe function for time-average holography.

Frozen Time-Average Holographic Interferometry

Consider that a hologram is recorded of an object, which is vibrating sinusoidally in a direction normal to its surface (Figure 8a). The exposure time is supposed to be much longer than the period of vibration. The intensity distribution of the image reconstructed by this hologram is

$$I(x, y) = I_o(x, y) J_o^2\left[\frac{2\pi}{\lambda} d(x, y)(\cos\theta_e + \cos\theta_o)\right] \quad [11]$$

where J_o is the zero-order Bessel function of the first kind. The virtual image is modulated by the $J_o^2(\xi)$ function. The dark fringes correspond to the zeros of the function $J_o^2(\xi)$. A plot of the function, shown in Figure 8b, is characterized by a comparatively brighter zero-order fringe, which corresponds to the nodes, a decreasing intensity, and an unequal spacing between the successive zeros. The interferogram in Figure 9 shows the vibrational modes of a helicopter component. The nodes that represent zero motion are clearly seen as the brightest areas in the time average reconstructed pattern.

Real-Time Time-Average Holographic Interferometry

The possibility of studying the response of vibrating objects in real-time extends the usefulness of the technique to identify the resonance states (resonant vibration mode shapes and resonant frequencies) of the object. A single exposure is made of the object in its state of rest. The plate is processed, returned to its original condition and reconstructed. The observer looking through the hologram at the sinusoidally

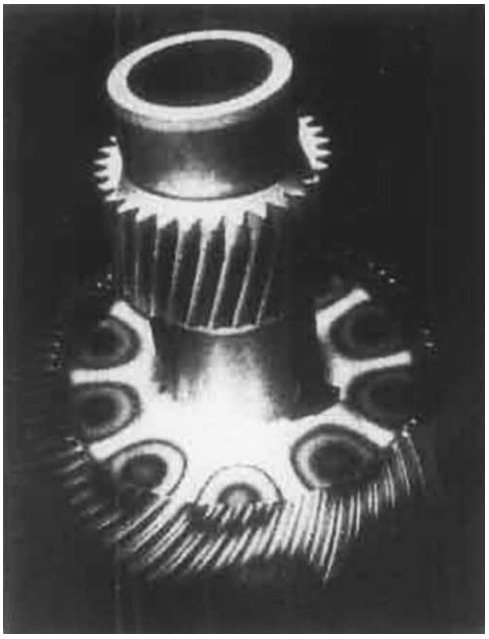

Figure 9 Fringe contours showing the mode shape of a vibrating helicopter component.

vibrating object sees the time-averaged intensity:

$$I(x,y) = I_o(x,y)\left[1 - J_o\left\{\frac{2\pi}{\lambda} d(x,y)(\cos\theta_e + \cos\theta_o)\right\}\right] \quad [12]$$

Stroboscopic Holographic Interferometry

Stroboscopic holography is another interesting variant in the study of vibrations. The hologram is recorded by exposing the photographic plate twice for short time intervals during a vibration cycle. The pulsed exposures are synchronized with the vibrating surface, which is equivalent to making the surface virtually stationary during the recording. Reconstruction of the hologram yields cosinusoidal fringes, which are characteristic of double exposure holography. In real-time stroboscopic holography, a hologram of a nonvibrating object is first recorded. If the vibrating object is illuminated stroboscopically and viewed through the hologram, the reconstructed image from the hologram interferes directly with the light scattered from the object to generate live fringes.

Flow Measurement

Application of holographic interferometry to flow visualization and the measurement of spatial refractive index, density or temperature distributions have led to an advancement of understanding in areas such as aerodynamics, plasma diagnostics, and heat transfer. In the holographic interferometer shown in Figure 10 two consecutive exposures are made, usually the first exposure without flow and the second in the presence of a flow field. Double pulsed holography is used if the flow field is changing rapidly. The optical phase change due to flow between the exposures is

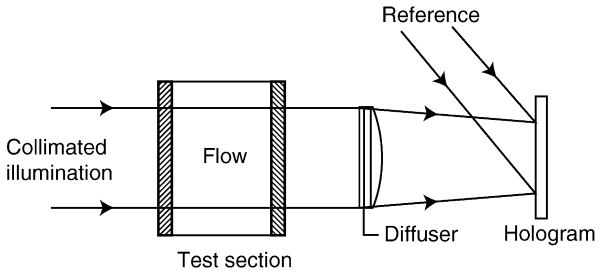

Figure 10 Schematic of a configuration for studying flow.

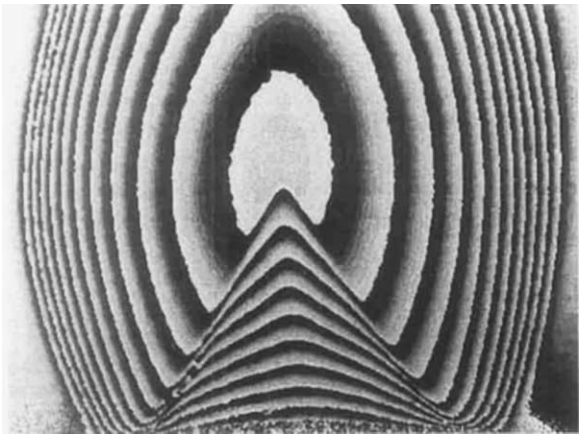

Figure 11 Fringe contours showing the phase distribution of a test flame.

$$\Delta\varphi(x,y) = \frac{2\pi}{\lambda}\int_0^t \{n'(x,y,z) - n'_o\}dz \quad [13]$$

where $n'(x,y,z)$ is the refractive index distribution during the second exposure, n'_o is the uniform refractive index during the first exposure, and t is the length of the test section. Assuming that the properties of the flow are constant in the z direction, the expression for phase change can be expressed as

$$\Delta\tau(x,y) = KL\{\rho(x,y) - \rho_o\} \quad [14]$$

where K is the Gladstone–Dale constant, ρ is the density of the gas, and ρ_o is the density in a no-flow situation. The interference pattern contours the change in the density field of the flow. The change in density per fringe is given by λ/Kt. An example of application related to temperature measurements in an axisymmetric premixed flame is illustrated in Figure 11.

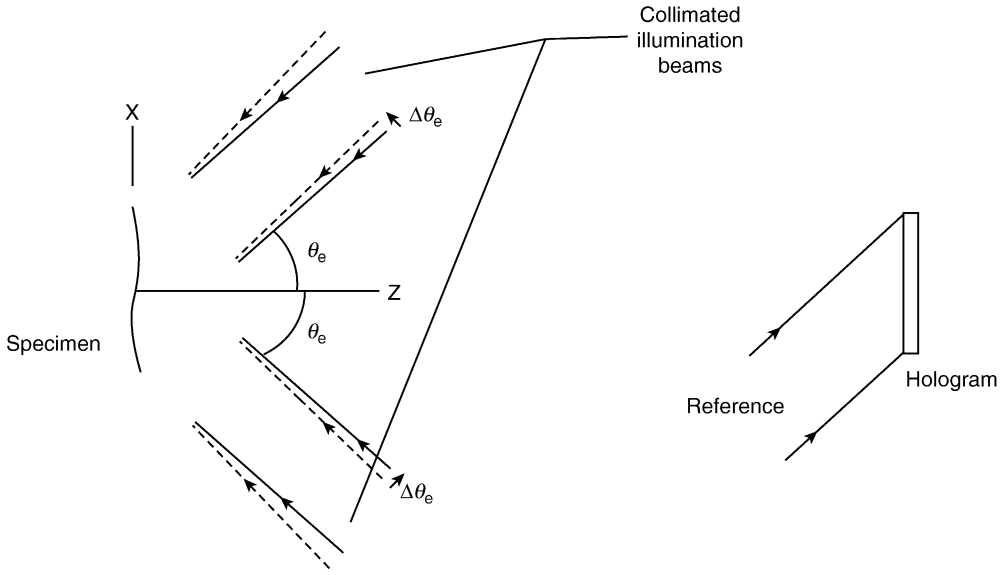

Figure 12 Schematic diagram of a two-beam method for shape measurement.

Surface Contouring

A practical way to display the shape of an object is to obtain contour maps showing the intersection of the object with a set of equidistant planes orthogonal to the line of sight.

The Dual Refractive Index Method

The method requires placing the model in a glass tank filled with a liquid (or gas) of refractive index n'_1. A hologram of the object is recorded, and the liquid contained in the tank is replaced by one of refractive index n'_2. An observer looking through the hologram sees the object surface modulated by a set of interference fringes arising from the change of optical phase in the light rays traversing the two liquids. The contour interval is given by

$$\Delta z = \frac{\lambda}{2(n'_1 - n'_2)} \qquad [15]$$

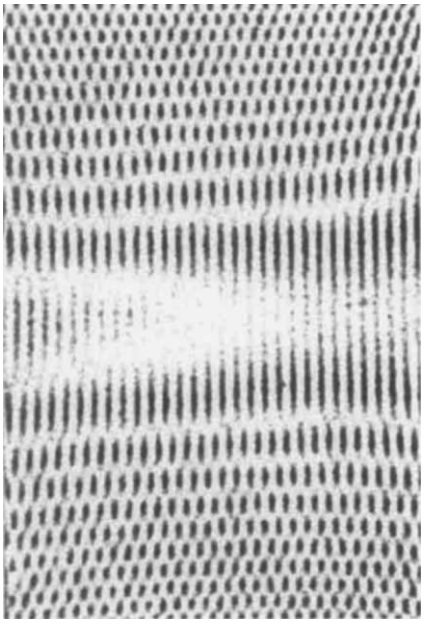

Figure 13 Example of a moiré topographic contour pattern obtained using the two-beam method.

The Dual Illumination Method

In this method, the object is illuminated obliquely by collimated beams along two directions symmetric to the surface normal. The scattered waves are recorded on a holographic plate and the object and its reconstructed image are viewed through the hologram. Two sets of parallel equidistant fringes are projected onto the object surface by introducing small tilts, $\Delta\theta_e$, to the illumination beams (Figure 12). The contour sensitivity per fringe is given by

$$\Delta z = \frac{\lambda}{2\sin\theta_e \sin\Delta\theta_e} \qquad [16]$$

The sensitivity of the method can be tuned in a wide range. An example of topographic contour pattern is shown in Figure 13. The distance between two adjacent moiré contour planes is 172 μm.

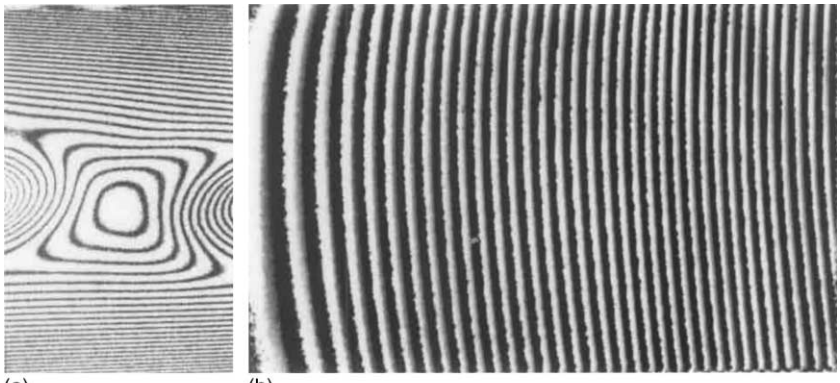

Figure 14 Examples of (a) shape measurement: the distance between two adjacent contour planes is 208 μm; and, (b) very large out-of-plane deformation measurement on a cantilever beam. The distance between two adjacent contour planes is 19 μm.

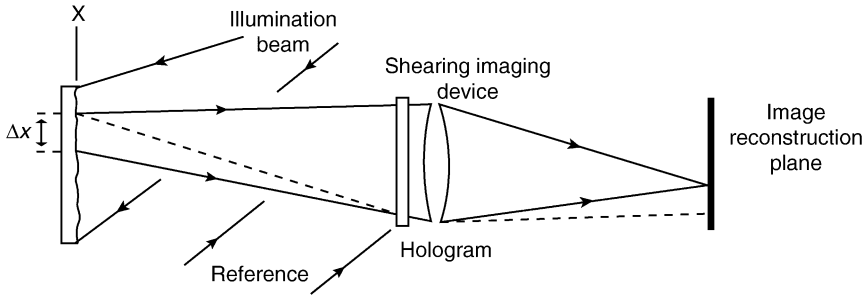

Figure 15 Schematic diagram of the principle used in holographic shearing interferometry.

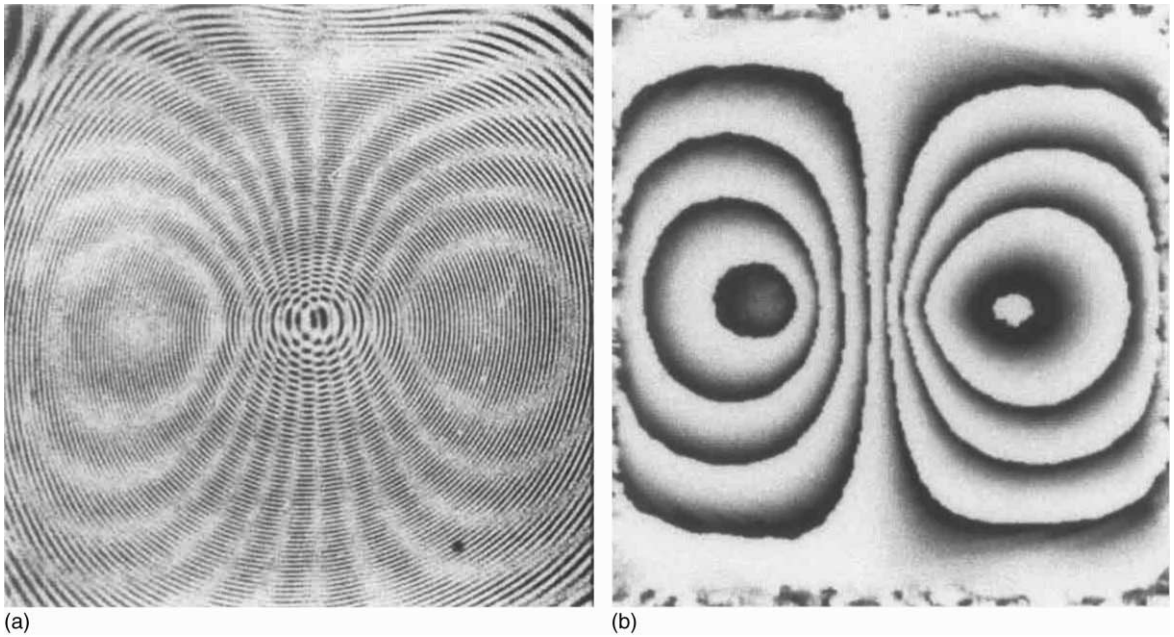

Figure 16 Examples of (a) moiré fringe contour, and (b) phase distribution corresponding to slope change produced on a centrally loaded aluminum plate clamped along its boundary.

In another method a collimated beam obliquely illuminates the object and a set of parallel equidistant fringes is projected onto the object surface by introducing a small tilt, $\Delta\theta_e$, to the illumination beam. Providing an appropriate reference beam rotation and a holographic plate translation generates contouring surfaces normal to the line of sight. A typical result using one beam illumination is shown in Figure 14a. The distance between two adjacent moiré contour planes is 208 μm.

This approach has been used to obtain measurement of large out-of-plane deformations undergone by a deformed object. The fringe pattern in Figure 14b corresponds to the out-of-plane displacement of a cantilever beam subjected to load at its free end. The distance between two adjacent contour planes is 19 μm.

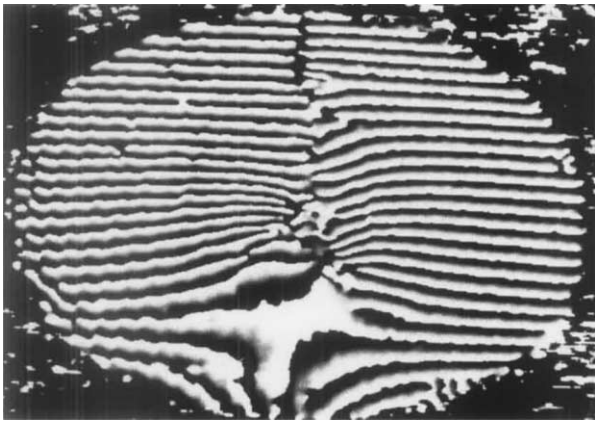

Figure 17 Example taken from the study of the fracture process zone in concrete: phase distribution corresponds to in-plane displacements on a notched concrete specimen subjected to a wedge splitting test.

Holographic Shearing Interferometry

Holographic shearing interferometry directly provides the patterns of slope change contours by laterally shearing wavefronts diffracted from the object surface. There are numerous ways to achieve shearing, such as, by introducing a Michelson type configuration, an inclined glass plate device, or a split-lens assembly in a holographic interferometer. The role of the shearing device is to enable the observation of a point on the object along two distinct neighboring directions. As a result of lateral wavefront shearing in the interferometer, a point in the image plane receives contributions from two different points on the object (Figure 15). Assuming that the illumination beam lies in the x–z plane and makes an angle θ_e with the z-axis, and the observation is carried along the direction normal to the object surface, the change of optical phase due to deformation is

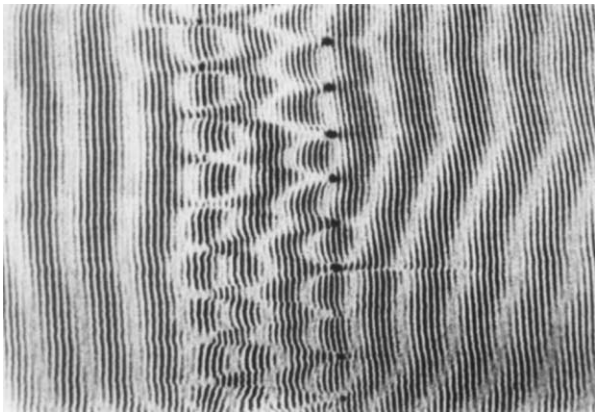

Figure 18 Example of application to nondestructive testing on a fingertip-joint wood specimen under tension using an in-plane sensitive holographic moiré setup.

$$\Delta\varphi = \frac{2\pi}{\lambda}\left[\frac{\partial u}{\partial x}\sin\theta_e + \frac{\partial w}{\partial x}(1+\cos\theta_e)\right]\Delta x \qquad [17]$$

where Δx is the object shear along the x-direction. For $\theta_e = 0$, eqn [11] reduces to

$$\frac{\partial w}{\partial x} = \frac{n\lambda}{2\Delta x} \qquad [18]$$

Equation [18] displays a family of holographic moiré fringes corresponding to the contours of constant slope change. The fringe pattern shown in Figure 16a illustrates a moiré corresponding to contours of constant slope change for a centrally loaded square aluminum plate clamped along its boundary. An example of phase distribution

corresponding to slope change along x-direction, is shown in Figure 16b.

Examples of Applications

Holographic interferometry has firmly established itself as an attractive and useful class of technique in nondestructive testing. Defects in a specimen are made apparent by the presence of anomalies in the interference fringe distribution of the deformed state of the specimen. The presence of flaws such as voids, disbonds, delaminations, and cracks weakens the strength of the specimen. The resulting strain concentration areas produced by the presence of flaws in the specimen are detected through their effect on the surface deformation map. The flaws in the specimen manifest themselves as distortion of the fringes, pockets of fringe concentrations, or localized discontinuities of the fringes in the full-field display of the deformation field of a test specimen in response to the applied load.

Figure 17 shows phase distribution corresponding to in-plane displacements of a notched fiber-reinforced concrete specimen subjected to a wedge-splitting test. The application is taken from the study of a fracture process zone in fiber-reinforced concrete. Another example of the application of holography in nondestructive testing is shown in Figure 18. The fringe pattern corresponds to in-plane displacements on a fingertip joint wood specimen under tension. Figure 19 shows an example of an application of holography in the tyre industry. The interferogram reveals, through the changes in the fringe pattern, defects in the tyre. The picture in Figure 20a is taken from the study of the embryonic behavior of embryos during incubation. The photograph shows a specific limb movement near the air space. The method also allows for a lively display of the hatching behavior of the chick. The point on the shell receiving blows is clearly visible in Figure 20b.

Conclusions

The aim of this article is to introduce readers to holographic techniques available for the noninvasive and whole-field investigation of the time-evolution and spatial distribution of the displacement and refractive index fields. Diverse techniques to obtain contourgrams of three-dimensional objects are also presented. The method offers strong potential in nondestructive testing applications, such as in the detection of flaws, in the conception of prototypes, in the evaluation of the performances of structural components, and in the verification of the reliability of finite-element computer codes.

Sandwich Holography and Light in Flight

N Abramson, Royal Institute of Technology, Stockholm, Sweden

Introduction to Holographic Interferometry

Holography is a photographic principle that produces 3D images that are so real that it is possible to take measurements inside this image with a precision of a fraction of a thousandth of a millimeter. Contours are formed within the holographic image that, like the relief lines of a map, indicate the displacements of every point on the object surface. The method is named holographic interferometry (*see* **Holography, Techniques:** Holographic Interferometry) and it can be used to measure deformation, vibration and also, with slightly lower resolution, dimension.

In real time holography the deformed object is directly compared to the holographic image of its undeformed state. In double exposure holography the comparison is made between two holographic recordings on the same plate, while in sandwich holography the two states are recorded on two different plates that are sandwiched together for comparison.

Sandwich holography is useful in industrial environments, because it can measure much larger deformations and also compensate for unwanted movement of the object or the setup between the two exposures. Further on in the process it will produce any sign of deformation and comparison can be made at any time without referring back to original setup. However, processing of the two plates is needed before the comparison can be made and the plates have to be positioned with high accuracy.

Interferometric Sensitivity

To calculate the interferometric sensitivity let us name (A) the point from which the laser light is emitted, (B) the point behind the hologram plate from which the observation is made, and (C) the displaced point on the object surface to be measured. Draw an ellipsoid through (C) with (A) and (B) as focal points. If (C) is displaced along the surface of the ellipsoid, the path length ACB will remain unchanged and no interference fringes are formed, while a displacement normal to this surface produces maximal interference. A diagram, the holodiagram, is based on these ellipsoids and used for the making and evaluation of holograms.

The bisector to ACB will be the normal to the ellipsoids. If the path length ACB is repeatedly increased by δL a diagram like Figure 1 is formed where the separation (s) of the ellipses, and thus the interferometric sensitivity, varies over the diagram. If δL is the wavelength of the laser light, one interference fringe is formed each time an object point has moved the distance (s) because of a deformation of the object between the two exposures. The displacement (d) can be calculated:

$$d = ns \qquad [1]$$

$$s = k0.5\delta L \qquad [2]$$

$$k = 1/\cos\alpha \qquad [3]$$

where n is number of fringes between fixed and studied point, k is constant along arcs of circles through A and B, and α is half the angle ACB.

When two slightly dissimilar patterns are placed one on top of the other, a moire pattern is formed that shows up the difference. The moire analogy to holographic interferometry is based on the fact that one fringe is formed for every ellipse that is crossed by an object point displaced between the two exposures.

If δL is the wavelength (λ) of the laser light the displacement (d) is

$$d = nk0.5\lambda \qquad [4]$$

If two-wavelength holography is used to measure the 3D shape of an undisturbed object, it will be seen intersected by ellipses where the separation (s) is

$$s = k0.5\lambda_1\lambda_2/(\lambda_1 - \lambda_2) \qquad [5]$$

If δL is the coherence length or the pulse length of the laser source, the object will be seen intersected by one single bright fringe, the thickness (s) of which is

$$s = k\delta L \qquad [6]$$

Everything outside that ellipse will be dark during reconstruction. This phenomenon can be used either to optimize the use of a limited coherence length or to explain the results of 'light-in-flight recordings', as described later.

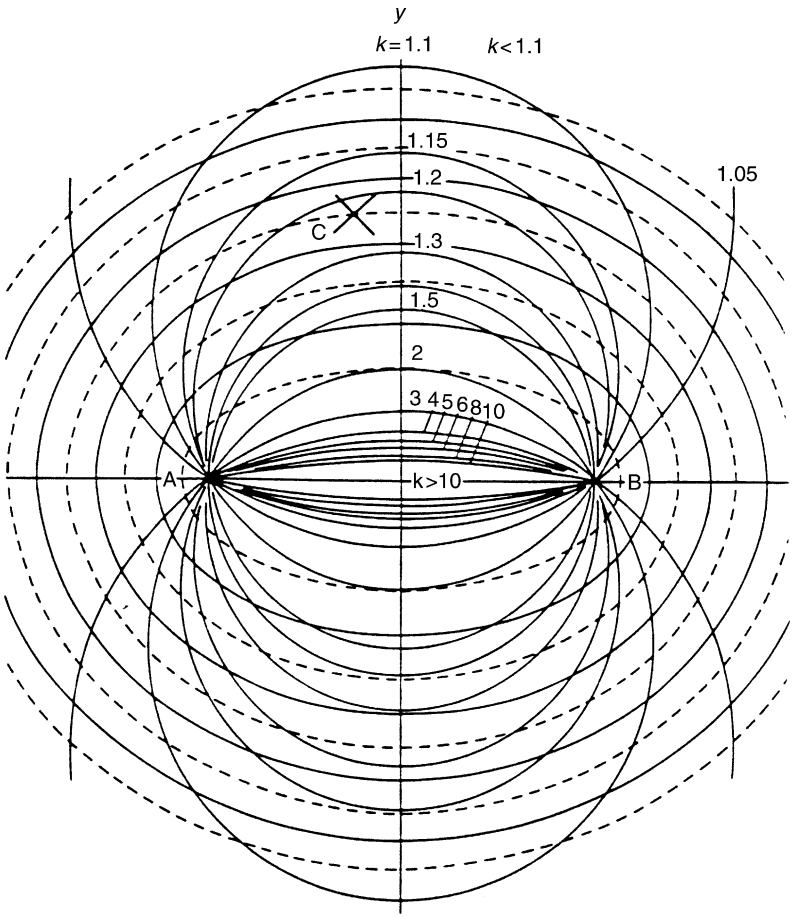

Figure 1 The holodiagram used for the evaluation of holograms.

The Principle of Sandwich Holography

In the following discussion on sandwich holography, we will only study the simplified example where the directions of illumination and observation are normal to the studied displacement and therefore α is equal to zero. The reflected light from an object point combined with the reference light produces a set of hyperbolas (Young's fringes) on the hologram plate.

When the object point is displaced between exposures on two different hologram plates, the hyperbolas will be positioned differently on the plates. There is a one-to-one relationship between the ellipsoids and the hyperbolas. Thus one point on the hologram plate will be crossed by one hyperbola if the corresponding object point is moved so that it crosses one of the ellipses of the holodiagram. Thus, the moire effect of the displaced hyperbolas at the hologram plate represents the moire effect of the ellipses in the object space. The interference pattern in the reconstructed object image can therefore be manipulated by moving one plate in relation to the other during reconstruction.

We have found that the simplest way to do this is to glue the two plates together separated by the glass thickness of one plate. To make the situation identical during exposure and reconstruction, the plates also have to be recorded in pairs. Thus, the first exposure can be made with one front plate and one back plate in contact in the hologram holder (Figure 2). The second exposure is made in exactly the same position with two new plates. After processing the front plate of the second exposure is glued in front of the back plate of the first exposure.

Then a reconstruction beam similar to the reference beam, is used to reconstruct the sandwich hologram. The interference fringes seen on the image of the object are manipulated by tilting the sandwich hologram, which results in an addition or subtraction of new fringes as in the following examples:

1. If the object is rotated by the small angle ϕ_1, the number of fringes can, during reconstruction, be

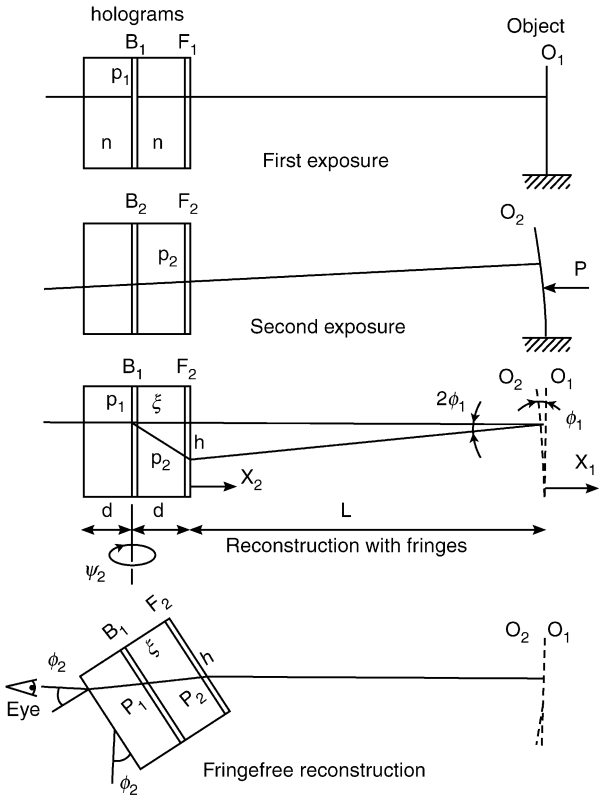

Figure 2 The exposures and reconstructions of a sandwich hologram.

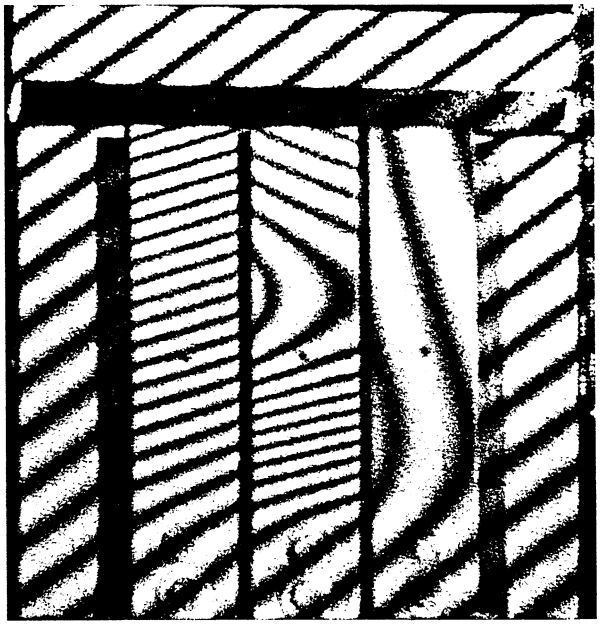

Figure 3 The movements of three steel bars in relation to a frame are to be measured by the fringes of sandwich holography. However, the unwanted motion of the total set-up makes the evaluation impossible.

eliminated by rotating the sandwich in the same direction by the much larger angle ϕ_2.

$$\phi_1 = \left[\frac{d}{2Ln}\right]\phi_2 \qquad [7]$$

2. If the sandwich during reconstruction is rotated around an axis perpendicular to that of the object rotation, new fringes are introduced at the angle γ, which is analogous to, but much larger than, the object rotation ϕ_1.

$$\phi_1 = \left[\frac{d}{2Ln}\right]\varphi_2 tg\gamma \qquad [8]$$

3. When the sandwich is rotated as described in (2) fringes are formed, the radius of curvature (r_2) of which are much larger than those of the bent object (r_1).

$$r_1 = \left[\frac{2Ln}{d}\right]\left[\frac{1}{\varphi_2}\right]r_2 \qquad [9]$$

Examples

The object consisted of three vertical steel bars (Figure 3) that were fixed by screws at their lower end to a rigid frame that surrounded all the bars. The middle bar was also supported at the upper end. Forces were applied at the middle of the bars. The right bar is deformed away from the observer while the other two are deformed towards him. After deformation of the three objects the second pair of plates were exposed. Then all four plates were processed.

The back plate of the first exposure (B_1 in Figure 2) was repositioned in the plate holder in front of the plate of the second exposure (F_2). The two plates were bonded together to form a sandwich hologram. O_1 and O_2 represent the two positions of one object, which between the two exposures was bent at angle ϕ_1 toward the hologram. (L) is the distance between the front hologram and the object (~1 m); (L) is also the distance between the point of illumination and the object. (D) is the distance between the point source of the reference beam and the hologram plate ($D = 2L$); (d) is the thickness of one hologram plate (~1.3 mm); (n) is the refractive index of the plates (~1.5 mm).

When the two plates were properly repositioned in the plate holder, fringes were seen everywhere, both on the steel bars and on the supposedly fixed frame which apparently had made an accidental movement (Figure 3). By tilting the plate holder in different directions, the fringes on the frame could be eliminated and the hologram could be evaluated as if the frame had remained fixed (Figure 4).

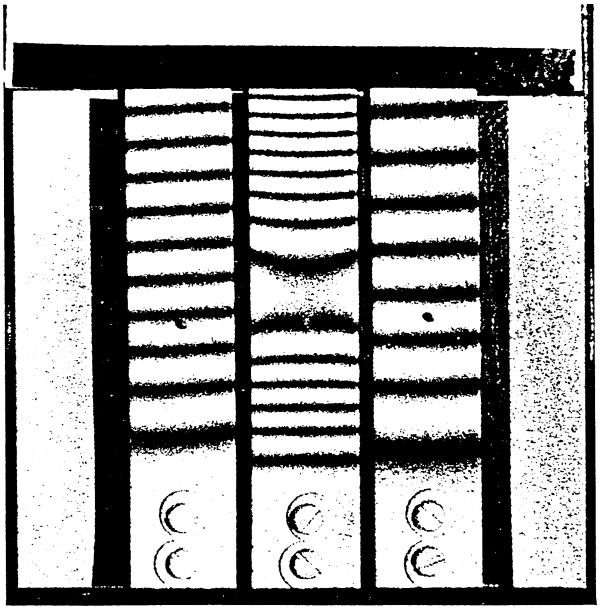

Figure 4 The unwanted fringes caused by the motion of the total set-up have been eliminated by a tilt of the sandwich hologram.

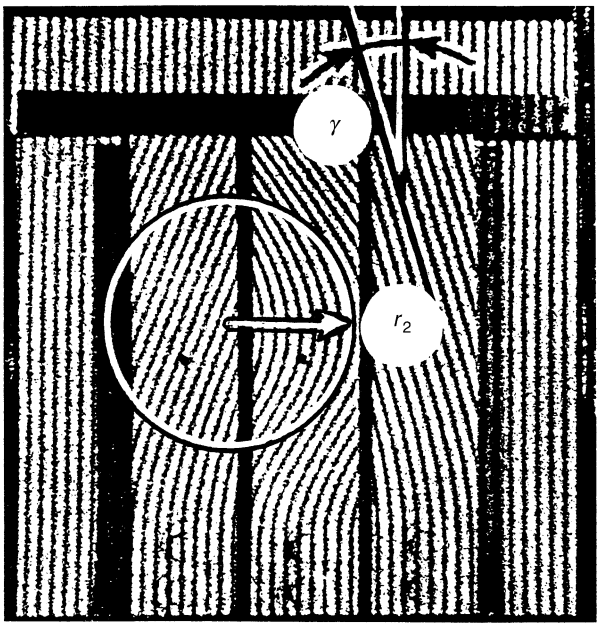

Figure 6 A rotation of the sandwich hologram around a vertical axis produces fringes that reveal direction of tilt and bending radius of all steel bars.

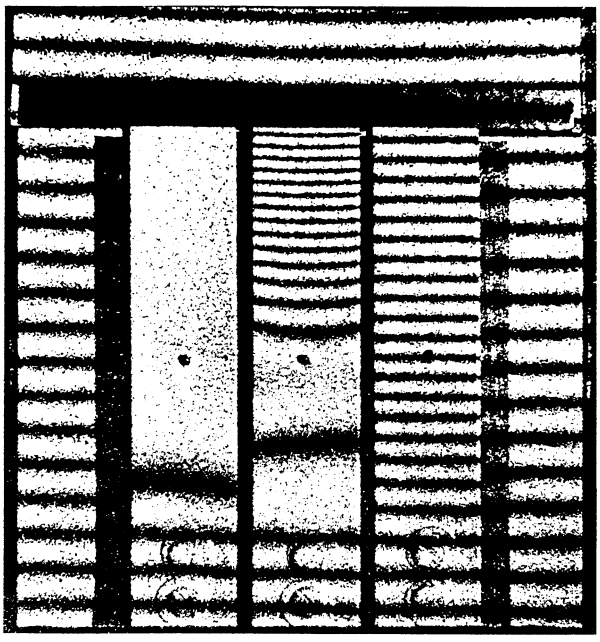

Figure 5 Another tilt of the sandwich hologram reveals that the left and the right bar have been deformed in opposite directions.

The plate holder was then tilted backwards at angle ϕ_2 and horizontal fringes were found on the frame while the top of the left bar became fringe-free (Figure 5). The number of fringes on the right bar increased, proving that it had been tilted in the opposite direction. If the sandwich were instead rotated around a vertical axis at angle φ_2, a set of vertical fringes were formed on the frame, while the bars became covered by fringes, the inclination and curvature of which represent a magnified view of the deformed bars as seen in profile (Figure 6).

Introduction to Light-in-flight Recording by Holography

Recording of light pulses in flight have been possible since the beginning of the 1990s, using two-photon fluorescence or ultrafast Kerr cells driven by laser pulses. Very fast optical phenomena, such as refractive-index changes in laser-produced plasmas, have been recorded by holography using short illumination pulses.

In 1968, Staselko *et al.* published a method of studying the time coherence pattern of wave trains from pulsed lasers by the use of autocorrelation in which the unknown pulse is compared to itself. The method we name 'light-in-flight recording by holography' (LIF) is based on studying both the temporal and the spatial shape of pulses by correlation, which means that we study the change in shape of a pulse before and after it has passed through the transformation we want to study. For this process, we want to start with as short a pulse (or short coherence length) as possible and then compare the transformed pulse to the original pulse.

In a hologram only those parts of an object will be recorded for which the path length from the laser to the holographic plate via the object does not differ from the path length of the reference beam by more than the pulse length (or coherence length) of the laser light used for the recording. If that length is short, during reconstruction a large object will be seen intersected by an imaginary surface in the form of an ellipsoid, one of its two foci being the point from which the spherical wavefronts of illumination are emitted (spatial filter (A) in Figure 1) and the other being the point of observation (B). A spherical wavefront appears distorted into an ellipsoid if it is divergent, and into a hyperboloid if it is convergent, while a flat wavefront appears distorted into a paraboloid. The general rule is that the apparent wavefront has the shape of a mirror that focuses light from (A) to (B).

By careful planning, it is possible to optimize the geometry of the holographic setup in such a way that the utilized portions of the ellipsoids and hyperboloids can be approximated into flat surfaces. Thus, the object is seen intersected by one flat imaginary interference surface, the depth of which can be altered during reconstruction by changing the point of observation at the hologram plate.

Light of short duration, or short coherence length, can, in this way, be used in a holographic method for finding depth contours. If, however, the 3D shape of the object is known a priori, e.g., if it is a flat surface, this method can just as well be used to study the 3D shape of the illuminating wavefront. As mentioned before, the intersections of the ellipsoids can be approximated by intersections of spherical wave fronts of illumination, if the distance between object and hologram plate is long and if the flat surface is perpendicular to the line of sight.

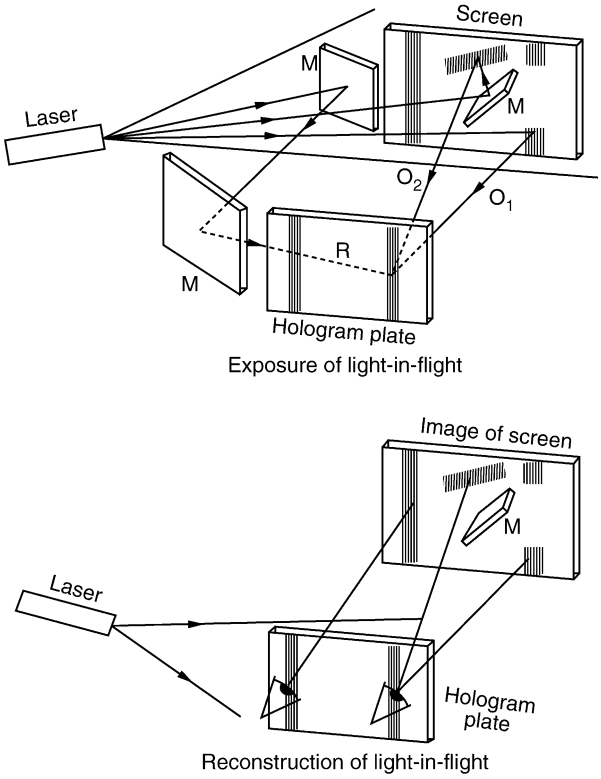

Figure 7 During exposure of the light-in-flight hologram, the short pulse from the laser is used to obliquely illuminate both the object and the hologram plate. Only those parts will be recorded where path length for object light and reference light are equal.

Examples of Wavefront Studies

As an example we will describe an experiment that consists of an opaque white diffusely reflecting flat screen, that is illuminated from the left at an oblique angle, as seen in Figure 7. A mirror is fixed to the screen so that some of the light is reflected upwards. During recording of the hologram, the reference pulse is reflected by the two mirrors (M) so that it arrives at the middle of the hologram plate at the same time as the object pulse, in the form of diffuse light, arrives from the middle of the screen. As the reference pulse passes over the hologram plate from left to right, it works like a curtain shutter (focal-plane shutter) recording early object light to the left and later light to the right. This 'light shutter' moves across the plate with a velocity faster than light which is possible as it is just an intersection between pulsefront and plate. The difference in time of the recordings made at the two ends of the hologram plate is the time it takes for the reference pulse to move across the plate, or about 800 picoseconds. During reconstruction with a continuous laser the early arriving object light is seen through the left part of the plate, while the later arriving light is seen through its right part. If the eye, or a TV camera scans from left to right, the pulse is seen moving continuously over the object screen, with some of it reflected upwards by the mirror (Figure 8a–d). The corresponding pulse length is 100 ps (~30 mm), and to minimize pulsefront distortions the screen is perpendicular to the line of sight.

The photo in Figure 9 shows the result of another experiment. A spherical wave expands from a point source at left and moves to the right. The spherical wavefront intersects a flat observation screen consisting of a white-coated aluminum plate of 20 × 30 cm. A cylindrical lens is fixed, with its axis normal to the screen, so that it focuses the arriving light almost parallel to the screen surface. Figure 8 is a composite of several photographs taken through different parts

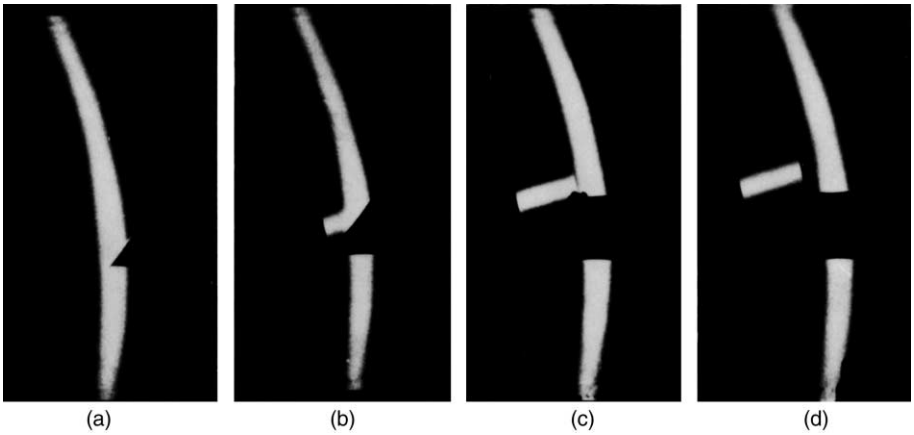

Figure 8 Resulting reconstructed images of the light reflected by a mirror at about 45°. These four photos were taken during reconstruction while the camera behind the hologram plate was moved from left to right in between each of the exposures.

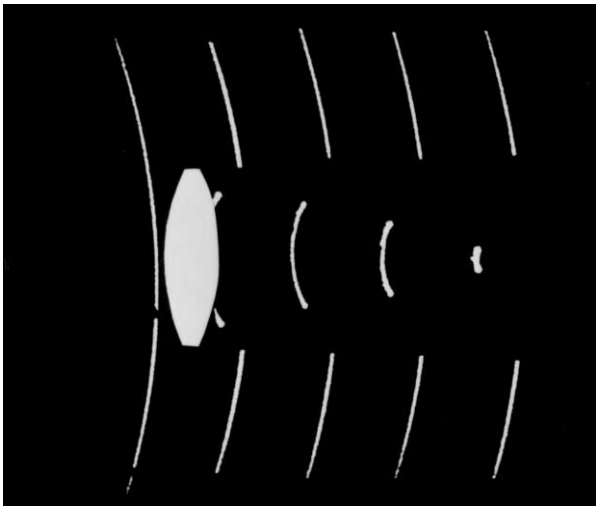

Figure 9 Light focused by a lens. A composite of several photos taken from different parts of the hologram plate. An image of the lens is included to make the picture clear.

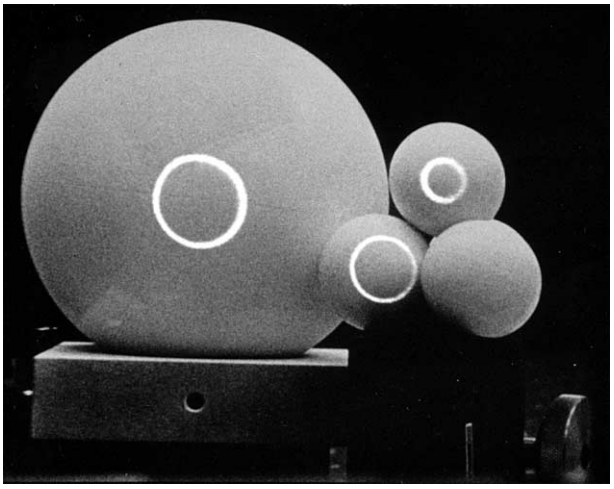

Figure 10 Spheres intersected by a thin sheet of light.

of the hologram plate. The pulse length was in this case 10 ps (~3 mm).

Measuring the Shape of 3D Objects

The wavefront (pulse front) of a short pulse forms a thin sheet of light. The intersection of this sheet by a 3D body produces on its surface a thin line representing a cross-section. It is advantageous if this cross-section represents a flat surface, which will be approximately the case if the illumination and observation beams are collimated or arrive from points at large distances.

By moving the point of observation along the hologram plate from left to right, the intersecting sheet of light can be moved in depth forward or backward. Determination of fringe order number (by finding the zero fringe) no longer represents any problem because only the zero order fringe exists. Therefore, this way of contouring has great advantages, especially when the observations and calculations are made by computer. Figure 10 shows a set of spheres intersected by a thin light sheet.

The intersecting light sheet can be manipulated in yet another way, i.e., it can be rotated. If the point of observation is moved away from the plate, the right part of an object will be seen through the right part of the plate were the recording made later than at the left part. During the time interval between left and right records, the intersecting light sheet has moved so that it intersects the object further away, resulting in a tilted cross-section of the object. This way it has been possible to rotate the cross-section up to 90 degrees, so that if, for example, a face is illuminated from the

front by a flat sheet of light, the reconstructed intersection will show the face in profile.

In a limited way it is also possible to produce results similar to those of LIF by using a CCD camera instead of the holographic plate. The great advantage is its compatibility with a PC, while the main disadvantage is a lower resolution.

Other Uses

Like all methods of 'gated viewing', LIF can be used to look through scattering media, e.g., to look through human tissue. By observing only the first light the influence of the later arriving scattered light is eliminated. Thus, LIF can be used as a diagnostic method based on the idea that the scattering, absorption, or refractive index of cancer is different from that of healthy tissue. Another use of LIF is to image just a thin section of a gas or liquid filled with particles. In this way it is possible to observe the distribution and velocity in a certain localization without influence of the scattering from particles in front of or behind the studied section.

Up to now we have discussed gated viewing by LIF in the laboratory using picosecond light pulses and distances of up to a few meters. Instead we could look at astronomical objects with light pulses of days (e.g., a supernova) and distances of many light years. Even in these cases we will see particles in space illuminated by ellipsoids with (A) being the supernova and (B) a telescope on Earth. While each ellipsoid in the laboratory may represent a pathlength of some nanoseconds, each ellipsoid in space might represent light years.

However, the methods we have shown here are not limited to the study of the apparent shape of spheres of light. They can also be used to study other objects moving at ultrahigh velocities. If an exploding supernova throws out particles in all directions at a rather slow velocity, it can be seen surrounded by an expanding sphere. If, instead, this sphere expanded with the speed of light (which is not possible) it would appear to us just like an ellipsoid of the holodiagram. If, however, it expanded at a very high velocity, but lower than that of light, the sphere would appear to us in the shape of an egg with its pointed end towards the observer. The velocity of expansion could, in this case, appear superluminal (higher than the speed of light). If the velocity is (v), its approaching velocity will to a first approximation appear to be the true velocity divided by ($1 - v/c$).

Finally, we will show a relationship between LIF and special relativity, by looking at a modification of the 'Minkowski light cones'. Figure 11 shows a diagram

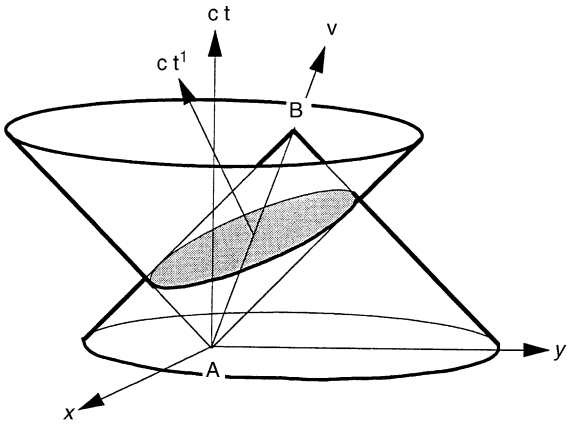

Figure 11 A modified Minkowski diagram consisting of one cone of illumination (A) and one cone of observation (B). The separation in time and space between (A) and (B) could either be static as in LIF or caused by a relativistic velocity of the observer from (A) to (B).

where (x) and (y) represent space coordinates, while (z) represents time multiplied by (c). A sphere from a short pulse of light that expands from the point A is represented by a cone with its apex at (A). A sphere from a short observation that converges to (B) is represented by a cone with its apex at (B). Only those object points, that are positioned at the elliptic intersection of the two cones, can be seen illuminated. This ellipse is identical to one of the ellipses of the holodiagram. The distance in time and space separating (A) and (B) could be either caused by the fixed distance between source of laser light and hologram plate in holographic LIF, or by a high velocity of the observer. Thus, the Lorentz contraction in special relativity could be explained as a measuring error because the high velocity of the observer traveling from (A) to (B) causes his sphere of observation to be transformed into an ellipsoid of observation. The tilt of the elliptic intersection indicates which observations that appear to be simultaneous depending on the separation of (A) and (B) along the y-axis, both in LIF and in relativity.

Introduction

Information theory is an intuitively attractive mathematical approach for combining observation with communication, or sensing with processing. So far, however, this approach has remained largely in the realm of signal processing and transmission, as first formalized by Shannon and Wiener over 50 years ago. Recent extensions of this approach to imaging have mostly addressed the interpretation of images, without explicitly accounting for the critical limiting factors that constrain image gathering and restoration. Yet, to be useful in the characterization of imaging, information theory must account for these constraints and lead to a close correlation between predicted and actual performance. The characterization that is outlined here traces the rate of information from the scene to the observer; and it pairs this rate, first, with the theoretical minimum data rate to assess the efficiency with which information can be transmitted, and, second, with the maximum-realizable fidelity to assess the quality with which images can be restored. Further details, especially for the mathematical development of figures of merit and for the design of imaging systems, can be found in the Further Reading.

Model of Imaging

Description

Modern imaging systems usually have the following three stages, as depicted in Figure 1:

1. *Image gathering*, to capture the radiance field that is either reflected or emitted by the scene and transform this field into a digital signal;

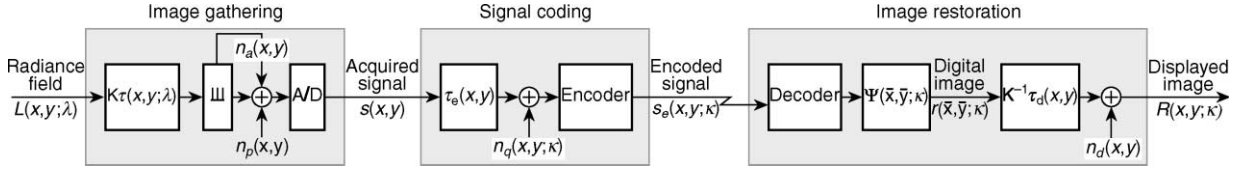

Figure 1 Model of digital imaging systems.

2. *Signal coding*, to encode the acquired signal for the efficient transmission and/or storage of data and decode the received signal for the restoration of images. The encoding may be either lossless (without loss of information) or lossy (with some loss of information), if a higher compression is required;
3. *Image restoration*, to produce a digital representation of the scene and transform this representation into a continuous image for the observer.

Human vision may be included in this model as a fourth stage, to characterize imaging systems in terms of the information rate that the eye of the observer conveys from the displayed image to the higher levels of the brain.

These stages are similar to each other in one respect: each contains one or more transfer functions, either continuous or discrete, followed by one or more sources of noise, also either continuous or discrete. The continuous transfer function of the image-gathering device (and of the human eye) is followed by sampling that transforms the captured radiance field into a discrete signal with analog magnitudes. In most devices the photodetection mechanism conveys this signal serially into an analog-to-digital (A/D) converter to produce a digital signal. However, analog signal processing in a parallel structure, akin to that in human vision, has many advantages that are increasingly emulated by neural networks.

This model of imaging differs from the classical model of communication that Shannon and Wiener addressed in two fundamental ways:

1. *The continuous-to-discrete transformation in image gathering*. Whereas communication is constrained critically only by bandwidth and noise, image gathering is constrained also by the compromise between blurring and aliasing, due to limitations in the response of optical apertures and in the sampling density of photodetection mechanisms. This additional constraint requires the rigorous treatment of insufficiently sampled signals throughout the imaging system.
2. *The sequence of image gathering followed by signal coding*. Whereas the characterization of communication addresses the perturbations that occur at the encoder and decoder or during transmission, the characterization of imaging systems must also address the perturbations in the image-gathering process prior to coding. These additional perturbations require a clear distinction between the information rate of the encoded signal and the associated theoretical minimum data rate or, more generally, between information and entropy.

The mathematical model of imaging that is outlined here accounts for the appropriate deterministic and stochastic (random) properties of natural scenes and for the critical limiting factors that constrain the performance of imaging systems. The corresponding formulations of the figures of merit are sufficiently general to account for a wide range of radiance field properties, photodetection mechanisms, and signal processing structures. However, the illustrations emphasize: (a) the salient properties of natural scenes that dominate the captured radiance field in the visible and near-infrared region under normal daylight conditions; and (b) the photodetector arrays that are used most frequently as the photodetection mechanism of image-gathering devices.

Radiance Field

The radiance field $L(x, y; \lambda)$, reflected by natural scenes, may be modeled approximately as

$$L(x, y; \lambda) = \frac{1}{\pi} I(\lambda)\rho(\lambda)\rho(x, y) \qquad [1]$$

where $I(\lambda)$ and $\rho(\lambda)$, respectively, represent the spectral irradiance and reflectance properties as a function of the wavelength λ, and $\rho(x, y)$ represents the random reflectance properties as a function of the spatial coordinates (x, y). Figure 2 illustrates a model of $\rho(x, y)$ for which the power spectral density (PSD) $\hat{\Phi}_\rho(\upsilon, \omega)$ corresponds closely to that typical of natural scenes, as given by

$$\hat{\Phi}_\rho(\upsilon, \omega) = \frac{2\pi\mu_\rho^2\sigma_\rho^2}{[1 + (2\pi\mu_\rho\zeta)^2]^{3/2}} \qquad [2]$$

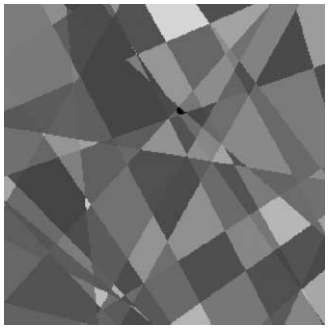

Figure 2 Model of reflectance $\rho(x, y)$.

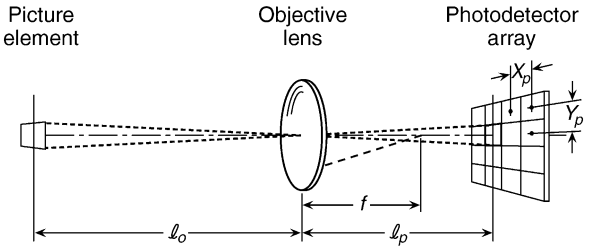

Figure 4 Optical geometry of image-gathering device.

where $\zeta^2 = \upsilon^2 + \omega^2$ and (υ, ω) are the spatial frequency coordinates of the Fourier-transform domain (see Figure 3). This model consists of random polygons, whose boundaries are distributed according to Poisson probability with a mean separation of μ_ρ, and whose magnitudes are distributed according to independent zero-mean Gaussian statistics of variance σ_ρ^2. The constraints associated with eqn [1] are satisfied by letting the mean reflectance $\bar{\rho} = 0.5$ and the standard deviation $\sigma_\rho \leq 0.2$.

Image Gathering

Figure 4 depicts the basic optical geometry of an image-gathering device, in which the objective lens forms an image of the captured radiance field across the photodetector array, and the array transforms this

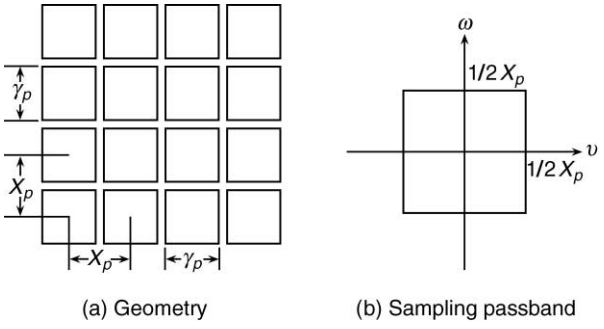

Figure 5 Photodetector-array geometry and sampling passband.

image into a discrete signal. The sampling lattice (X, Y), which determines the resolution of this device, is formed in angular units by the separation (X_p, Y_p) of the photodetector-array apertures and the distance ℓ_p as given for one of the dimensions by

$$X = 2\tan^{-1}\frac{X_p}{2\ell_p} \approx \frac{X_p}{\ell_p}\text{rad} = \frac{57.3X_p}{\ell_p}\text{deg} \qquad [3]$$

Normally, the sampling lattice is square, as shown in Figure 5, so that $X_p = Y_p$. Then the corresponding area of the photodetector apertures is $A_p = \gamma_p^2$, and the solid angle Ω of the instantaneous field of view (IFOV) is $\Omega \approx A_p/\ell_p^2$ ster.

The sampling lattice projected onto the scene at the distance ℓ_o has the dimensions $(X_o, Y_o) \approx (X\ell_o, Y\ell_o)$. Because these dimensions represent the finest spatial detail that normally can be restored, it is convenient to measure the mean spatial detail of the scene relative to the sampling lattice, as given by $\mu = \mu_\rho(X_o Y_o)^{-1/2}$, which reduces to $\mu = \mu_\rho X_o^{-1}$ for $X = Y$. Hence, $\mu = 1$ indicates that the sampling interval is equal to the mean spatial detail.

The image-gathering process that transforms the continuous radiance field $L(x, y; \lambda)$ into the discrete signal $s(\mathbf{x}, \mathbf{y})$ may be modeled by the expression

$$s(\mathbf{x}, \mathbf{y}) = K\rho(\mathbf{x}, \mathbf{y}) * \tau(\mathbf{x}, \mathbf{y}) + n_p(\mathbf{x}, \mathbf{y}) \qquad [4]$$

where the discrete coordinates $(\mathbf{x}, \mathbf{y}) = (mX, nY)$, and the symbol $*$ denotes continuous spatial convolution. This model accounts, in the simplest form, for the reflectance-to-signal conversion gain K, the reflectance $\rho(x, y)$ of the scene, the spatial response (SR) $\tau(x, y)$ of the image-gathering device, the continuous-to-discrete transformation by the photodetector-array lattice, and the discrete noise $n_p(\mathbf{x}, \mathbf{y})$ of the photodetectors. The discrete coordinates are

defined by the sampling function

$$\underline{\underline{\amalg}} \equiv \underline{\underline{\amalg}}(\mathbf{x}, \mathbf{y}) = XY \sum_{\mathbf{x},\mathbf{y}} \delta(x - \mathbf{x}, y - \mathbf{y}) \qquad [5]$$

where $\delta(x, y)$ is the Dirac delta function; and the gain is given by

$$K = \frac{1}{\pi} A_\ell \Omega \int I(\lambda)\rho(\lambda)r(\lambda)\mathrm{d}\lambda \qquad [6]$$

where $A_\ell = \pi D^2/4$ is the area of the objective lens with diameter D, and $r(\lambda)$ is the responsivity of the photodetectors. This gain relates the magnitude of the signal $s(\mathbf{x}, \mathbf{y})$ directly to that of the reflectance $\rho(x, y)$; and, together with the variances σ_ρ^2 and σ_p^2 of the reflectance and the photodetector noise, respectively, it also determines the rms-signal-to-rms-noise ratio (SNR) $K\sigma_\rho/\sigma_p$.

The DFT of $s(\mathbf{x}, \mathbf{y})$ is the periodic spectrum $\tilde{s}(v, \omega)$ given by

$$\tilde{s}(v, \omega) = K\hat{\rho}(v, \omega)\hat{\tau}(v, \omega) * \hat{\underline{\underline{\amalg}}} + \tilde{n}_p(v, \omega) \qquad [7]$$

where $\hat{\rho}(v, \omega)$ is the spectrum of the reflectance, $\hat{\tau}(v, \omega)$ is the spatial frequency response (SFR) of the image-gathering device, and $\tilde{n}_p(v, \omega)$ is the spectrum of the photodetector noise. The symbol $\hat{\underline{\underline{\amalg}}}$ is the Fourier transform of the sampling function $\underline{\underline{\amalg}}$. It accounts for the sidebands generated by the sampling process and is given by

$$\hat{\underline{\underline{\amalg}}} \equiv \hat{\underline{\underline{\amalg}}}(v, \omega) = \sum_{\mathbf{v},\mathbf{w}} \delta(v - \mathbf{v}, \omega - \mathbf{w}) \qquad [8]$$

where $(\mathbf{v}, \mathbf{w}) = (m/X, n/Y)$. The corresponding sampling passband is

$$\hat{B} = \left\{(v, \omega);\ |v| < \frac{1}{2X},\ |\omega| < \frac{1}{2Y}\right\} \qquad [9]$$

The above expression for $\tilde{s}(v, \omega)$ can be rewritten more conveniently as

$$\tilde{s}(v, \omega) = K\hat{\rho}(v, \omega)\hat{\tau}(v, \omega) + \hat{n}(v, \omega) \qquad [10]$$

where

$$\hat{n}(v, \omega) = \hat{n}_\mathrm{a}(v, \omega) + \tilde{n}_p(v, \omega) \qquad [11]$$

is the spectrum of the total noise in the acquired signal. The first term $\hat{n}_\mathrm{a}(v, \omega)$ represents the aliased signal components caused by insufficient sampling, as given by

$$\hat{n}_\mathrm{a}(v, \omega) = K\hat{\rho}(v, \omega)\hat{\tau}(v, \omega) * \hat{\underline{\underline{\amalg}}}_\mathrm{s} \qquad [12]$$

where

$$\hat{\underline{\underline{\amalg}}}_\mathrm{s} \equiv \hat{\underline{\underline{\amalg}}}_\mathrm{s}(v, \omega) = \sum_{\mathbf{v},\mathbf{w}\neq(0,0)} \delta(v - \mathbf{v}, \omega - \mathbf{w}) \qquad [13]$$

If, for spatial coordinates at either the scene or the photodetector array, the unit of (x, y) is meters, then the unit of (v, ω) is cycles m^{-1}; and if, for angular coordinates centered at the objective lens, the unit of (x, y) is radians, then the unit of (v, ω) is cycles rad^{-1}. Either way, it is convenient to normalize the sampling intervals to unity (i.e., $X = Y = 1$). Then the area of the sampling passband is $|\hat{B}| = 1$, the unit of (x, y) is samples, and the unit of (v, ω) is cycles sample^{-1}.

The SFR $\hat{\tau}(v, \omega)$ of the image-gathering device is

$$\hat{\tau}(v, \omega) = \hat{\tau}_\ell(v, \omega)\hat{\tau}_p(v, \omega) \qquad [14]$$

where $\hat{\tau}_\ell(v, \omega)$ and $\hat{\tau}_p(v, \omega)$ are the SFRs of the objective lens and photodetector apertures, respectively. This SFR may be modeled approximately by the circularly symmetric Gaussian shape

$$\hat{\tau}(v, \omega) = \exp[-(\zeta/\zeta_\mathrm{c})^2] \qquad [15]$$

where, as shown in Figure 6, the optical-response index ζ_c controls the trade-off between the blurring that is caused by the decrease of the SFR inside the sampling passband and the aliasing that is caused by the extension of the SFR beyond this passband.

Signal Coding

Signal coding may be divided into two stages, as depicted in Figure 1. The first stage, which is represented by the digital operator $\tau_\mathrm{e}(\mathbf{x}, \mathbf{y})$ and the quantization noise $n_q(\mathbf{x}, \mathbf{y}; \kappa)$, accounts for manipulations of the acquired signal that seek to extract those

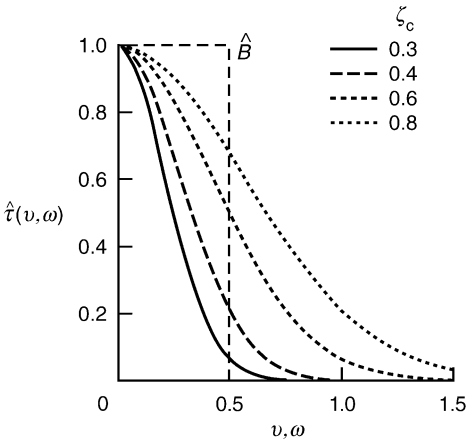

Figure 6 SFRs $\hat{\tau}(v, \omega)$ of the image-gathering device relative to the sampling passband $\hat{B}$ for unit sampling intervals (i.e., $X = Y = 1$).

features of the captured radiance field considered to be perceptually most significant, which usually entails some loss of information. The second stage, which is represented by the encoder, accounts for manipulations that seek to reduce redundancies in the acquired signal, without loss of information. The resultant encoded signal $s_e(\mathbf{x}, \mathbf{y}; \kappa)$ may be expressed in the same form as eqn [4] for the acquired signal $s(\mathbf{x}, \mathbf{y})$ as

$$s_e(\mathbf{x}, \mathbf{y}; \kappa) = s(\mathbf{x}, \mathbf{y}) \otimes \tau_e(\mathbf{x}, \mathbf{y}) + n_q(\mathbf{x}, \mathbf{y}; \kappa) \qquad [16]$$

where the symbol $\otimes$ denotes discrete spatial convolution, and $n_q(\mathbf{x}, \mathbf{y}; \kappa)$ is the quantization noise. If the data transmission and/or storage are error-free, as is assumed here, then the signal that leaves the decoder remains identical to the signal that enters the encoder.

The DFT of $s_e(\mathbf{x}, \mathbf{y}; \kappa)$ is the periodic spectrum $\tilde{s}_e(\upsilon, \omega; \kappa)$ given in the same form as eqn [10] by

$$\tilde{s}_e(\upsilon, \omega; \kappa) = K\hat{\rho}(\upsilon, \omega)\hat{\Gamma}_e(\upsilon, \omega) + \hat{n}_e(\upsilon, \omega; \kappa) \qquad [17]$$

where

$$\hat{\Gamma}_e(\upsilon, \omega) = \hat{\tau}(\upsilon, \omega)\tilde{\tau}_e(\upsilon, \omega) \qquad [18]$$

is the throughput SFR from image gathering to transmission, and

$$\hat{n}_e(\upsilon, \omega; \kappa) = \hat{n}(\upsilon, \omega)\tilde{\tau}_e(\upsilon, \omega) + \tilde{n}_q(\upsilon, \omega; \kappa) \qquad [19]$$

is the accumulated noise in the encoded signal. For η-bit quantization, where $\eta = \log \kappa$ and κ is the number of uniformly spaced quantization levels, $\tilde{n}_q(\upsilon, \omega; \kappa)$ may be treated (for $\eta \geq 4$) as independent Gaussian noise with the PSD

$$\tilde{\Phi}_q(\upsilon, \omega; \kappa) = \sigma_q^2 = (\sigma_{s_e}/\kappa)^2 \qquad [20]$$

where $\sigma_{s_e}^2$ is the variance given approximately by

$$\sigma_{s_e}^2 \approx K^2 \int_{\hat{B}} \int \hat{\Phi}_\rho(\upsilon, \omega)|\hat{\Gamma}_e(\upsilon, \omega)|^2 \mathrm{d}\upsilon \mathrm{d}\omega \qquad [21]$$

Image Restoration

Image restoration, as depicted in Figure 1, transforms the decoded signal $s_e(\mathbf{x}, \mathbf{y}; \kappa)$ into the digital image $r(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \kappa)$, as modeled by the expression

$$r(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \kappa) = \overline{\overline{\mathbb{III}}} s_e(\mathbf{x}, \mathbf{y}; \kappa) \otimes \Psi(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \kappa) \qquad [22]$$

The operation indicated by $\overline{\overline{\mathbb{III}}} s_e(\mathbf{x}, \mathbf{y}; \kappa)$ (called zero padding) prepares the decoded signal for image restoration with interpolation, and the operator $\Psi(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \kappa)$ produces the digital image $r(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \kappa)$ on the interpolation lattice $\overline{\overline{\mathbb{III}}}$ that is Z times denser than the sampling lattice $\underline{\mathbb{III}}$. If the interpolation in the image restoration is sufficiently dense (normally, for $Z \geq 4$), then the blurring and raster effects of the image-display process are suppressed entirely. This condition leads not only to the best realizable image quality but also to the simplest expression for the continuous displayed image, as given in the same form as eqns [10] and [17] by

$$\hat{R}(\upsilon, \omega; \kappa) = \hat{\rho}(\upsilon, \omega)\hat{\Gamma}_r(\upsilon, \omega; \kappa) + \hat{n}_r(\upsilon, \omega; \kappa) \qquad [23]$$

where

$$\hat{\Gamma}_r(\upsilon, \omega; \kappa) = \hat{\tau}(\upsilon, \omega)\tilde{\tau}_e(\upsilon, \omega)\hat{\Psi}(\upsilon, \omega; \kappa) \qquad [24]$$

is the throughput SFR from image gathering to display, and

$$\begin{aligned}\hat{n}_r(\upsilon, \omega; \kappa) &= K^{-1}\hat{n}_e(\upsilon, \omega; \kappa)\hat{\Psi}(\upsilon, \omega; \kappa) \\ &= \hat{n}_{ar}(\upsilon, \omega; \kappa) + \hat{n}_{pr}(\upsilon, \omega; \kappa) \\ &\quad + \hat{n}_{qr}(\upsilon, \omega; \kappa)\end{aligned} \qquad [25]$$

is the accumulated noise in the restored image. This noise may be expressed explicitly by substituting the noise components given above. The noise due to the granularity in image-display mediums is not accounted for here.

The Wiener filter, that minimizes the mean-square error due to the perturbations in image gathering and coding, is given by

$$\hat{\Psi}(\upsilon, \omega; \kappa) = \frac{\hat{\Phi}'_\rho(\upsilon, \omega)\hat{\Gamma}^*_e(\upsilon, \omega)}{\hat{\Phi}'_\rho(\upsilon, \omega)|\hat{\Gamma}_e(\upsilon, \omega)|^2 + \hat{\Phi}'_{n_e}(\upsilon, \omega; \kappa)} \qquad [26]$$

where $\hat{\Phi}'(\upsilon, \omega) = \sigma_\rho^{-2}\hat{\Phi}_\rho(\upsilon, \omega)$ is the normalized PSD of the radiance field and

$$\begin{aligned}\hat{\Phi}'_{n_e}(\upsilon, \omega; \kappa) = (K\sigma_\rho)^{-2}\Big[&\hat{\Phi}_n(\upsilon, \omega)|\tilde{\tau}_e(\upsilon, \omega)|^2 \\ &+ \tilde{\Phi}_q(\upsilon, \omega; \kappa)\Big]\end{aligned}$$

is the normalized PSD of the accumulated noise in the encoded signal. If the photodetector noise is white so that the PSD $\tilde{\Phi}_p(\upsilon, \omega)$ is equal to its variance σ_p^2 and the PSD $\tilde{\Phi}_q(\upsilon, \omega; \kappa)$ is equal to its variance σ_q^2, then the PSD of the noise simplifies to

$$\hat{\Phi}'_{n_e}(\upsilon, \omega; \kappa) = \hat{\Phi}'_{n_e}(\upsilon, \omega) + \tilde{\Phi}'_q(\upsilon, \omega; \kappa) \qquad [27]$$

where

$$\begin{aligned}\hat{\Phi}'_{n_e}(\upsilon, \omega) = \Big[&\hat{\Phi}'_\rho(\upsilon, \omega)|\hat{\tau}(\upsilon, \omega)|^2 * \underline{\hat{\mathbb{III}}}_s \\ &+ (K\sigma_\rho/\sigma_p)^{-2}\Big]|\tilde{\tau}_e(\upsilon, \omega)|^2\end{aligned} \qquad [28]$$

and

$$\hat{\Phi}'_q(\upsilon, \omega; \kappa) = (K\sigma_\rho/\sigma_{s_e})^{-2}\kappa^{-2} \qquad [29]$$

These simplifying conditions permit the Wiener filter given above and the figures of merit given below to be expressed as a function of the SNR $K\sigma_\rho/\sigma_p$, which can be specified without accounting explicitly for either the gain K or the variances σ_ρ^2 and σ_p^2.

Figures of Merit

Information Rate $\mathcal{H}$

The information rate $\mathcal{H}$ (in bits sample^{-1}) of the encoded signal $s_e(\mathbf{x}, \mathbf{y}; \kappa)$ is defined by

$$\mathcal{H} = \mathcal{E}[\tilde{s}_e(\upsilon, \omega; \kappa)] - \mathcal{E}[\tilde{s}_e(\upsilon, \omega; \kappa)|\hat{\rho}(\upsilon, \omega) : (\upsilon, \omega) \in \hat{B}] \quad [30]$$

where the first term, $\mathcal{E}[\cdot]$, represents the entropy of $\tilde{s}_e(\upsilon, \omega; \kappa)$ and the second term, $\mathcal{E}[\cdot|\cdot]$, represents the conditional entropy of this signal when the reflectance spectrum $\hat{\rho}(\upsilon, \omega)$ within the sampling passband $\hat{B}$ is known. For the assumptions that have been made about image gathering and coding, the conditional entropy becomes the entropy of the accumulated noise $\hat{n}_e(\upsilon, \omega; \kappa)$, so that $\mathcal{H}$ simplifies to

$$\mathcal{H} = \mathcal{E}[\tilde{s}_e(\upsilon, \omega; \kappa)] - \mathcal{E}[\hat{n}(\upsilon, \omega; \kappa) : (\upsilon, \omega) \in \hat{B}] = \frac{1}{2}\int_{\hat{B}}\int \log\left[1 + \frac{\hat{\Phi}'_\rho(\upsilon, \omega)|\hat{\Gamma}_e(\upsilon, \omega)|^2}{\hat{\Phi}'_{n_e}(\upsilon, \omega; \kappa)}\right] d\upsilon d\omega \quad [31]$$

The theoretical upper bound of $\mathcal{H}$ is Shannon's channel capacity $\mathcal{C}$ for a bandwidth-limited system, with white photodetector noise and an average power limitation (here the variance σ_ρ^2), as given by

$$\mathcal{C} = \frac{1}{2}\log\left[1 + (K\sigma_\rho/\sigma_p)^2\right] \quad [32]$$

$\mathcal{H}$ can reach $\mathcal{C}$ only when

$$\hat{\Phi}_\rho(\upsilon, \omega) = \begin{cases} \sigma_\rho^2, & (\upsilon, \omega) \in \hat{B} \\ 0, & \text{elsewhere} \end{cases}$$

$$\hat{\tau}(\upsilon, \omega) = \begin{cases} 1, & (\upsilon, \omega) \in \hat{B} \\ 0, & \text{elsewhere} \end{cases} \quad [33]$$

However, neither of these two conditions can occur in practice because both the PSD $\hat{\Phi}_\rho(\upsilon, \omega)$ of natural scenes and the SFR $\hat{\tau}(\upsilon, \omega)$ of image-gathering devices decrease gradually with increasing spatial frequency, as depicted in Figures 3 and 6, respectively. Hence, $\mathcal{H}$ can never reach $\mathcal{C}$.

Theoretical Minimum Data Rate $\mathcal{E}$

The theoretical minimum data rate $\mathcal{E}$ (also in bits sample^{-1}) that is required to convey the information rate $\mathcal{H}$ is defined by

$$\mathcal{E} = \mathcal{E}[\tilde{s}_e(\upsilon, \omega; \kappa)] - \mathcal{E}[\tilde{s}_e(\upsilon, \omega; \kappa)|\tilde{s}(\upsilon, \omega)] \quad [34]$$

where the second term, $\mathcal{E}[\cdot|\cdot]$ is the uncertainty of $\tilde{s}_e(\upsilon, \omega; \kappa)$, when $\tilde{s}(\upsilon, \omega)$ is known. For the assumptions that have been made about the coding process, the conditional entropy becomes the entropy $\mathcal{E}[\tilde{n}_q(\upsilon, \omega; \kappa)]$ of the quantization noise, so that $\mathcal{E}$ simplifies to

$$\mathcal{E} = \mathcal{E}[\tilde{s}_e(\upsilon, \omega; \kappa)] - \mathcal{E}[\tilde{n}_q(\upsilon, \omega; \kappa)] = \frac{1}{2}\int_{\hat{B}}\int \log\left[1 + \frac{\hat{\Phi}'_\rho(\upsilon, \omega)|\hat{\Gamma}_e(\upsilon, \omega)|^2 + \hat{\Phi}'_{n_e}(\upsilon, \omega)}{\tilde{\Phi}'_q(\upsilon, \omega; \kappa)}\right] d\upsilon d\omega \quad [35]$$

This expression for $\mathcal{E}$ represents the entropy of completely decorrelated data.

Information Efficiency $\mathcal{H}/\mathcal{E}$

The information efficiency of completely decorrelated data is defined by the ratio $\mathcal{H}/\mathcal{E}$. This ratio reaches its upper bound $\mathcal{H}/\mathcal{E} = 1$ when $\hat{\Phi}'_{n_e}(\upsilon, \omega) \ll \hat{\Phi}'_\rho(\upsilon, \omega)|\hat{\Gamma}_e(\upsilon, \omega)|^2$ and $\hat{\Phi}'_{n_e}(\upsilon, \omega) \ll \tilde{\Phi}'_q(\upsilon, \omega; \kappa)$, because then both eqn [31] for $\mathcal{H}$ and eqn [35] for $\mathcal{E}$ reduce to the same expression

$$\mathcal{H} = \mathcal{E} = \frac{1}{2}\int_{\hat{B}}\int \log\left[1 + \frac{\hat{\Phi}'_\rho(\upsilon, \omega)|\hat{\Gamma}_e(\upsilon, \omega)|^2}{\tilde{\Phi}'_q(\upsilon, \omega; \kappa)}\right] d\upsilon d\omega \quad [36]$$

This upper bound can be approached with a small loss in $\mathcal{H}$ only when the aliasing and photodetector noise are small. Hence, the electro-optical design that optimizes $\mathcal{H}$ also optimizes $\mathcal{H}/\mathcal{E}$. However, a compromise always remains between $\mathcal{H}$ and $\mathcal{H}/\mathcal{E}$ in the selection of the number of quantization levels: $\mathcal{H}$ favors fine quantization, whereas $\mathcal{H}/\mathcal{E}$ favors coarse quantization.

Maximum-Realizable Fidelity $\mathcal{F}$

The maximum-realizable fidelity $\mathcal{F}$ of the images restored with the Wiener filter $\hat{\Psi}(\upsilon, \omega; \kappa)$ can be expressed as a function of the throughput SFR $\hat{\Gamma}_r(\upsilon, \omega; \kappa)$ given by eqn [24] as

$$\mathcal{F} = \int\int \hat{\Phi}'_\rho(\upsilon, \omega)\hat{\Gamma}_r(\upsilon, \omega; \kappa)\, d\upsilon d\omega \quad [37]$$

or, equivalently, as a function of the integrand $\hat{\mathcal{H}}(\upsilon, \omega; \kappa)$ of the information rate $\mathcal{H}$ given by eqn [31] as

$$\mathcal{F} = \int\int \hat{\Phi}'_{\rho}(\upsilon, \omega)\left[1 - 2^{-\hat{\mathcal{H}}(\upsilon,\omega;\kappa)}\right] d\upsilon d\omega \qquad [38]$$

This relationship between fidelity and information rate can be extended to other goals. For example, the enhancement of spatial features (e.g., edges and boundaries), for robotic vision, can be accommodated by letting $\tilde{\tau}_e(\upsilon, \omega)$ be the desired feature-enhancement filter.

Performance and Design Trade-offs

Electro-optical Design

Figure 7 presents the information rate $\mathcal{H}$ (for lossless encoding) as a function of the optical-response index ζ_c and the mean spatial detail μ. The information rate $\mathcal{H}$ versus ζ_c is given for several SNRs $K\sigma_\rho/\sigma_p$ and $\mu = 1$, and $\mathcal{H}$ versus μ is given for the three informationally optimized designs specified in Table 1.

The curves show that $\mathcal{H}$ can reach its highest possible value only when both of the following conditions are met:

1. The relationship between the SFR $\hat{\tau}(\upsilon, \omega)$ and the sampling passband $\hat{B}$ is chosen to optimize $\mathcal{H}$ for the available SNR $K\sigma_\rho/\sigma_p$. This design is said to be informationally optimized.
2. The relationship between the sampling passband $\hat{B}$ and the PSD $\hat{\Phi}_\rho(\upsilon, \omega)$ is chosen to optimize $\mathcal{H}$. For the PSDs $\hat{\Phi}_\rho(\upsilon, \omega)$ typical of natural scenes, the best match occurs when the sampling interval is near the mean spatial detail of the scene (i.e., when $\mu \approx 1$).

These conditions are consistent with those for which the information rate $\mathcal{H}$ reaches Shannon's channel capacity $\mathcal{C}$. However, blurring and aliasing constrain $\mathcal{H}$ to values that are smaller than $\mathcal{C}$ by a factor of nearly two (i.e., $\mathcal{H} \lesssim \mathcal{C}/2$). Hence, these conditions replace the role of white and band-limited signals in classical communication theory, to establish an upper bound on the information rate in imaging systems.

The above two conditions appeal intuitively when the problem of image restoration is considered:

1. The result that the SFR $\hat{\tau}(\upsilon, \omega)$ that optimizes $\mathcal{H}$ depends on the available SNR is consistent with the observation that, in one extreme, when the SNR is low, substantial blurring should be avoided because the photodetector noise would constrain the enhancement of fine spatial detail even if aliasing were negligible. In the other extreme, when the SNR is high, substantial aliasing should be avoided so that this enhancement is relieved from any constraints except those that the sampling passband inevitably imposes.

Table 1 Informationally optimized designs

Design	$K\sigma_\rho/\sigma_p$	ζ_c	$\mathcal{H}^*$
1	256	0.3	4.4
2	64	0.4	3.3
3	16	0.5	2.2

*$\mu = 1$.

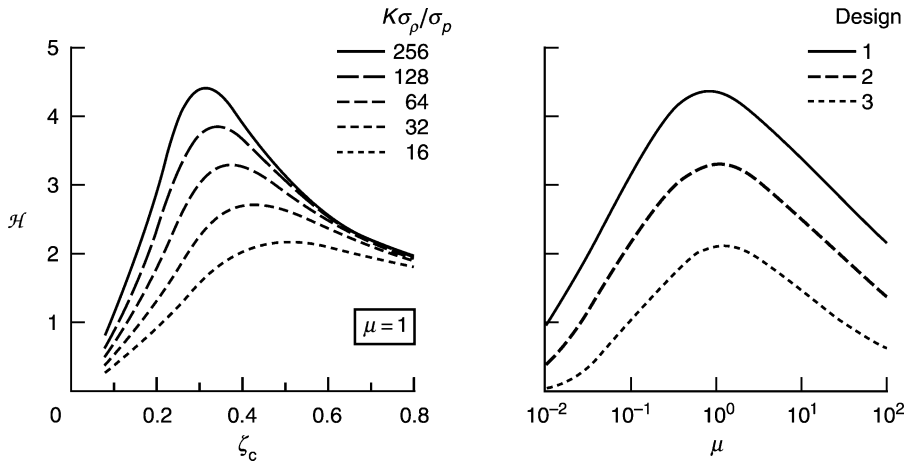

Figure 7 Information rate $\mathcal{H}$ versus the optical-response index ζ_c and the mean spatial detail μ (relative to the sampling interval). The designs are specified in **Table 1**, and the SFRs $\hat{\tau}(\upsilon, \omega)$ for ζ_c are shown in **Figure 6**.

2. The result that $\mathcal{H}$ reaches its highest value when the sampling interval is near the mean spatial detail of the scene is consistent with the observation that, ordinarily, it would not be possible to restore spatial detail that is finer than the sampling interval, whereas it would be possible to restore much coarser detail from fewer samples.

Information Rate and Data Rate

Figure 8 presents an information-entropy $\mathcal{H}(\mathcal{E})$ plot that characterizes the relationship between the information rate $\mathcal{H}$ of the encoded signal and the associated theoretical minimum data rate, or entropy, $\mathcal{E}$ for η-bit quantization. The encoder SFR $\tilde{\tau}_e(\upsilon, \omega)$ is assumed to be unity. The plot illustrates the trade-off between $\mathcal{H}$ and $\mathcal{E}$ in the selection of the number of quantization levels for encoding the acquired signal. It shows, in particular, that the design that realizes the highest information rate $\mathcal{H}$ also enables the encoder to realize the highest information efficiency $\mathcal{H}/\mathcal{E}$. This result appeals intuitively, because the perturbations due to aliasing and photodetector noise that interfere with the image restoration can also be expected to do so with the signal decorrelation.

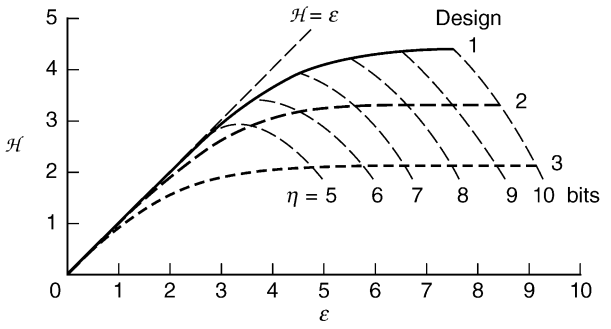

Figure 8 The information-entropy $\mathcal{H}(\mathcal{E})$ plot of the information rate $\mathcal{H}$ versus the associated theoretical minimum data rate $\mathcal{E}$ for η-bit quantization. The designs are specified in Table 1.

Throughput SFR

Figure 9 illustrates the SFRs $\hat{\tau}(\upsilon, \omega)$ and $\hat{\Psi}(\upsilon, \omega; \kappa)$ of the image-gathering device and Wiener filter, respectively, and of their product, the throughput SFR $\hat{\Gamma}_r(\upsilon, \omega; \kappa)$, for the three designs specified in Table 1. As the accumulated noise becomes negligible, $\hat{\Gamma}_r(\upsilon, \omega; \kappa)$ approaches the ideal SFR of the classical communication channel, which is unity inside the sampling passband and zero outside.

Information Rate, Fidelity and Robustness

The PSD $\hat{\Phi}_\rho(\upsilon, \omega)$ of a scene is seldom known when images are restored. Moreover, even if the PSD were known to be the one given by eqn [2], then the mean

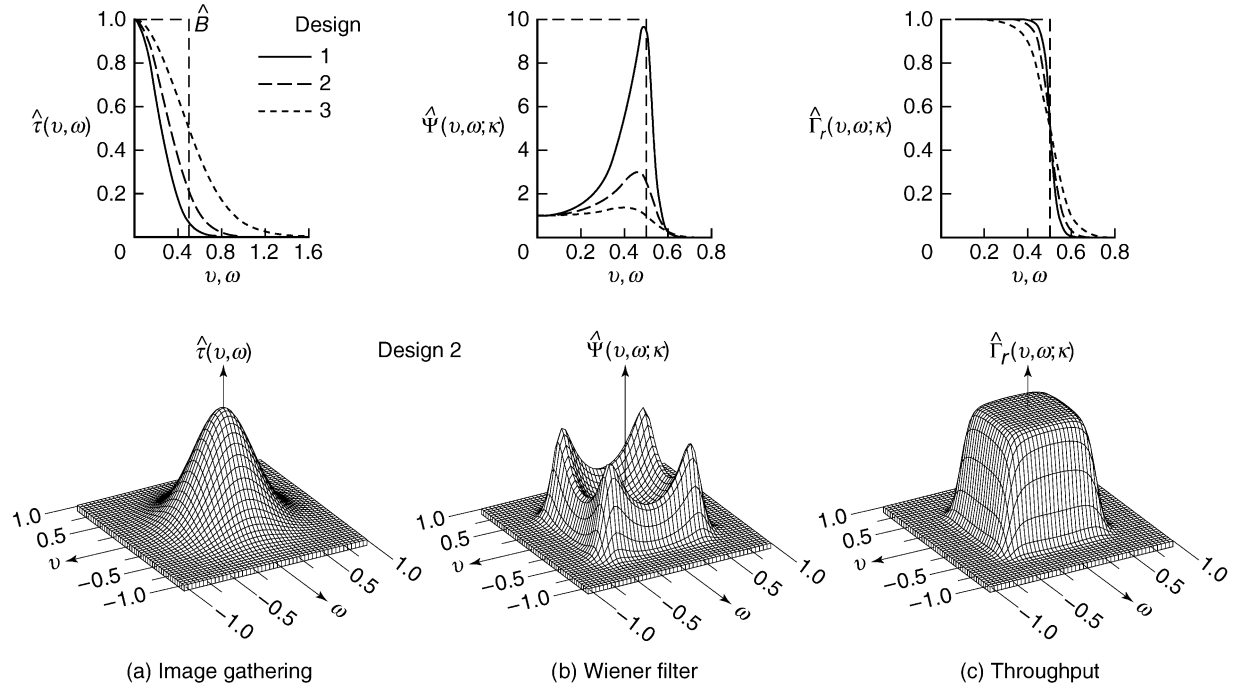

Figure 9 SFRs of image gathering, restoration, and throughput. The designs are specified in Table 1.

spatial detail μ would usually remain uncertain because it depends, not only on the properties of the scene, but also on the angular resolution and viewing distance of the image-gathering device.

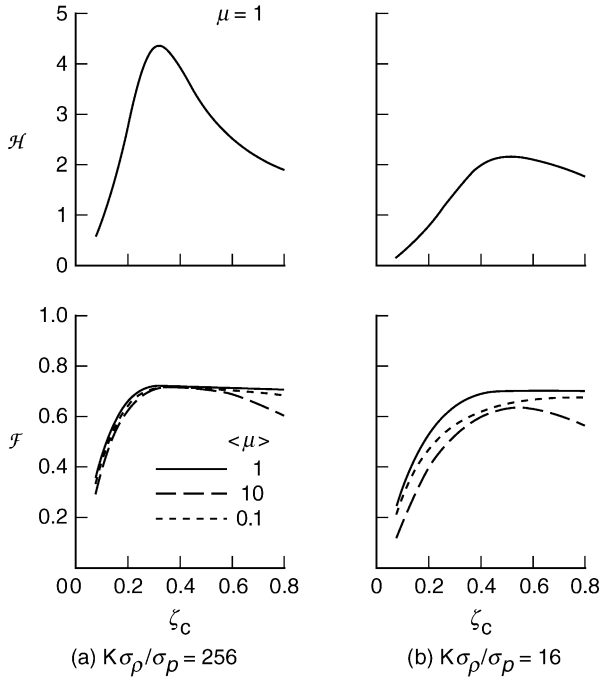

Figure 10 Information rate $\mathcal{H}$ and maximum-realizable fidelity $\mathcal{F}$ versus the optical-response index ζ_c for two SNRs $K\sigma_\rho/\sigma_p$. $\mathcal{F}$ is given for the matched ($\langle\mu\rangle = 1$) and two mismatched Wiener restorations.

In practice, therefore, image restorations have to rely on estimates of the statistical properties of scenes. The tolerance of the quality of the restored image to errors in these estimates is referred to as the robustness of the image restoration.

Figure 10 presents the information rate $\mathcal{H}$ and the corresponding maximum-realizable fidelity $\mathcal{F}$ for matched and mismatched Wiener restorations. These restorations represent the digital image $R(\bar{x}, \bar{y}; \kappa)$ or, equivalently, the continuous image $R(x, y; \kappa)$ displayed on a noise-free medium. The matched restorations use the correct value of μ, whereas the mismatched restorations use wrong estimates of μ. These curves reveal that the informationally optimized designs produce the highest fidelity and robustness, and that both improve with increasing $\mathcal{H}$. Moreover, these curves reveal that, ordinarily, one cannot go far wrong in Wiener restorations by assuming that the mean spatial detail is equal to the sampling interval (i.e., $\mu = 1$). This observation appeals intuitively because spatial detail that is much smaller cannot be resolved, and detail that is larger is not degraded substantially by blurring and aliasing.

Information Rate and Visual Quality

Figures 11 and 12 present Wiener restorations and their three components, as given by eqn [23], where $\rho(x, y) * \Gamma_r(x, y; \kappa)$ accounts for blurring, $n_{ar}(x, y; \kappa)$ accounts for aliasing, and $n_{pr}(x, y; \kappa)$ accounts for

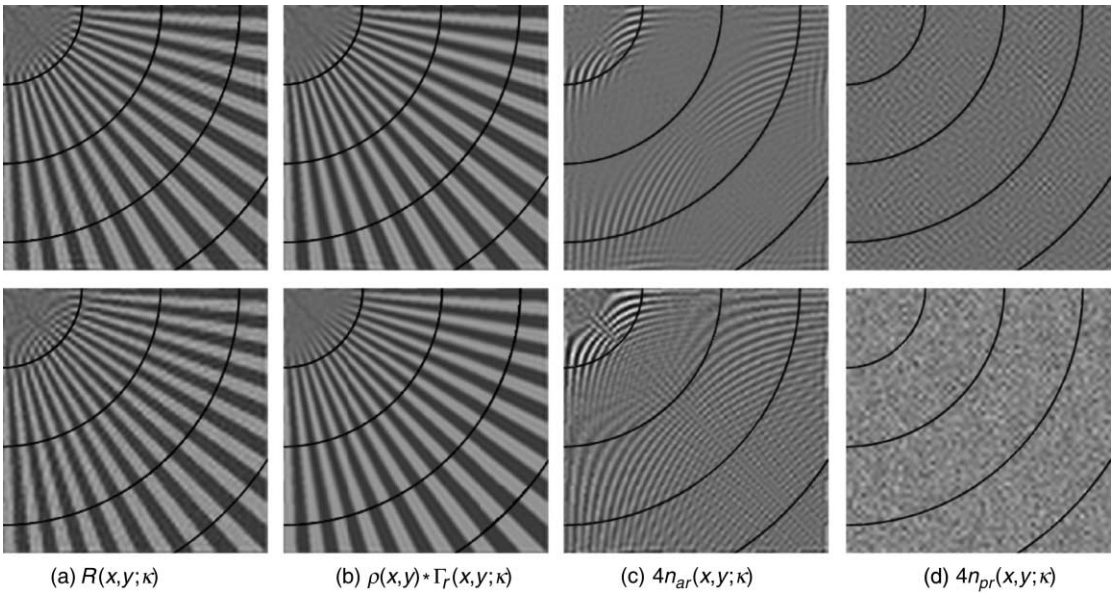

Figure 11 Images restored with the Wiener filter and their three components for designs 1 (top) and 3 (bottom).

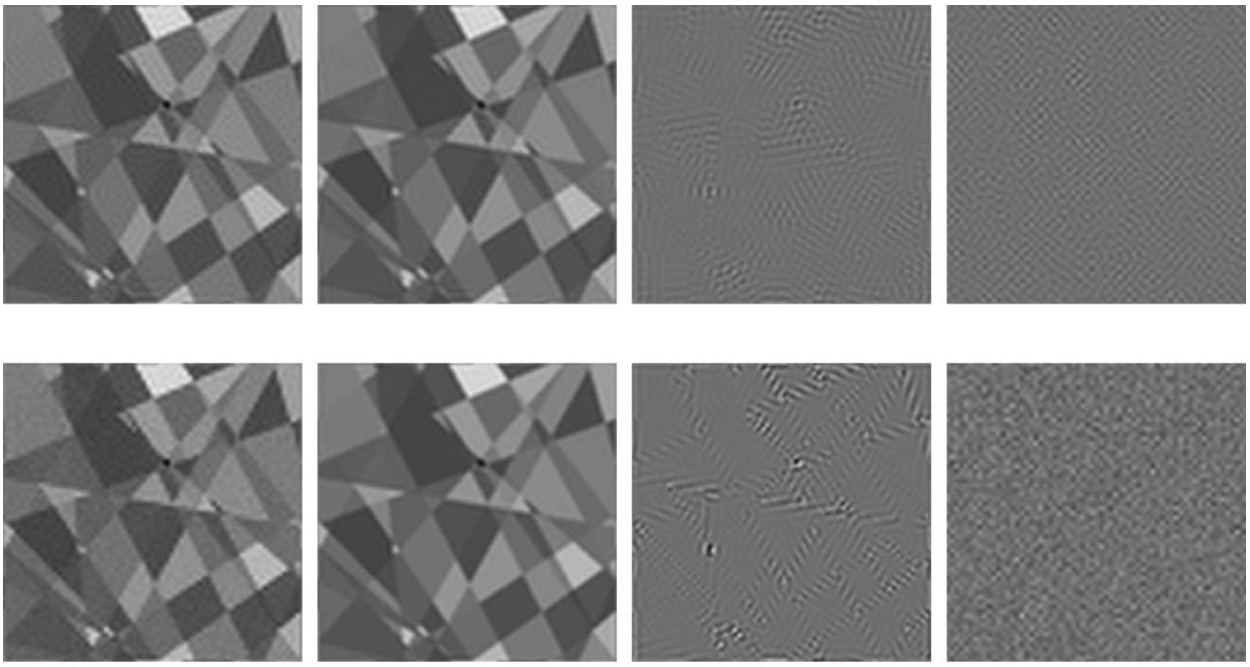

Figure 12 Images restored with the Wiener filter and their three components for designs 1 (top) and 3 (bottom).

photodetector noise. The contrast of the illustrations of the two noise components has been increased by a factor of four to improve their visibility. The extraneous structure that aliasing produces in the images of the resolution wedges is commonly referred to as Moiré pattern. The corresponding distortion in the images of the random polygons emerges more subtly as jagged (or staircase) edges.

The images are formed from a set of 64×64 samples with a $Z = 4$ interpolation and have a 4×4 cm format. If these images were displayed in a smaller format, then the jagged edges could not be resolved by the observer and would appear to be the result of blurring or photodetector noise instead of aliasing. Aliasing has, therefore, often been overlooked as a significant source of image degradation.

The Wiener restoration produces images in which fine spatial detail near the limit of resolution normally has a high contrast approaching that in the scene. However, these images also tend to contain visually annoying defects, due to the accumulated noise and the ringing near sharp edges (Gibbs phenomenon). Hence, it is often desirable to combine this restoration with an enhancement filter that gives the user some control over the trade-off among fidelity, sharpness and clarity.

Figure 13 presents images for which the Wiener restorations given in Figures 11 and 12 are enhanced for visual quality by suppressing some of the defects due to aliasing and ringing. This enhancement improves clarity at the cost of a small loss in sharpness. The images are produced again from 64×64 pixels, but they are displayed in three different formats. The smallest format, with a density of 64 pixels/cm, corresponds to a display of 256×256 pixels in a 4×4 cm area, which is typical of the images found in the prevalent digital image-processing literature. As can be observed, this small format leads to images that are indistinguishable from each other because they hide many of the distortions that larger formats clearly reveal.

In general, if the images are displayed in a format that is large enough to reveal the finest spatial detail near the limit of resolution of the imaging system, then distortions due to the perturbations in this system become also visible. When no effort is spared to reduce these distortions without a perceptual loss of resolution and sharpness, then it becomes strongly evident that the best visual quality with which images can be restored improves with increasing information rate, even after the fidelity has essentially reached its upper bound. This improvement continues until it is gradually ended by the unavoidable compromise among sharpness, aliasing, and ringing as well as by the granularity of the image display.

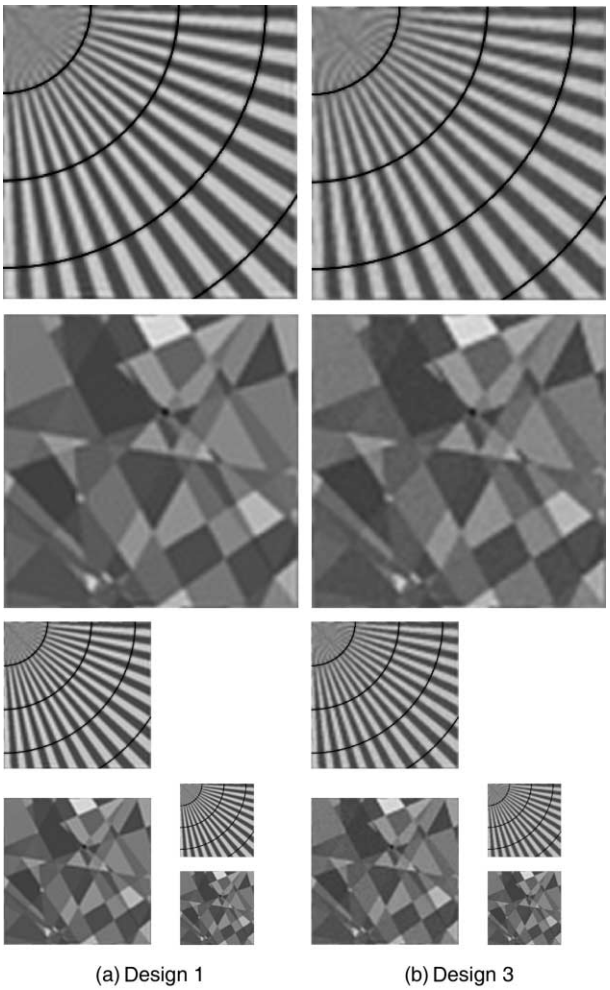

Figure 13 Images restored with the Wiener filter and enhanced for visual quality. The large, medium, and small formats contain 16, 32 and 64 pixels/cm, respectively.

Concluding Remarks

The performance of image-gathering devices and the human eye is constrained by the same critical limiting factors. When these factors are accounted for properly, then it emerges that the design of the image-gathering device that is optimized for the highest realizable information rate corresponds closely, under appropriate conditions, to the design of the human eye that evolution has optimized for viewing the real world. This convergence of information theory and evolution toward the same design clearly supports the extension of information theory to the characterization of imaging systems.

Numerous other information-theoretic characterizations of imaging are now emerging. However, none of these characterizations accounts for the critical limiting factors that constrain image gathering and restoration, as outlined here. Hence, it is not possible for them to address the efficiency and accuracy with which images can be conveyed. Moreover, none of these characterizations combines observation with communication, or sensing with processing, in a general formalization. Instead, each of them still deals with a particular measurement or imaging problem. Hence, the role of information theory in imaging is far from mature. Many challenges remain: to develop general formalizations, to account for physical phenomena, and to correlate predictions with measurements.

Introduction

A digital image is an array (2D image) or a cube (3D image) of quantized numbers, providing a representation of a physical object or a map of some distributed property of the object (density of matter, energy, etc.). It can be obtained by digitizing the original image (for instance, a photograph) or can be directly formed by the outputs of the imaging system (digital camera, microscope, telescope, etc.). When visualized on a suitable image display device, a digital image must provide a representation of the physical object which can be easily interpreted and analyzed. In many cases, however, this condition is not satisfied. We give two typical examples.

The first is that of an image degraded by blurring which can be introduced by defects of the optical systems (such as aberrations) or by image motion, image defocusing, etc. The representation of the object does not have the quality which should be desirable for its interpretation.

The second case is even more important and arises when the output of the imaging system is not directly related to the physical quantity to be imaged. For instance, in X-ray tomography, the output of a detector is the attenuation of an X-ray pencil crossing the body while the quantity to be imaged is the density of the body.

In the situations described above, the desired image can be obtained by solving a number of mathematical problems. If we denote f as the object, namely the target of the imaging system, and g as the image of f provided by the system, then the problems to be solved can be summarized as follows:

- develop a physical model of the system to obtain a mathematical relationship between the object f and the image g; the computation of g from a given f is usually called the solution of the direct problem;
- solve the problem of obtaining the physical quantity f from given outputs g of the system; this second step is usually called the solution of the inverse problem.

The digital image of f, obtained by solving an inverse problem, is a computed one, generated by the computer where the algorithm for the solution of the inverse problem has been implemented.

It may be convenient to formulate both the direct and the inverse problem in terms of functions rather than arrays, cubes, etc., because such a formulation allows the use of powerful tools of functional analysis for their investigation. Next, the results obtained in the continuous case can be used for understanding the features of the corresponding discrete problem. In most important applications, for instance, the relationship between f and g is linear so that, in the discrete version of the direct problem, one obtains g by applying a suitable matrix A to f while, in the discrete version of the inverse problem, one obtains f from g by solving a linear algebraic system. However, the solution of the inverse problem is not so simple and the difficulties can be understood by looking at the corresponding continuous problem.

The basic reason relies on the fact that inverse problems are ill-posed in the sense of Hadamard: the solution may not exist; even if it exists it may not be unique; and, even if it exists and is unique, it may not depend continuously on the data. The last statement means that a small perturbation of the data, such as that caused by noise or any kind of experimental error, can completely modify the solution.

Inverse problems are ill-posed because imaging systems do not transmit complete information about the physical object. Therefore, the problem is to extract the useful information contained in the data or, in mathematical terms, to look for approximate solutions which are stable against noise. This is the purpose of a mathematical theory introduced in its general form by the Russian mathematician, Tikhonov and known as regularization theory.

We illustrate the general framework outlined above by means of a specific example – image deconvolution, also known as image deblurring, image restoration, etc. The object f is the image which should be recorded in the absence of degradation, while g is the image corrupted by aberrations or other causes of blurring. Both f and g are functions of 2D (or 3D) space variables $\mathbf{x}$ which are the coordinates of a point in the image domain. If the imaging system is isoplanatic, then it is described by a space-invariant point spread function (PSF) $K(\mathbf{x})$, which is the image of a point source located in the center of the image domain. The PSF provides the response of the system to any point source wherever it is located. On the other hand, its Fourier transform, the transfer function $\hat{K}(\omega)$ (the hat denotes Fourier transform

and ω, the spatial frequencies associated to the space variables $\mathbf{x}$), tells us how a signal of a fixed frequency is propagated through the linear system, so that the blurring can also be viewed as a sort of frequency filtering.

Under these assumptions the image g is the convolution product of object f and PSF K:

$$g(\mathbf{x}) = \int K(\mathbf{x} - \mathbf{x}')f(\mathbf{x}')\mathrm{d}\mathbf{x}' \qquad [1]$$

and the solution of the direct problem is just the computation of a convolution product.

The image g, as given by eqn [1], is the so-called noise-free image. The actually recorded image g_r is affected by a noise term and, in general, it can be written in the following form:

$$g_r(\mathbf{x}) = g(\mathbf{x}) + n(\mathbf{x}) \qquad [2]$$

where $n(\mathbf{x})$ is a function describing noise contamination. It is a random function and, therefore, it is unknown even if one understands its statistical properties. We point out that eqn [2] does not imply that the noise is additive or signal independent. For instance, in microscopy and astronomy, the contamination of the image is due both to photon noise, which satisfies Poisson statistics, and read-out noise, which is basically Gaussian and white. Therefore the noise term in eqn [2] must only be intended as the difference between the noisy and the noise-free image.

In a first attempt at approaching the inverse problem, it seems quite natural to ignore the noise term $n(\mathbf{x})$ and to solve eqn [1] for $f(\mathbf{x})$ with $g(\mathbf{x})$ replaced by $g_r(\mathbf{x})$. Then, by taking the Fourier transform of both sides of this equation and using the well-known convolution theorem, one finds the following relationship:

$$\hat{g}_r(\omega) = \hat{K}(\omega)\hat{f}(\omega) \qquad [3]$$

which relates the Fourier transform of f and g to the transfer function of the imaging system.

The solution of this equation looks elementary. However, a first problem is due to the fact that an optical system is generally band-limited; its band Ω is the bounded domain of spatial frequencies where the transfer function is different from zero. Since the noise is not band-limited or, at least, has a band much broader than that of the optical system, outside Ω the right-hand side of eqn [3] is zero while the left-hand side is not; in other words, the solution of the deconvolution problem, as formulated above, does not exist because no object f satisfies eqn [3] everywhere. In this particular case, one can circumvent the problem by applying a suitable filter to $g_r(\mathbf{x})$, in order to suppress the out-of-band noise.

The second problem is the nonuniqueness of the solution of the problem with the filtered data. This is due to the so-called invisible objects, namely objects whose Fourier transform is zero on Ω, so that the corresponding images are exactly zero. If we find a solution of the deconvolution problem, by adding an arbitrary invisible object to this solution, we find another solution of the same problem. A well-defined solution can be obtained by requiring its Fourier transform to be zero outside Ω. In other words, we set to zero what is not transmitted by the imaging system.

The standard way for approaching the previous questions is to look for solutions in the least-squares sense, namely for objects which minimize the functional:

$$\varepsilon^2(f) = \|K * f - g_r\|^2 \qquad [4]$$

where $*$ denotes the convolution product, as defined in eqn [1], and the right-hand side is the square of the L^2-norm (which can also be interpreted as energy) of the discrepancy between the recorded image g_r and the computed image $K * f$. If one looks for a least-squares solution with minimal energy then one automatically re-obtains the solution discussed above, namely an object whose Fourier transform in Ω is given by

$$\hat{f}_{\mathrm{inv}}(\omega) = \frac{\hat{g}_r(\omega)}{\hat{K}(\omega)} \qquad [5]$$

and is zero outside Ω. Such a solution is that provided by the so-called inverse filter.

However, there is an additional difficulty in that the transfer function usually tends to zero at the boundary of the band while the Fourier transform of the noise, hence that of g_r, does not, or tends to zero in a different way. It follows that $\hat{f}_{\mathrm{inv}}(\omega)$ is divergent or very large at the boundary of the band. We conclude that its inverse Fourier transform does not exist or, if it exists, is affected by large artifacts due to noise propagation. The latter is the typical situation in the case of digital images. In **Figure 1** we give the result of a numerical simulation showing the typical effect produced by the inverse filter. The object is a beautiful picture of a galaxy recorded by the Hubble Space Telescope (HST), while the PSF is a computed one describing the blurring of HST before installation of the optics correction. The blurred image is obtained by convolving the object with the PSF and by adding white noise. The restored image produced by the inverse filter is completely corrupted by noise.

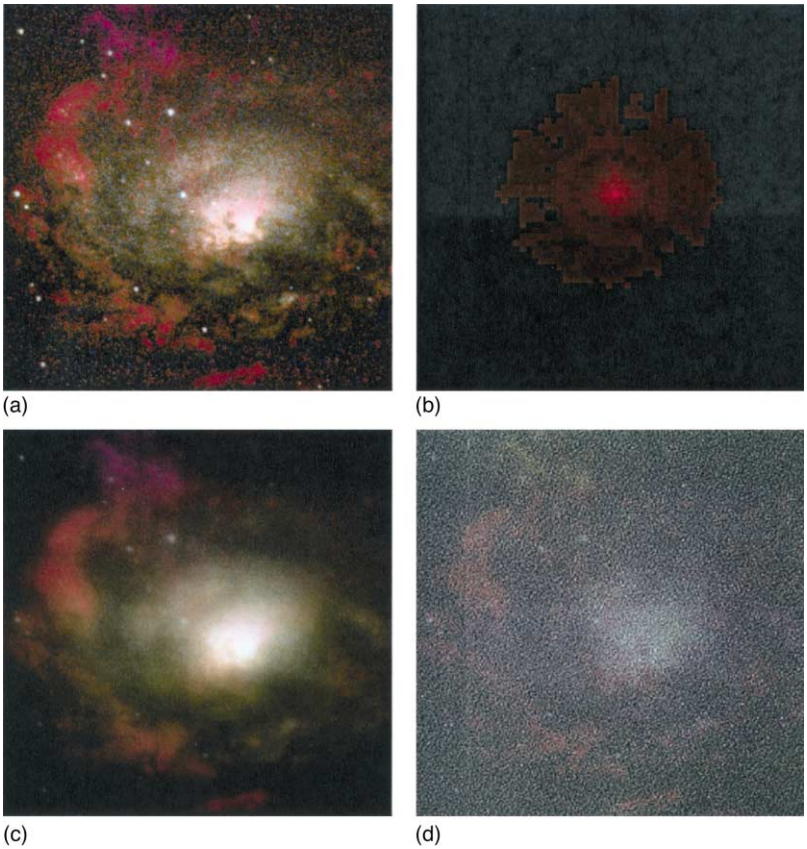

Figure 1 Illustrating the effect of the inverse filter: (a) Image of the Circinus galaxy taken on 10 April 1999, with the Wide Field Planetary Camera 2 of the Hubble Space Telescope; (b) the PSF used for blurring the RGB components of the image (here shown in red); (c) the blurred image obtained by convolving the components of the image in (a) with the corresponding PSFs and adding noise; (d) the restoration obtained by applying the inverse filter to the three components of (c). Part (a) courtesy of NASA/Space Telescope Science Institute.

The inverse filter provides a solution which fits the data in the best possible way and therefore also fits the noise in the frequency domains where the signal is weakly transmitted by the imaging system. This can be achieved at the cost of an energy (L^2-norm) of the solution which is too large. Therefore, such a conclusion suggests that one must search for a reasonable compromise between data fitting and energy of the solution. This is the basic idea of regularization theory, at least in its most simple form. The mathematical formulation is obtained by looking for objects which minimize the functional:

$$\Phi_\mu(f) = \|K * f - g_r\|^2 + \mu\|f\|^2 \qquad [6]$$

where μ, the so-called regularization parameter, is a parameter controlling the trade-off between data fitting and energy of the solution: when μ is small, the data fitting is good and the energy is large while, when μ is large, the data fitting is poor and the energy is small.

For a given μ, the function f_μ, which minimizes the functional of eqn [6] is called the regularized solution of the problem. It is easy to show that its Fourier transform is given by

$$\hat{f}_\mu(\omega) = \frac{\hat{K}^*(\omega)}{|\hat{K}(\omega)|^2 + \mu}\hat{g}_r(\omega) \qquad [7]$$

The regularized solutions form a one-parameter family of functions. When μ is small these functions are strongly contaminated by noise whose effect is gradually reduced when μ increases. For too large values of μ, one re-obtains blurred versions of the original object.

Such behavior is illustrated by the sequence of regularized solutions given in Figure 2 and corresponding to the example of Figure 1. The regularization parameter increases starting from left to right and from top to bottom. Its values are $\mu = 0$ (inverse filter), 0.001, 0.01, 0.05, 0.1, and 0.5 (the noise is of the order of a few percent and the PSF is normalized in such a way that the sum of all its value is 1). The sequence makes evident the well-established theoretical result of the existence of an optimal value of the regularization parameter. Such an optimal value can

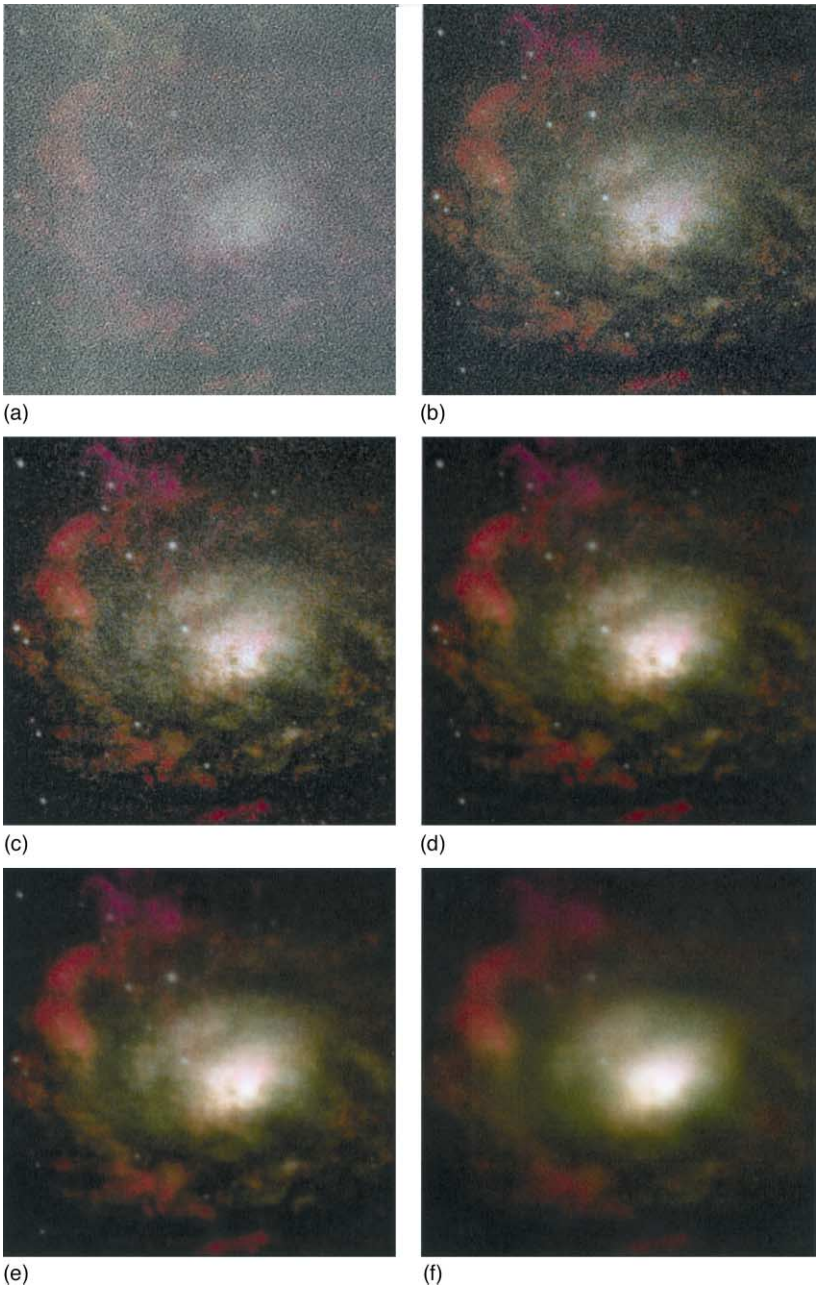

Figure 2 Illustrating the effect of the regularization parameter. The blurred image is that shown in **Figure 1c**. The sequence is obtained by increasing the value of the regularization parameter: (a) $\mu = 0$ (inverse filter); (b) $\mu = 0.001$; (c) $\mu = 0.01$; (d) $\mu = 0.05$; (e) $\mu = 0.1$; (f) $\mu = 0.5$. It is evident that the best restoration is that shown in (c).

be determined in the case of numerical simulations as that represented in **Figure 2**. However, its estimation in the case of real images is more difficult. Several methods for the selection of μ have been proposed. We only mention the so-called discrepancy principle. It consists of determining the value of μ, such that the value of the discrepancy functional at f_μ, $\varepsilon^2(f_\mu)$ coincides with an estimate of the energy of the noise. In other words, the data are fitted with an accuracy comparable with their uncertainty.

As shown by eqn [7], the regularized solution has the same band Ω of the imaging system, because $\hat{K}^*(\omega)$ is zero outside Ω. As is known, a band-limited function can be represented in terms of its samples taken at a rate which is roughly proportional to the size of the band. This is the content of the famous Shannon sampling theorem (more precisely its 2D extension). On the other hand, the sampling distance can be taken as a measure of the resolution provided by the restored image so that one concludes that the

restoration method discussed above does not produce an improvement of the resolution of the imaging system. It certainly produces an improvement of the quality of the image which makes possible a visual verification of that resolution.

In many circumstances, the term super-resolution is used for describing methods which allow an improvement of resolution beyond the limit provided by the sampling theorem. Therefore, a super-resolving method must produce a restored image with a band broader than that of the imaging system. Therefore, super-resolution is related to the problem of out-of-band extrapolation.

Such an approach was already proposed in the 1960s, when it was observed that the Fourier transform of an object with a finite spatial extent (all objects have this property) is analytic; then the theorem of unique analytic continuation implies that the Fourier transform of the object can be determined everywhere from its values on the band of the imaging system.

Unfortunately this problem is ill-posed, so that out-of-band extrapolation is not feasible in practice. Only recently it has been recognized that a considerable amount of super-resolution is possible when the spatial extent of the object is not much greater than the resolution distance of the instrument. For example, super-resolving methods could be used for detecting unresolved binary star in astronomical images.

The important point is that a super-resolving method must implement explicitly the finite extent of the object: the domain of the object must be estimated and the method must search for a solution which is zero outside this domain. This introduces an important question in object restoration and, more generally, in the theory of inverse problems, namely the design of regularized solutions satisfying additional conditions (constraints). This question is also important from the theoretical point of view: the problem is ill-posed because of insufficient information on the object as transmitted by the imaging system; the use of additional constraints reduces the class of the solutions which are compatible with the data and therefore can improve the restoration. This is the use of a priori information in the solution of inverse problems.

A constraint which has been widely investigated and used is the positivity of the solution, i.e., all the values of the restored image must be positive or zero. The physical meaning of the constraint is obvious. Its beneficial effect is to reduce ringing artifacts which affect the regularized solutions previously discussed, in cases where the object contains bright spots over a black background or sharp intensity variations from zero to some positive value. The ringing is essentially related to the well-known Gibbs effect in the truncation of the Fourier series.

The requirement of positivity is the requirement of a particular lower bound on the values of the solution. Therefore, one can consider more general constraints in requiring a given lower and/or upper bound on the values of the solution, eventually combined with a constraint on the domain to produce, for instance, a super-resolved positive solution. The most general form of these constraints requires that the solution belongs to a given closed and convex set $\mathcal{C}$ in some functional space. A general method producing regularized solutions in a convex set is an iterative method which is essentially a gradient method for the minimization of the least-squares functional, with a projection on the set $\mathcal{C}$ at each iteration. In the case of object deconvolution, the least-squares functional is that given in eqn [4] and the method has the following form: if f_k is the result of the k-th iteration, then f_{k+1} is given by

$$f_{k+1} = P_{\mathcal{C}}[f_k + \tau K^{\mathrm{T}} * (g_r - K * f_k)] \qquad [8]$$

where $P_{\mathcal{C}}$ is the convex projection onto the set $\mathcal{C}$, τ is a relaxation parameter and $K^{\mathrm{T}}(\mathbf{x}) = K(-x)$. In general, the algorithm, known as the projected Landweber method, is initialized with $f_0 = 0$. An important property is that it has a regularization effect, in the sense that iterations must not be pushed to convergence but stopped after a suitable number of iterations to avoid strong noise contamination. In Figure 3 we compare, in a specific example, the result obtained by means of the linear regularization method and that obtained by means of the projected iterative method with a lower and upper bound on the solution. The reduction of ringing is evident.

Among the methods producing positive solutions we must mention the most popular one in astronomy, the so-called Richardson–Lucy method, which is an iterative method for Maximum-Likelihood estimation. If the PSF has been normalized in such a way that the sum of all its values is one, it takes the following form:

$$f_{k+1} = f_k\left(K^{\mathrm{T}} * \frac{g_r}{K * f_k}\right) \qquad [9]$$

The method is normally initialized with a uniform image and it must not be pushed to convergence to avoid noise amplification. Another algorithm suggested by statistical arguments and producing positive solution is the so-called Maximum Entropy Method (MEM).

The image restoration methods described above have wide applications both in microscopy and

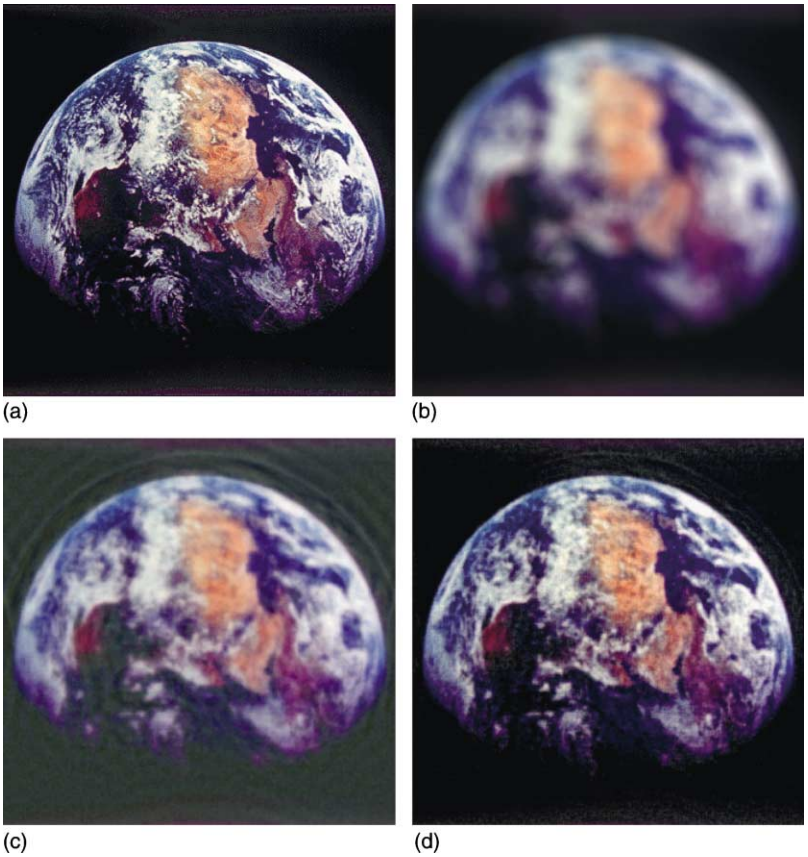

Figure 3 Illustrating the effect of constraints on image restoration: (a) Image of the Earth taken during the Apollo 11 mission; (b) blurred image of (a) obtained by assuming out-of-focus blur and adding noise; (c) optimal restoration provided by the regularization method; the ringing around the boundary of the Earth is evident; (d) optimal restoration obtained by means of the projected Landweber method with a lower and an upper bound on the solution at each iteration. Part (a) courtesy of NASA.

astronomy. For instance, the minimization of the functional eqn [6], with the additional constraint of positivity, has been used for deconvolving images in microscopy to reduce the effect of the missing cone. On the other hand, the Richardson–Lucy method was widely used for deconvolving the images of HST before installation of corrective optics.

Nowadays, image deconvolution is becoming more important for the ground-based telescopes equipped with adaptive optics. Indeed, even if adaptive optics is able to provide a considerable compensation of the atmospheric blur, a further improvement can be obtained by deconvolving the detected images. The PSF is provided by the image of a suitable guide star.

Finally, it is worth mentioning the Large Binocular Telescope, in construction on the Mount Graham in Arizona, because this instrument requires image restoration methods for a full exploitation of its imaging properties. The telescope (Figure 4) consists of two 8 m mirrors on a common mount: both mirrors are equipped with adaptive optics and are combined interferometrically to reach the resolution

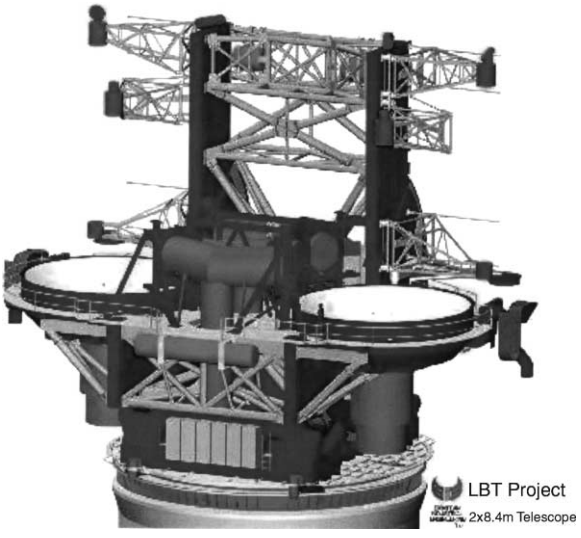

Figure 4 Picture of the Large Binocular Telescope (LBT) in construction on the Mount Graham in Arizona. It consists of two mirrors on the same mount. The images of the two mirrors are combined interferometrically to produce a high-resolution image in the direction of the line joining the centers of the mirrors (baseline).

of a 22.8 m mirror in the direction of the baseline. The telescope can be rotated to record images of the same astronomical target with different orientations of the baseline, i.e., the line joining the centers of the two mirrors. Finally the images must be processed by means of multiple images deconvolution methods to obtain a unique high-resolution image, equivalent to that produced by a 22.8 m mirror.

The applications of inverse problems with major social impact are in the area of medical imaging. The spectacular success of X-ray computerized tomography (CT), invented by GH Hounsfield at the beginning of the 1970s, has stimulated the development of other imaging modalities, based essentially on the same principle, such as positron emission tomography (PET) and single photon emission computerized tomography (SPECT). Computed images are also provided by magnetic resonance imaging (MRI). In such a case, however, the computational problem is rather simple since it consists essentially in Fourier transform inversion.

The basic principle of X-ray CT is described as a finely collimated source S (see Figure 5a) emitting a pencil of X-rays which propagates through the body along a straight line L up to a well collimated receiver R. If we know both the intensity I_0 of the source and the intensity I detected by the receiver, the logarithm of the ratio I_0/I is the integral of the linear attenuation function (roughly proportional to the density function of the body) along the line L. If the source and the receiver are moved along two parallel lines, having direction θ and defining the plane Π (in practice a planar slice of the body under consideration), one obtains the integrals of the linear attenuation function $f(\mathbf{x})$ along all parallel lines orthogonal to θ. The scanning variables in the plane Π are defined in Figure 5b: φ is the angle formed by the unit vector θ with the x-axis and s is the signed distance between the origin and the integration line L. The integrals along all parallel lines orthogonal to θ define a function of s which is called the projection of $f(\mathbf{x})$ in the direction θ:

$$P_\theta(s) = \int_{-\infty}^{+\infty} f(s\cos\varphi - u\sin\varphi, s\sin\varphi + u\cos\varphi)\mathrm{d}u \qquad [10]$$

The set of the projections of $f(\mathbf{x})$ for all possible θ is called the Radon transform of $f(\mathbf{x})$, in honor of the mathematician Johann Radon, who first investigated the problem of recovering a function of two variables from its line integrals. Today, such a problem is known as Radon transform inversion or object restoration from projections. Sampled values of the Radon transform, i.e., sampled values of the projections for a number of possible directions between 0 and π, are the outputs of the acquisition system of the medical equipment known as CT-scanners (Figure 6). Their data-processing system contains the implementation of an algorithm for Radon transform inversion and the final result is a set of computed images providing maps of slices of the human body.

The plot of the Radon transform of f in the (s, φ)-plane, obtained by representing its values as gray levels, is called the sinogram of f. In Figure 7, we give the image of the sinogram of a brain slice. The horizontal rows provide representations of the projections of the phantom. In the image, the angle φ defining the direction θ takes values between 0 and 2π

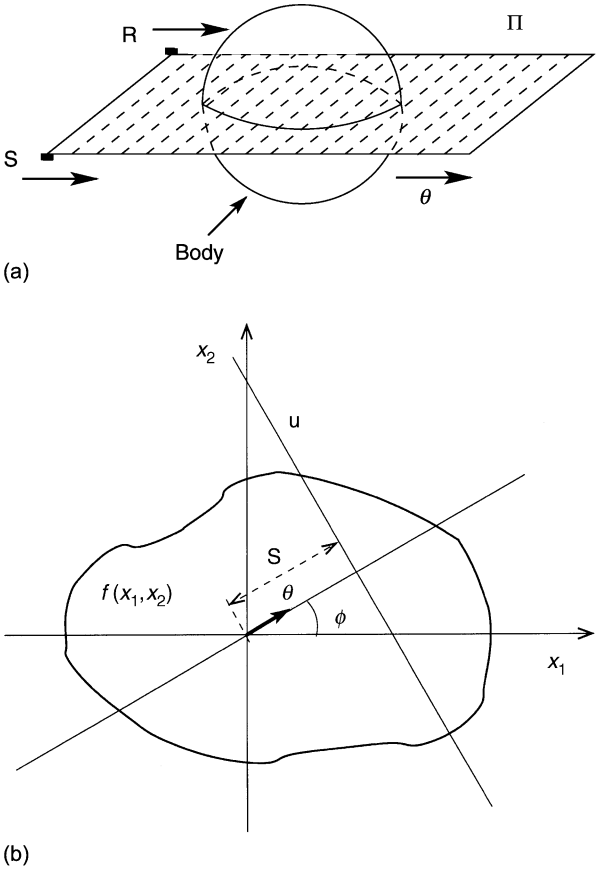

Figure 5 (a) Scheme of the scanning procedure in X-ray tomography: the source(S)–receiver(R) pair is moved along a direction θ orthogonal to the line S–R, defining the plane Π to be imaged; when the scanning has been completed the system is rotated by a certain angle, the scanning procedure is repeated, and so on. (Reproduced with permission from Bertero M and Boccacci P (1998) *Introduction to Inverse Problems in Imaging.* Bristol, UK: IOP Publishing.) (b) Definition of the variables used in the representation of the Radon transform; φ is the angle formed by the S–R line with the x_1-axis; s is the signed distance between the origin and the integration line (orthogonal to θ); and u is the coordinate on the integration line.

while the variable s takes values between $-a$ and a, if a is the radius of a disc containing the phantom. As is evident, the sinogram is symmetric with respect to the point $(0, \pi)$. Each point in the rectangle corresponds to a straight line crossing the phantom and the straight lines through a fixed point of the phantom describe a sinusoidal curve in the (s, φ)-plane. This property has given rise to the name sinogram.

The sinogram is, in a sense, the image of the body slice under investigation, as provided directly by a CT-scanner. However, an inspection of this image does not easily provide information about the body. Therefore, it must be processed to obtain a more significant image. Radon transform inversion is an example of inverse and ill-posed problem and its solution must be treated with extra care.

The crucial point in Radon transform inversion is the Fourier slice theorem, whose content is the following: the Fourier transform of the projection in the direction θ of the function f, is the Fourier transform of f on the straight line passing through the origin and having direction θ:

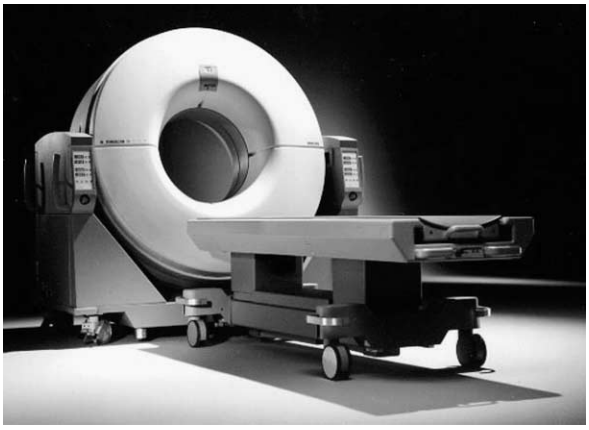
$$\hat{P}_\theta(\omega) = \hat{f}(\omega\theta) \qquad [11]$$

This theorem clarifies the information content of CT data: each projection provides the Fourier transform of the function f along a well-defined straight line in the plane of the spatial frequencies. It is also the starting point for deriving the basic algorithm of data inversion in tomography, the filtered back-projection (FBP). It is obtained from Fourier transform inversion in polar coordinates and is a two-step algorithm: the first step is a filtering of the projections by means of a ramp-filter; the second is the back-projection of the filtered sinogram. More precisely the two steps are as follows:

- *Filtering*: for each θ the projection $P_\theta(s)$ is replaced by a filtered projection given by

$$Q_\theta(s) = \int_{-\infty}^{+\infty} |\omega| \hat{P}_\theta(\omega) e^{i\omega s} \, \mathrm{d}\omega \qquad [12]$$

  where the multiplication by the ramp filter $|\omega|$ derives from the Jacobian of polar coordinates;
- *Back-projection*: this operation is the dual of the projection operation: indeed the projection assigns to a straight line L with coordinates (s, φ), hence to a point of the domain of definition of the Radon transform, the integral of f along L; on the other hand, the back-projection assigns the value of the Radon transform at (s, φ) to all points of the straight line L with the same coordinates (a pictorial representation of projection and back-projection is given in Figure 8); as a consequence the back-projection operator $R^\#$ assigns to each



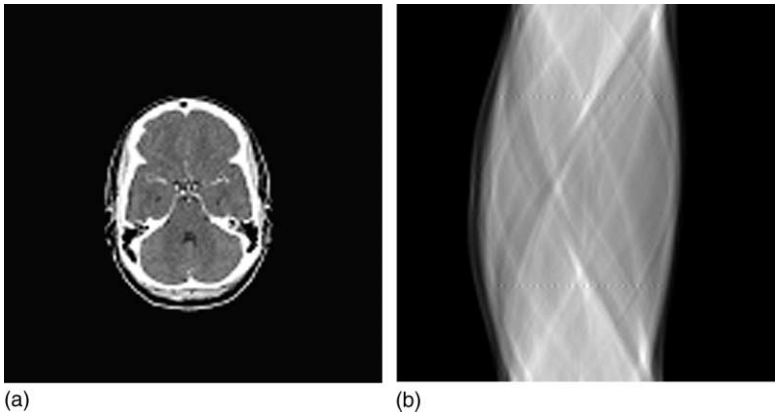


Figure 6 Picture of a scanner for X-ray tomography. The annular part contains the acquisition and scanning systems.

(a) (b)

Figure 7 (a) Picture of a brain slice; (b) the corresponding sinogram. As explained in the text, the sinogram is a gray-level representation of the Radon transform in the s, φ plane. Each horizontal line in (b) corresponds to a projection of (a).

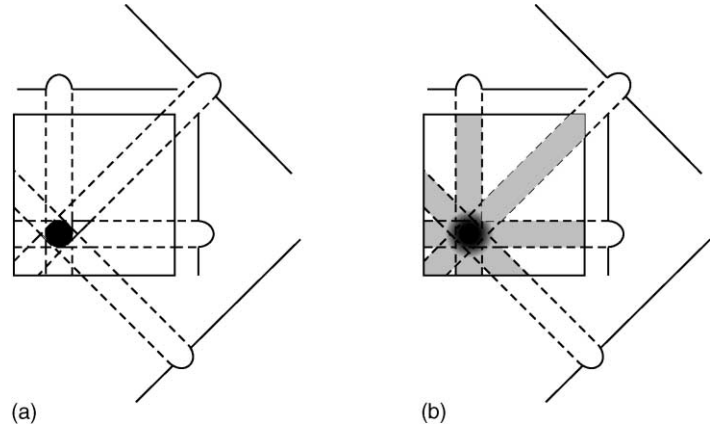

Figure 8 (a) The effect of the projection operation is shown by drawing the projections of a circular phantom corresponding to three directions. (b) shows the result obtained by applying the back-projection operation to the three projections given in (a). It is evident that the picture provided by this operation has a maximum on the domain of the circular phantom.

point $\mathbf{x}$ the sum (integral) of all values of the Radon transform corresponding to straight lines passing through $\mathbf{x}$:

$$R^{\#}P_{\theta}(\mathbf{x}) = \int_0^{2\pi} P_{\theta}(x\cos\varphi + y\sin\varphi)\mathrm{d}\varphi \qquad [13]$$

The back-projection operator, when applied directly to the projections as in eqn [13], provides a blurred image of f; in order to get a satisfactory restoration it must be applied to the filtered projections $Q_{\theta}(s)$. This point is illustrated in Figure 9.

We point out that the ramp filter introduced in eqn [12] amplifies the high frequency components of the projections hence the noise corrupting these components. This remark clarifies that Radon transform inversion is an ill-posed problem and requires some kind of regularization. This is obtained by introducing an additional low-pass filter which reduces the effect of the high frequencies. The most frequently used combination of ramp and low-pass filter is the so-called Shepp–Logan filter.

X-ray tomography is also called transmission computerized tomography (TCT) because the image is obtained by detecting the X-rays transmitted by the body. It provides information about anatomical details of human organs because the map of the linear attenuation function is essentially the map of the density of the tissues.

A different type of information is obtained by the so-called emission computerized tomography (ECT) which is based on the administration of radio-nuclide-labeled agents known as radio-pharmaceuticals. Their distribution in the body of the patient depends on factors such as blood flow, metabolic processes, etc. Then a map of this distribution is obtained by detecting the γ-rays produced by the decay of the radio-nuclides. Therefore, ECT yields functional information, in the sense that the images produced by ECT show the function of the tissues of the organs.

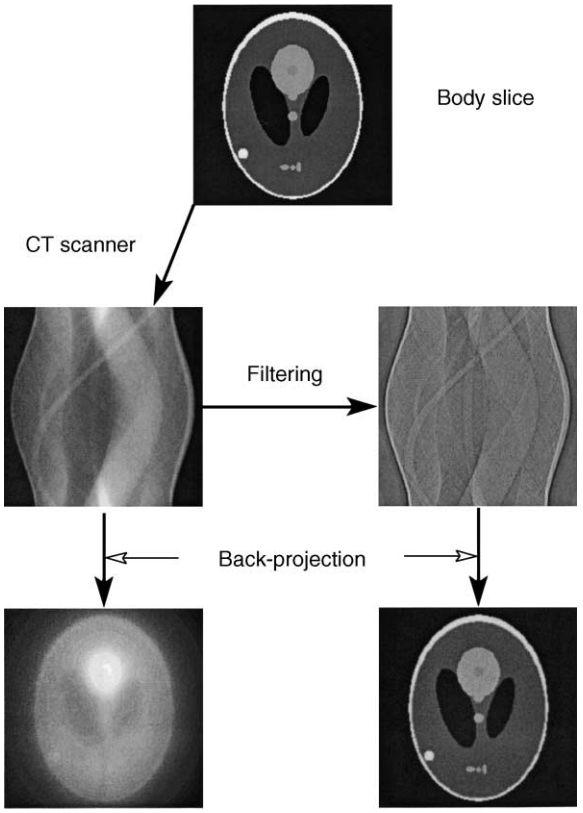

Figure 9 Illustrating the effect of the filtered back-projection. Shown here is: a slice of the so-called Shepp–Logan phantom; the corresponding sinogram (indicated by the arrow CT scanner); the filtered sinogram (indicated by the arrow filtering; the restorations obtained by applying the back-projection operation both to the original sinogram and to the filtered sinogram.

Two different modalities of ECT are usually considered:

- single photon emission computerized tomography (SPECT), which makes use of radio-isotopes where a single γ-ray is emitted per nuclear disintegration;
- positron emission tomography (PET), which makes use of β^+-emitters, where the final result of a nuclear disintegration is a pair of γ-rays, propagating in opposite directions, produced by the annihilation of the emitted positron in the tissues.

In both cases it is necessary to detect the γ-rays coming from well-defined regions of the body and, to this purpose, different methods are used in each case.

In SPECT, the discrimination of the γ-rays is obtained by means of a collimator, consisting of holes in a large lead slab covering the crystal detector face. In PET the collimation is obtained by means of pairs of detectors in coincidence. This technique, which is also called electronic collimation, is more accurate than the physical collimation used in SPECT and allows the design of systems with a great efficiency.

The basic reconstruction method in TCT, namely FBP, is often used in the reconstruction of SPECT and PET data. However, several corrections are necessary in practice. The principal ones are due to the collimator blur and to the scattering of photons in the body. If one develops a more accurate model of data acquisition by taking into account these effects, then the restoration problem implies the inversion of a very large matrix which is sparse and ill-conditioned. To this purpose iterative regularization methods are used such that the basic operation required at each step is matrix-vector multiplication. Other imaging modalities, which have been proposed for medical applications, are electrical impedance and microwave tomography. The underlying inverse problems are basically nonlinear so that the computational cost of the methods for their solution is, in general, too high for clinical applications. However the research in these areas is very active and, therefore, the situation could be improved in the near future.

Adaptive Optics

Introduction

The image quality of a perfect optical system is ideally limited by its diffraction figure. In the real world there are many effects which degrade that physical limit, resulting in poorer image quality at the focal plane. These effects may be static (e.g., time-independent, as, for example, error in the alignment of the optical train) or dynamic (e.g., variable with time, such as optical misalignment introduced by thermo-mechanical distortion). Active and adaptive optics, the topics of this article, are technologies able to correct for the optical aberrations induced by dynamical effects.

There are a variety of causes liable for dynamical image degradation, among these time-variable optical misalignments, pointing and tracking errors (for motorized instruments), and atmospheric perturbations. In practice, both atmospheric turbulence and misaligned instrument introduce random spatial and temporal perturbations on the optical beam, distorting the spherical (ideal) wavefront incoming on to the focal plane. This leads to loss of both the diffraction limited condition and image resolution. A typical situation for astronomical application is shown in Figure 1. A target (a star in this case) emits light whose wavefront, being far from the observing system, can be considered plane. When this wavefront passes through the atmosphere it is distorted with a temporal frequency of the order of hundreds of Hertz. This dynamically distorted wavefront fills the aperture of the optical system and will once more be distorted by the dynamic misalignment of the optical system itself. The final wavefront will be deformed with respect to the ideal (spherical) wavefront.

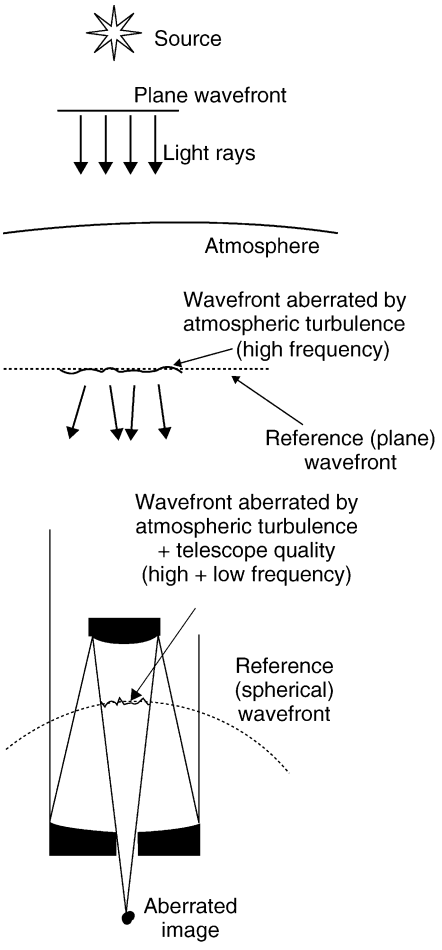

Figure 1 Dynamical wavefront aberration.

Dynamic optical misalignment may depend on gravitational and thermal deformation, while pointing error may appear as very slow (drift), slow (wander), or fast (jitter) tilt of the image on the focal plane. Atmospheric perturbations are produced by air turbulence and may be natural (as in the astronomical or satellite tracking cases) or induced by the experiment itself (thermal blooming in high power laser applications). All these effects appear on very different time-scales, as shown in Figure 2. As noticeable, atmospheric turbulence introduces aberrations of all orders, at a frequency above about 1 Hz. Pointing and tracking errors introduce an image tilt with different time-scale. Gravitational effects induce mechanical deformation of the optics, mainly in astronomical applications because of the massive components (the telescope primary mirror in particular). Thermal deformation produces optical misalignment among optical components mainly resulting in defocus. Figure 2 is purely illustrative, because some effects may produce wavefront aberrations at different frequencies than indicated there. For example, drift may be faster than indicated in the figure, and thermal blooming (a thermal effect) introduces aberrations at a higher frequency, and so on.

The correction of the wavefront errors is usually made by means of devices able to change the phase wave somewhere in the light path. Though the concept for correcting aberrated wavefront at slow or high frequency is the same, for example, the use of one or more deformable elements in the optical path, the technologies developed for each area are quite

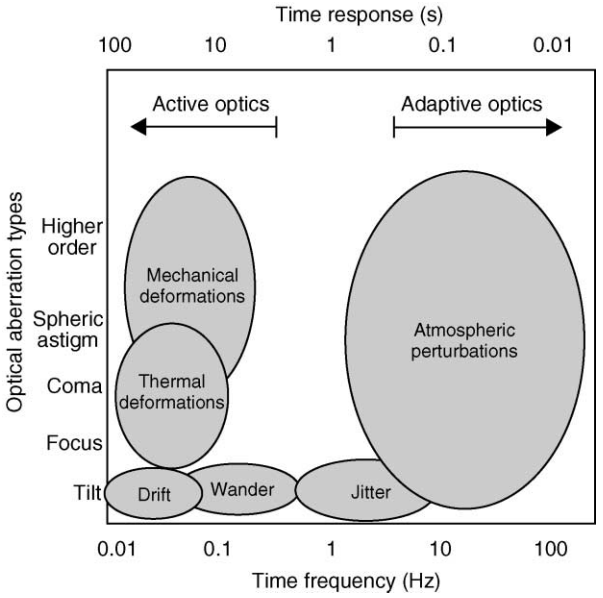

Figure 2 Wavefront aberration time-scale and associated aberrations.

different: variations at slow frequency (approximately below 0.1 Hz in Figure 2) are indicated as quasi-static errors and the techniques developed to overcome them are properly called active optics, while adaptive optics indicates the techniques to overcome the unwanted effects at high frequency (above about 1 Hz in frequency). The frequency value dividing the active from adaptive optics is not well defined and depends on the field of application and its scientific engineering communities. The important point is that a correct use of a combination of the two techniques may ultimately lead to bringing the imaging system close to its diffraction limit.

Slow Corrections: Active Optics

The analysis of the wavefront is required before its correction, and one or more deformable/movable mirrors and their control system, to operate the corrections. A typical system for low frequency correction is shown in Figure 3. A telescope contains three mirrors (M1, M2, and M3) and an instrument to detect its scientific target, usually placed on its optical axis. The dynamic deformations present in this kind of instrument are mainly third-order spherical (thermal deformation of M1), third-order astigmatism (a saddle-horse deformation of M1 due to gravity when the telescope is pointing away from the zenith), and third-order coma (due to gravitational decentering between M1 and M2). Since a telescope has a tracking system some pointing error may be present, causing motion of the image in the focal plane. The observation of an off-axis target (typically a star for astronomical applications) is made to measure the deformations of the incoming wavefront by means of a wavefront sensor (WS) system. This step is completed using some of the wavefront sensing technique described elsewhere in this encyclopedia. The WS must measure the information on the wavefront distortion with adequate spatial resolution to compensate for aberrations across the full aperture of the system. Once the wavefront distortion has been measured by the WS, the needed corrections are sent to the control system which apply the appropriate mirror deformation/movements. In the example of Figure 3 only the primary mirror (entrance pupil) is deformable and it is used for correcting spherical and astigmatism aberrations. M2 is used to compensate the decentering coma by means of lateral displacement. M3 may be tilted to correct for low-frequency pointing errors. In astronomical applications active optics is essential for telescopes with primary-mirror diameters larger than approximately four meters which cannot be manufactured rigidly at reasonable cost. Active optics requires a thin deformable or a segmented primary mirror maintained on the correct shape at every elevation. Using this method, low-frequency correction has been achieved to date in telescopes with primary mirrors of the order of ten meters.

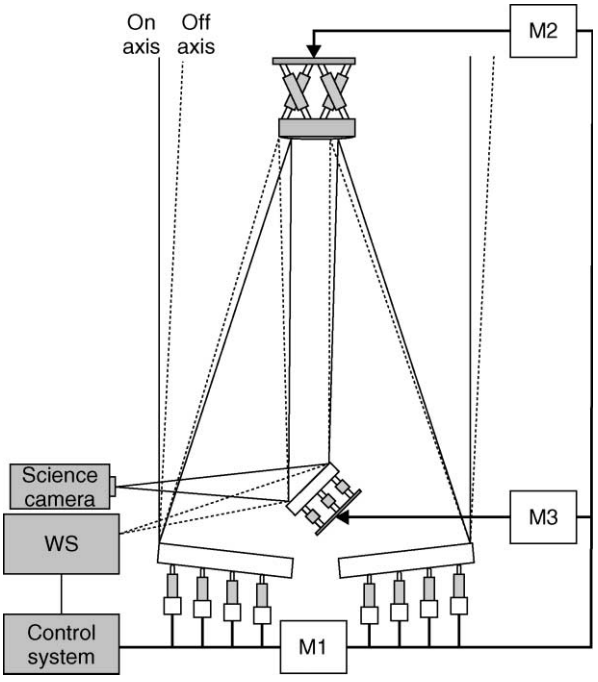

Figure 3 A typical system for correcting low-frequency dynamical aberrations (active optics).

Fast Corrections: Adaptive Optics

It is clear that corrections at high frequency are impossible using the approach discussed above, because of the large dimensions and weight of the mirror and the low response time required. For an adaptive correction it is necessary to image a smaller system pupil in the optical train and make the active correction of the wavefront. A typical configuration is shown in Figure 4. The light from the telescope focal plane (corrected for low frequency errors by means of active optics) is collimated and a pupil is located in this beam. Behind the active mirror a beamsplitter is used to send part of the light into the WS and measure wavefront distortions. The analysis results are sent to the control system which performs the active mirror deformation for the wavefront compensation. If the WS and the control system are sufficiently fast (typically faster than the time-variations of the wavefront distortion), this system is able to produce a plane wavefront which can be focused at the diffraction limit of the system. For this reason

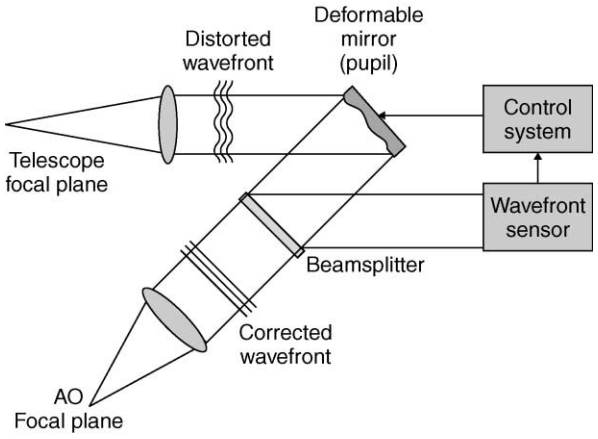

Figure 4 A typical setup for correcting high-frequency dynamical aberrations (adaptive optics).

adaptive optics are often referred to as real-time system.

The seminal paper on the adaptive optics concept was written by H.W. Babcock of the Mount Wilson and Palomar observatories in 1953. Since then a great improvement has been made, especially in military and astronomical fields. In recent years, however, many applications of adaptive optics have developed in fields different from traditional ones, such as precision manufacturing by means of high-power lasers, telecommunications, aero-optics, medical physics, and ophthalmology.

We describe adaptive optics with particular reference to astronomical applications. We provide a brief description of other applications at the end of this article.

Imaging Through the Atmosphere

The optical effects of the atmospheric turbulence are due to local temperature variations that induce fluctuations in the refractive index of air. The refractive index changes depend on the air density as well as the range of the temperature variations. Air density is highest at sea level and decreases exponentially with altitude. Optical effects of turbulence decrease with the altitude of the site, the reason for locating astronomical telescopes on mountains. The effects of turbulence on a point source image are depicted in Figure 5. Hereafter we consider an ideal telescope, for example, one without need for active correction at low frequencies. We consider the source 1 (continous line). The radiation emitted by the source is a spherical wavefront that can be treated as a plane, because of the very long distance to the Earth's atmosphere.

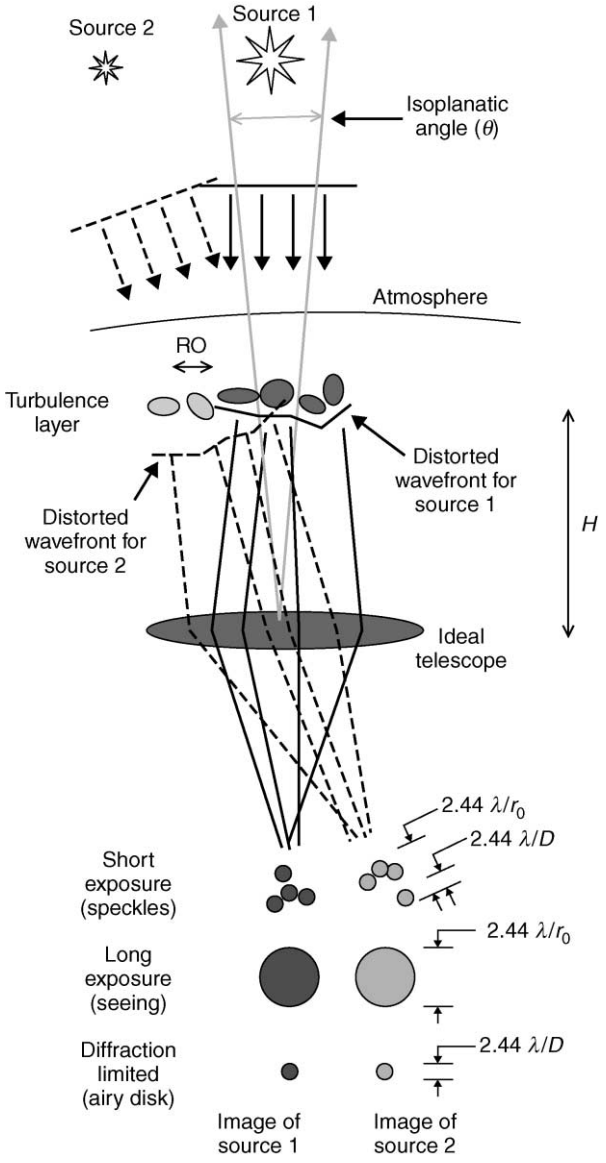

Figure 5 Imaging through the atmosphere.

In absence of wavefront distortion, the angular diameter of the image (Airy disk), is approximately 2.44 λ/D, with λ the wavelength of the observation and D the telescope aperture (the mirror diameter). In this case the image is said to be diffraction limited, and it is the best possible performance for the observation. This is the performance of a space-based ideal telescope.

In the presence of the atmosphere the incoming wavefront is distorted by the turbulence and when it reaches the telescope aperture it is no longer a plane (see in Figure 5). The so-called Fried's parameter r_0 (also called atmospheric coherence length) is the most common parameter used to quantify the distortion effects of atmospheric turbulence. It is defined as the

distance over which the wavefront phase is highly correlated (in this way it provides a measure of the turbulence scale size). For an undistorted plane wave, r_0 is infinity, while for atmospheric distortion it typically varies between 5 cm (bad sites) and 20 cm (excellent sites). We depict Fried's parameter schematically in Figure 5, as bubbles of dimension r_0 in the turbulent layer (referred to as Fried's cells). r_0 is a statistical parameter, which depends on time and wavelength ($r_0 = r_0(t, \lambda^{6/5})$). Its variability with time may be considerable, sometimes changing by a factor of 2 within a few seconds. A small telescope, with a diameter less than r_0, will always operate at this diffraction limit. When the r_0 is smaller than the telescope aperture, the angular size of the image is different if we consider long- or short-time exposures. If the exposure time is very short (less than hundredths of a second) it is possible to image a structure in the focal plane (see short exposure image in Figure 5). This structure, which varies with time, is due to high-order wavefront distortions that occur within the aperture. The short exposure image is broken into a large number of speckles of diameter $2.44\,\lambda/D$, which are randomly distributed over a circular region of approximately $2.44\,\lambda/r_0$ in angular diameter. A lower-order wavefront distortion is correlated with the size of the largest disturbances produced by atmospheric turbulence (the so-called outer scale) which varies considerably (from 1 m to over 1 km). Such disturbances produce a time-dependent tilt of the overall wavefront that causes fluctuations in the angle of arrival of the light from a star and randomly displace the image. For D of the order of the Fried parameter r_0, image motion dominates, and a simple tip-tilt mirror (not just deformable) provides useful correction. For D greater than r_0, speckles dominate and a deformable mirror is necessary to account for the wavefront distortion. For long exposures the dimension of the image is determined by the ratio λ/r_0 rather than λ/D. The angular resolution is diminished due to the atmospheric turbulence (see Figure 5). For a 4 m telescope, atmospheric distortion degrades the spatial resolution by more than one order of magnitude compared to the diffraction limit, and the intensity at the center of the star image is lowered by a factor of 100 or more. Even at the best astronomical sites, ground-based telescopes observing at visible wavelengths cannot, because of atmospheric turbulence alone, achieve an angular resolution better than telescopes of about 20 cm diameter.

Most of the distortions imposed by the atmosphere are in the wave-phase and an initially plane wavefront traveling 20 km through the turbulent atmosphere accumulates, across the diameter of a large telescope, phase errors of a few micrometers.

Turbulence is distributed along the propagation path through the atmosphere, and then the wavefront errors become uncorrelated as the field angle increases. This effect is known as angular isoplanatism and is one of the major limitations to the astronomical adaptive optics. The structure becomes completely uncorrelated out of the isoplanatic angle, approximately equal to r_0/H, where H is the altitude of the turbulence layer. This decorrelation is sketched in Figure 5, where the short exposure images for objects 1 and 2 have different speckles structure.

In Earth's atmosphere significant turbulence occurs at altitudes up to 20 km, often with large peaks in the vicinity of the tropopause, at around 10 km there exist, in practice, more than one parameter H in Figure 5, one for each turbulence layer. This three-dimensional distribution of the turbulence considerably restricts the angle over which adaptive compensation is effective and leads to the design of multiconjugate adaptive optics, as we next explain.

Adaptive System Design

As stated above, an active system is composed of at least one wavefront sensor and one deformable mirror. Typically, the wavefront is corrected by making independent tip, tilt, and piston movements of the deformable mirror surface, as shown in Figure 6. As a rule of thumb, a deformable mirror used for atmospheric correction should have one actuator for each Fried's cell, such that the total number of actuators should be equal to the number of Fried's cells filling the telescope aperture, i.e., D^2/r_0^2. For instance, a near-perfect correction for an observation in visible light (0.6 μm) with an 8 m telescope placed in a good astronomical site ($r_0 = 20$ cm), would require a deformable mirror with approximately 6400 actuators in its adaptive optics system. Recalling that r_0 is strongly dependent on the wavelength (i.e., proportional to $\lambda^{6/5}$), similar performance in the infrared at 2 μm requires only 250 actuators. This is one reason why adaptive correction is easier in the infrared. A large number

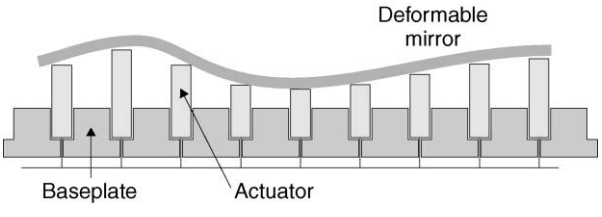

Figure 6 A sketch of a deformable mirror.

of Fried's cells requires a similarly large number of subapertures in the wavefront sensor. Commonly used WSs are based on modifications of the classic Hartmann screen test or of curvature type. In the former case the adaptive device is made with individual piezoelectric actuators (see Figure 6), while in the latter the correction is achieved with a bimorph adaptive mirror, made of two bonded piezoelectric plates. With both methods, wavefront sensing is done on a reference off-axis object (Figure 3), or even on the observed object itself (Figure 4) if it is bright enough. In the former case the angular distance of the reference object must fall inside the isoplanatic angle and must be sufficiently luminous. In typical astronomical sites the isoplanatic angle at a wavelength of 0.6 μm is ~5 arcsec, while it can be ~20 arcsec at 2 μm. This is an additional reason why the adaptive optics system is most efficient in the infrared range. Correction in the visible requires a reference star approximately 25 times brighter than in the infrared. Most current astronomical systems are designed to provide diffraction-limited images in the near-infrared (1 to 2 μm) with the capability for partial correction in the visible. However, some military systems for satellite observations do provide full correction in the visible on at least 1 m class telescopes.

The control system is generally a specialized computer that calculates, from the WS measurements, the commands to send the actuators of the deformable mirror. The calculation must be performed quickly (within 0.5 to 1 ms), otherwise the state of the atmosphere may have changed making the wavefront correction inaccurate. The required computing power can exceed several hundred million operations for each command set sent to a 250 actuator deformable mirror. As in active optics systems, zonal or modal control methods are used. In zonal control, each zone or segment of the mirror is controlled independently by wavefront signals that are measured for the subaperture of that zone. In modal control, the wavefront is expressed as the best-fit linear combination of polynomial modes of the wavefront distorted by the atmospheric perturbations.

Future Development

As explained above, a convenient method for measuring the wavefront distortion is to look for an off-axis reference star (also known as natural guide star, NGS) within the isoplanatic angle. However, it is generally impossible to find a bright reference star close to an arbitrary astronomical target. Conditions are far better in the infrared than in the visible because atmospheric turbulence (and in particular its high spatial frequencies) is, for a given AO correction, less pronounced at longer wavelengths. The spatial and temporal sampling of the disturbed wavefront can be reduced, which in turn can permit the use of fainter reference stars. Coupled with the larger isoplanatic angle in the infrared, this gives a much better outlook for AO correction than in the visible.

Nevertheless, even for observations at 2.2 μm, the sky coverage achievable by this technique (equal to the probability of finding a suitable reference star in the isoplanatic patch around the chosen target) is of the order of 0.5 to 1%. It is therefore unsurprising that most scientific applications of AO have to date been limited to the study of objects which provide their own reference object. The most promising way to overcome the isoplanatic angle limitation is by the use of artificial reference stars, also referred to as laser guide stars (LGS). These are patches of light created by the back-scattering of pulsed laser light of sodium atoms in the high mesosphere or by molecules and particles located in the low stratosphere. The laser beam is focused at an altitude of about 90 km in the first case (sodium resonance) and 10 to 20 km in the second case (Rayleigh diffusion). Such an artificial reference star can be created as close to the astronomical target as desired, and a wavefront sensor measuring the scattered laser light is used to correct the wavefront aberrations on the target object.

Military laboratories have reported the successful operation of adaptive optics devices at visible wavelengths using laser guide star on both a 60 cm telescope and a 1.5 meter telescope, achieving an image resolution of 0.15 arcsec. Nevertheless, there are still physical limitations of a LGS. The first problem, focus anisoplanatism, or cone-effect, was realized long ago. Since the artificial star is created at a relatively low altitude, back-scattered light collected by the telescope forms a conical beam, which does not cross the same turbulence-layer areas as light from the astronomical target. This leads to a phase estimation error, which in principle can be solved by the simultaneous use of several laser guide stars surrounding the targeted object. A more significant problem is image motion or tilt determination. Since the paths of the outgoing and returning light rays are the same, the centroid of the artificial light appears to be stationary in the sky, while the apparent position of an astronomical source suffers lateral motions (also known as tip/tilt). The simplest solution is to supplement the AO system and LGS with a tip/tilt corrector set on a (generally) faint close NGS. Performance is then limited by poor photon statistics in the tip/tilt correction.

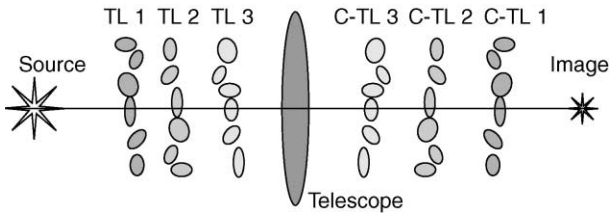

Figure 7 Conjugated planes of turbulent layers.

Adaptive optics with a multicolor laser probe is another concept that has been studied to solve the tilt determination problem of laser beacon based AO. Only applicable to sodium resonant scattering at 90 km, it excites different states of the sodium atoms and makes use of the slight variation in the refraction index of air with wavelength. Its main drawback is the limited returned flux, due to the saturation of mesospheric sodium layer.

The quality of a site for adaptive optics is determined not only by the median seeing, but also by the height and thickness of the turbulent layers (often only a few thin layers dominate). Some adaptive-optics systems can be adapted to correct for turbulence originating at a particular height by using several reference stars. This technique is known as multiconjugate adaptive optics (MCAO) and is still in his infancy. This concept deals with a 3-D view of the atmosphere, and for this reason it is also called turbulence tomography. Several wavefront sensors are needed for tomography. Turbulence tomography is also useful to correct for the cone effect when using LGS. When several deformable mirrors are placed on the appropriate conjugate planes, as shown in Figure 7, anisoplanatism reduces and the size of the corrected field of view increases. The situation is roughly depicted in Figure 7, where each turbulent layer (indicated as TL) has a proper conjugated plane (C-TL).

Another challenging optical solution is one of utilizing large secondary adaptive mirrors. This application seems especially interesting at thermal wavelengths, where any additional mirror raises the significant thermal background detected by instruments.

Other Adaptive Optics Applications

In recent years the adaptive optics technique has been developed in many applications beside astronomy and the military, for example, as in high-power laser welding or cutting, in ophthalmology and in aero-optics.

In high-power laser applications, thermal blooming takes place when laser light is absorbed by the gases and particles that make up the atmosphere. Since energy is conserved, the energy lost by the laser (its intensity diminishes) is gained by the atmosphere that heats up. This inhomogeneity at the boundary of the laser beam generates wavefront distortions by turbulence, as shown in Figure 8. This means that laser light that passes through the air at a later time interacts with a different atmosphere than the light that passed by earlier. The net effect is that, in the case of a Gaussian laser beam, light following a wavefront which passed at an earlier time, 'sees' a concave lens that deflects the successive rays out of the beam (away from the axis) causing the beam to appear to grow in radius or 'bloom'. Adaptive optics techniques for real-time compensation of blooming in laser beams were developed in the late 1960s. Given the high coherence and monochromaticity of a laser, the technique is more straightforward than for more common white-light applications of the astronomical applications.

Density fluctuations in a compressible shear layer are sufficiently high to cause a time varying index of refraction of the layer. This situation is common in a turbulent flowfield, and the study of the wavefront aberrations induced by this flowfield, when it is of relatively short propagation length in the near-field of the optical system, is referred to as aero-optics. Turbulent flowfield induces various types of degradations in the performances of an optical system. For example the jitter and defocusing of laser-based weapons cause a reduction in the amount of energy delivered to the target. Tracking systems experience bore-site errors and imaging systems experience blurring. Recent work suggests that adaptive optics compensation may successfully overcome these problems.

In ophthalmology the adaptive technique finds application in studying the retina of the eye. In this case the eye itself produces wavefront aberration, and the retina is seen as blurred. Techniques in ophthalmic laser surgery are being developed to use adaptive optics to correct for detected distortions.

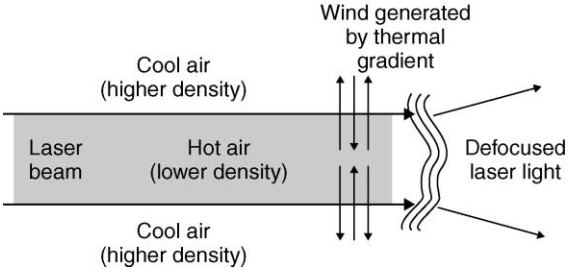

Figure 8 Thermal blooming effect in high-power laser applications.

In the field of telecommunications, studies are in progress for using adaptive techniques in data transmission between ground-based stations and satellites.

Hyperspectral Imaging

M L Huebschman, R A Schultz and H R Garner, University of Texas, Dallas, TX, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Hyperspectral imaging techniques on a microscopic level have paralleled the hyperspectral remote astronomical sensing which has developed over the years. It is especially apparent in remote sensing of our own planet's land masses and atmosphere, such as in the LANDSAT satellite program. In biology, biochemistry, and medicine, hyperspectral imaging and multispectral imaging are often interchanged, although there is a distinct difference in the two techniques.

A multispectral imager produces images of each of a number of discrete but relatively wide spectral bands. Multispectral imagers employ several wide bandpass filters to collect the data for the images. A hyperspectral imager produces images over a contiguous range of spectral bands and, thus, offers the potential for spectroscopic analysis of data. Hyperspectral imagers may use gratings or interferometers to produce the contiguous range of spectral bands to record.

Fluorescent dyes (also referred to as fluorophores or fluorochromes) and recently quantum dots, as markers, are a very powerful tool for analyzing organic tissues for researchers in cytology (study of cell function), cytogenetics (study of the human chromosomes), histology (study of structure and function of tissues), microarray scanning (analysis of concentrations of multiple varied probes), and biological material science. Without the correlation of the spectral and spatial data in biological images, there would be little useful information for the researcher. Therefore, hyperspectral imaging in the biological sciences must combine imaging, spectroscopy, and fluorescent probe techniques. Such imaging requires high spatial resolution to present a true physical picture, and the spectroscopy must also have high spectral resolution in order to determine the quantities of biochemical probes present. The correlation must provide the color-position relation for identification of meaningful information.

This description will begin with an initial review of multispectral imaging to lead into a discussion of hyperspectral imaging. The discussion will examine aspects of hyperspectral imaging based on an interferometric method and on a grating dispersion method similar to the methods in multispectral imaging.

Image Parameters

The analysis of fluorophores involves the excitation of the dye with a shorter wavelength and thus higher energy than the emission spectrum. The use of the appropriate excitation wavelength will yield a maximum emission intensity at a characteristic wavelength. The quality of a fluorescent image generally combines contrast and brightness. Contrast depends on the ratio of emission intensity to that of background light. Consequently, the use of filters to block the excitation wavelength and prevent it from overwhelming the field is critical in providing high contrast for the detection of fluorophore emission. However, the use of narrow filters to restrict the background can severely limit the brightness of the fluorescent image. This is due to the barrier filters allowing only a portion of the actual emission spectrum to pass. Brightness is an intrinsic property of each individual fluorophore, but is also dependent on the ability to illuminate with the peak excitation wavelength for that fluorophore.

The balance between contrast and brightness may be further complicated by applications designed to facilitate the evaluation of multiple fluorophores. The selection of appropriate excitation and emission filters within a single set to allow for the simultaneous viewing of multiple fluorophores can be very inhibiting. Although quad-band beamsplitters are currently available, commercial advances to date have yielded only triple-pass combinations for simultaneous detection, such as one of which permits the simultaneous detection of the widely used fluorophore combination fluorescein-5-isothiocyanate (FITC), Texas Red and 4′,6-diamidino-2-phenylindole (DAPI) (e.g., Chroma Technology Corp.).

Although the capture of digital images has propelled this field, efforts to collect multicolored images as digital files also suffer from technical limitations. Color CCD cameras often utilize filters or liquid crystals to segregate the red, green, and blue wavelengths onto the imaging chip. The employment of these cameras is restricted to resolving colors as discriminated by the filters used. For scientific applications, then, the greatest sensitivity and selectivity has been achieved through black and white CCD cameras with optimized filters for a specific application. While this approach is widely used, it suffers from the inherent limits of the spectra of data that can be analyzed since it is defined by the characteristics of the optical filters employed. Thus, the system is restricted to the use of fluorophores that can be effectively resolved from each other by filters, and the filters selected limit the data collected to a portion of the total emission spectrum for any one fluorophore.

Multispectral Imaging

Multispectral imaging systems in biomedical research are composed of a microscope, filters and/or interferometer for spectral selection, a charged coupled device (CCD) camera to record the data, and computer control for acquisition, analysis, and display (Figure 1a). The introduction of CCD cameras has offered a means to document results and capture images as digital computer files. This has facilitated the analysis of results with more and more complex probe sets and has allowed the use of more sophisticated computer algorithms for data analysis. The other major component of the multispectral imaging system is a light source to excite the sample's fluorescent dyes whose emissions are selected by filters or an interferometer for recording on the CCD camera.

An example of the use of multispectral imaging is in the identification of the 24 human chromosomes. A scheme was presented for the analysis of human chromosomes by differentially labeling each chromosome with a unique combination of 5 fluorophore-labeled nucleotides (building blocks of DNA and RNA, consisting of a nitrogenous base, a five-carbon sugar, and a phosphate group). These complex probes are simultaneously hybridized to metaphase chromosomes and analyzed to determine which of the fluorophores are present. Combinations of one, two, or three of the five fluorophores are enough to distinguish a particular chromosome from the others.

An interferometric multispectral system used to perform this type of analysis is the Spectral Karyotyping (chromosome typing) or SKY System (Figure 1a). This technology does not represent hyperspectral imaging, but is presented for comparison. Illumination light passes through a triple band-pass dichroic filter which allows for the simultaneous excitation of all the fluorochromes in, for instance, Speicher's scheme. Modern multi-band pass filters add little to image distortion while effectively blocking unwanted autofluorescence or excitation illumination. The fluorescence emissions from the sample are split into two separate beams by the interferometer. The beams are then recombined with an optical path difference (OPD) between them such that the two beams are no longer in register and interfere with each other. By adjusting the OPD, a particular wavelength band can be selected for, which results in constructive interference and thus can be collected by the CCD camera pixels. After adjusting the OPD to record

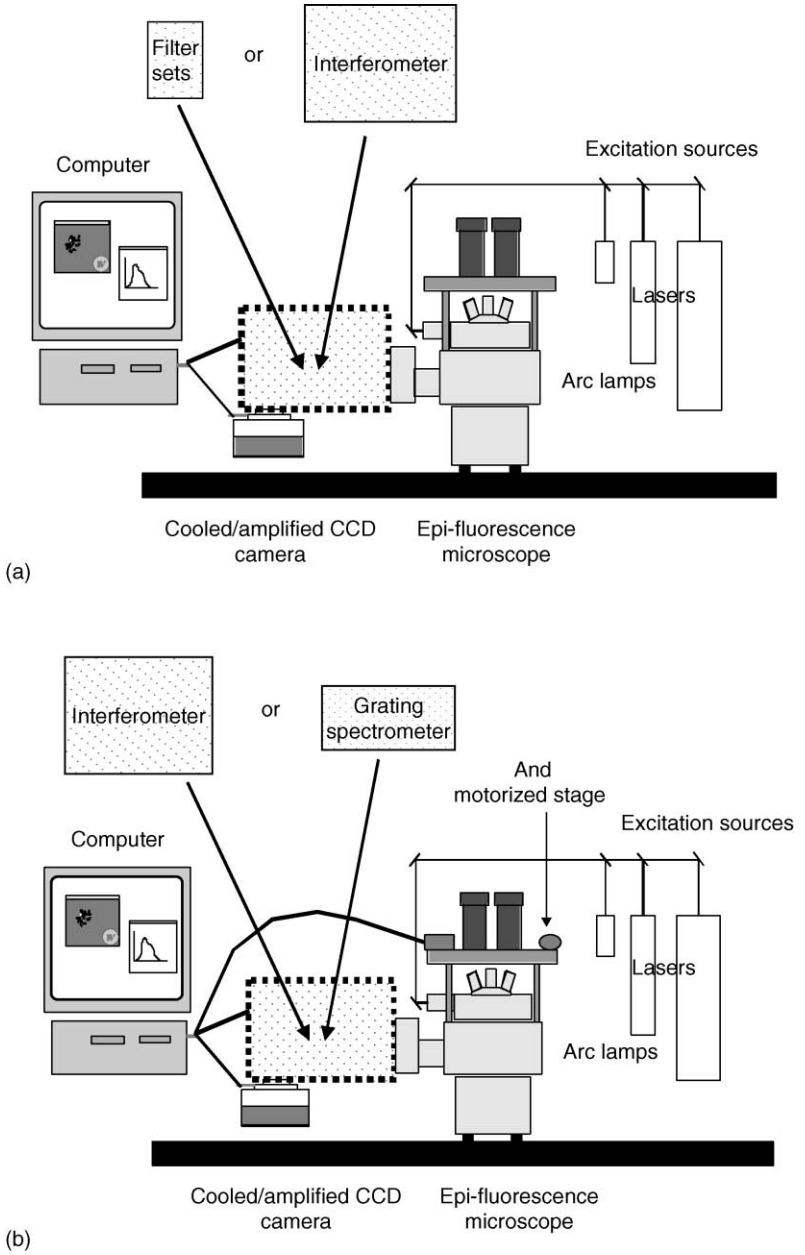

Figure 1 The instruments for multispectral and hyperspectral imaging are similar. (a) Multispectral imagers use interferometers or bandpass filters to collect noncontiguous emission wavelengths. (b) Hyperspectral imagers employ interferometers or gratings to collect a contiguous wavelength band. Computers, microscopes, CCD cameras, and excitation light sources are common to all the techniques. The systems which use filter sets or interferometers use motorized filter placement systems or automated interferometers. The gratings systems employ a motorized stage for the sample movement. Adapted with permission from Schultz RA, Nielsen T, Zavaleta JR, Ruch R, Wyatt R and Garner HR (2001) Hyperspectral imaging: a novel approach for microscopic analysis. *Cytometry* 43: 239–247.

the 5 dye wavelengths, each pixel's 5 records are then compared to the known probe-labeling scheme to identify the corresponding chromosome material. The image of the metaphase chromosome spread can be karyotyped using specific pseudo-colors for maximal visual discrimination of the chromosomes.

Another nonhyperspectral method is the Multi-Fluorescence *In Situ* Hybridization or M-FISH System. It uses five single-band-pass excitation/emission filter sets where each filter set is specific for one of the five fluorochromes used in the combinatorial labeling process (Figure 1a). Again, five separate exposures are taken (one exposure for each filter set) and combined to create a multicolor image. Most M-FISH systems now have motorized filter set selectors which minimize any image registration

shifts that may occur between exposures. For each pixel, the presence/absence of signal from each of the five fluorochromes is assessed and then matched to the probe-coding scheme to determine which chromosome material is present. As with the SKY System, an image of the metaphase spread is converted into a karyotype and specific pseudo-colors are used to maximize visual discrimination of the chromosomes.

Hyperspectral Imaging

As has been stated, the main difference between multi- and hyper-spectral imaging is the collection of a broad contiguous band of wavelengths. The apparatus and methods for hyperspectral imaging are similar to multispectral imaging (Figure 1). Instead of collecting sections of the emission spectrum using filters or interferometers, hyperspectral imaging collects a continuous emission spectrum by dispersing the wavelength of light using gratings and measuring the wavelength intensity, or by dispersing Fourier components of light using interferometers and measuring interference intensity (Figure 1b). Multispectral images are limited to measuring total intensity within the selected wavelength band. Determining the abundance of more than one dye per pixel is less accurate when only a small segment of each dyes' spectrum is passed by the emission filter. This has not been considered a limitation in the past because most research depended on just identifying the presence and not the abundance of several spectrally broad and overlapping dyes which also occupied relatively large spatial areas. With the advent of smaller and smaller featured microarrays, the desire to use more dyes in identification schemes, and the use of quantum-dot markers which can be used to indicate both genetic makeup and quantity, the limitations of multispectral imaging has led to a move to hyperspectral imaging.

In contrast to the fluorescence multispectral imaging approaches, a hyperspectral image is fully three-dimensional. Every XY spatial pixel of the image has an arbitrarily large number of wavelengths allied with it. An intensity cube of data is collected. Two of the axes of the cube are spatial and one axis is wavelength (see Figure 2). At each of the 3D points, there is an associated intensity of emitted energy. Therefore, it is a four-dimensional information space. The individual intensity signature of differing emitting bodies can then be separated to give a complete view. Spectral decomposition is a mathematical/algorithmical process by which individual emission spectra of the dyes can be uniquely separated from a composite (full spectral) image by knowing the signature of each dye emission spectra component measured separately. Spectral decomposition may be performed using standard algorithms with codes which are readily available.

Interferometric Hyperspectral Imaging

The system architecture of the interferometric hyperspectral imager resembles that of the SKY System (Figure 1). But, instead of just sequencing the interferometer to select a set of specific wavelengths to record as in the SKY System, the interferometer in the hyperspectral imager is sequenced through

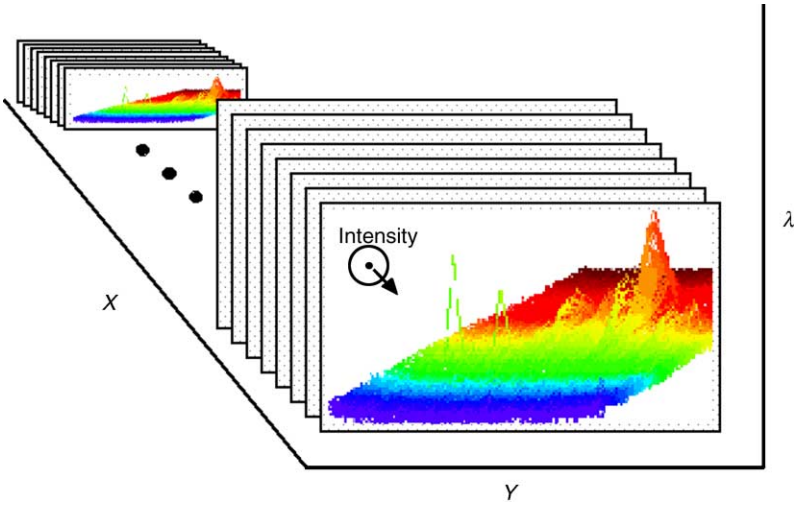

Figure 2 Intensity data cube. In this data cube, each CCD exposure captures a measurement in intensity (number of counts) by wavelength for a small spatial area in Y and ΔX. Many displacements in X with subsequent CCD acquisitions yield a 'cube' of data in X, Y, and λ. The intensity counts may be thought of as another dimension, $I(x,y,\lambda)$. Another form of the data cube is with each CCD acquisition comprising intensity counts for a spatial X and Y area for a small $\Delta\lambda$ and multiple displacements in λ for each acquisition.

discrete optical path differences to record the intensity at each pixel for each OPD. Fourier spectroscopy techniques are used to transform the OPD intensities at each pixel into the wavelength intensities at each pixel. Each pixel may be thought of as a Fourier spectrometer which is not dependent on any other pixel. Then, spectral decomposition algorithms can be run to determine which dyes are present (see the next section).

Like the multifilter methods, the interferometer approach provides a real two-dimensional image that can be observed, focused, and optimized prior to measurement. But like the filtering methods, the excitation source must be filtered for sufficient contrast to view the fluorescent emissions. Interferometers have high optical throughput, relative to other methods, and can have high and variable spectral resolution. The spectral range can cover from the ultraviolet to the infrared. The high and variable spectral resolution allows the user to trade off sensitivity, spectral resolution, and acquisition time in a way that is not possible with any other technique. And interferometers do not cause polarization of light as a filter may.

However, interferometric instruments are susceptible to image registration and lateral coherence difficulties. They are limited by the extreme precision required of the optical components which results in the continuous need for monitoring and adjustment, since aberrations are not tolerated in interferometric instruments. The throughput is reduced by loss due to the beamsplitter design and from the mirrors. Additionally, the Fourier transform instrument deconvolutes based on a two-step process; the correlation of the light passed by an interferometer followed by an inverse Fourier transform in software.

To mitigate the extreme precision and sensitivity of the most interferometric systems, Sagnac interferometers have been employed because of their common path intrinsic stability. The common path compensates any misalignment, vibration, or temperature affect. The OPD is provided by the Sagnac affect. When the Sagnac interferometer is rotated, the path traveled in one direction will be different from that of the light on the common path in the other direction. Although, this interferometer method is trading one difficulty for another, it is somewhat easier to manage the rotation of a physical system than to maintain the exacting precision of mirror alignments in a standard interferometer.

Spatial Resolution

The spatial resolution of a Sagnac Hyperspectral Imager is set by the size of the pixels of the CCD camera and the microscope system magnification, since the interferometric hyperspectral viewer sees the entire field of view at once. Let the x- and y- dimensions of the CCD pixel be δx and δy, respectively, and the magnification be M, then the spatial resolutions in the x and y directions are $2\delta x/M$ and $2\delta y/M$, respectively. For CCD pixel sizes of 10 microns square, binning together two pixels in the x- and two pixels in the y- direction, and an overall magnification of 60, the x and y resolutions are both 0.66 microns.

Field of View

For N pixel rows and C pixel columns, the field of view will be $N\delta y/M$ and $C\delta x/M$ for the length of the area along the y- and x- axis, respectively. For a CCD array of 1536 columns by 1024 rows, and the parameters above, the field of view is 171 microns by 256 microns, x and y, respectively.

The sensitivity, dynamic range, and spectral response are set by the CCD camera optical components.

Spectral Resolution

Spectral resolution will depend on the ability to vary the OPD and the Fourier transform. While the interferometer is used basically as a filter in the multispectral imager to select a wavelength, in the hyperspectral imager it is used to vary the OPD for all the wavelengths whose energy is integrated at the CCD camera pixels.

The electric field, E, for emissions at one wavelength, λ, or wave number, $k = 1/\lambda$, radial frequency, ω, and amplitude, A, can be written as

$$E(k) = A(k)\, \mathrm{e}^{-\mathrm{i}(2\pi kx - \omega t)} \qquad [1]$$

and the intensity which is measured is the magnitude squared of the electric field:

$$I = E^{*}E \qquad [2]$$

Emissions from fluorescent sources are usually noncoherent and composed of a range of wavelengths, even with only one dye present. The intensity measured at a pixel is the superposition of many wave numbers. After traveling a certain OPD, L, the intensity integrated over all wave numbers may be written as

$$I_{\mathrm{pxl}}(L) = \frac{1}{2}\left[\int I(k)\mathrm{d}k + \int I(k)\cos(2\pi kL)\mathrm{d}k\right] \qquad [3]$$

or

$$I_{\mathrm{pxl}}(L) = C_0 + C_1 \cdot \mathrm{Re}\{\mathrm{FT}[I(k)]\} \qquad [4]$$

where FT stands for Fourier transform.

The inverse transform is

$$\int I_{\text{pxl}}(L)\, e^{-i2\pi k' L}\, dL = C_0 \int e^{-i2\pi k' L}\, dL + C_1 \int\int I(k) e^{-i2\pi k L'}\, dk \cdot e^{i2\pi k' L}\, dL \quad [5]$$

$$\int I_{\text{pxl}}(L) e^{-i2\pi k' L}\, dL = C_3 + C_4 I(k)$$

The integration constant, C_3, can be ignored for large wave numbers, as in the case of the visible range, since C_3 will be proportional to the inverse of the wave number. The intensity as a function of wave number is then

$$I(k) = C_5 \int I_{\text{pxl}}(L) e^{-i2\pi k L}\, dL \quad [6]$$

For absolute quantitative measurements, the constant C_5 can be determined by calibration with a known emission. For discrete measurements made by changing the optical path length, then the working formula is

$$I_{\text{pxl}}(k) = \sum_{L_i} I_{\text{pxl}}(L_i) e^{-i2\pi k L_i}\, \Delta L \quad [7]$$

This is the discrete Fourier transform which must be preformed for each pixel to determine the intensity as a function of wavelength. Per the Nyquist sampling tenets:

$$\Delta L = \frac{1}{(N/2)\Delta k} \quad \text{or} \quad \Delta k = \frac{2}{N \Delta L} \quad [8]$$

where Δk is the discrete wave number interval and N the number of different OPDs. Sagnac interferometers can make rotations which give at least a change of $\Delta L = \lambda/4$, so substituting in eqn [8]:

$$\Delta k = k_1 - k_0 = \frac{1}{\lambda_1} - \frac{1}{\lambda_0} = \frac{\Delta\lambda}{\lambda^2 + \lambda\Delta\lambda} = \frac{8}{N\lambda} \quad [9]$$

$$\frac{\Delta\lambda}{\lambda^2} \approx \frac{8}{N\lambda} \quad \text{or} \quad \frac{\Delta\lambda}{\lambda} \approx \frac{8}{N}$$

A 5% resolution in wavelength (or 20 nm at 400 nm) requires $N = 160$ and, of course, a 2.5% resolution requires $N = 360$. Therefore, about 400 OPD changes and acquisitions of the intensity fringes will give calculated resolutions of less than 10 nm in wavelength.

Analysis of the spectrum based on this resolution can be conducted to determine which dyes are present. Software techniques for displaying data will be described in the next section.

Grating-Dispersion Hyperspectral Imaging

A hyperspectral imaging microscope collects the complete visible emission spectrum from a microscope slide by using a grating spectrometer to provide the wavelength dispersion. This microscope correlates spatial and spectral information with minimal use of optical filters. A hyperspectral microscope system is composed of a standard epi-fluorescence microscope (Olympus IX70) equipped with objectives lens (including 1.25 × and 10 × Plan Fluorite, 40 × Plan Apochromat Dry, and 60 ×, and 100 × Plan Apochromat Oil), as well as a set of standard filter cubes (Chroma Technology) to allow for traditional visualization of dyes through the eyepiece. (Prototype typical components are listed in parentheses.) Multiple excitation sources can be utilized including standard 100 W mercury and xenon arc lamps, tungsten brightfield illumination, a 532 nm solid state laser (Brimrose), a helium neon laser (Uniphase), an argon ion laser (Uniphase), and a pulsed-doubled nitrogen dye laser (Laser Science, Inc.) (Figure 1b).

One side port of microscope is optically coupled to a spectrograph (Acton Research SpectraPro® 556i). A narrow entrance slit into the spectrograph allows for only one line (ΔX) of the image to be captured at a time. A 50-micron slit permits 80% of maximum throughput for the spectrometer. The spectrograph separates the polychromatic light illuminated from this single line into its light components. Normal operation uses a grating with 50 grooves/mm and a 600 nm-blaze wavelength, which allows wavelengths of approximately 400–780 nm to be measured. Different spectrograph gratings can be used for special applications from near UV to near IR. The center wavelength and grating can be shifted under computer control. The output of the spectrograph is then captured with an air/liquid-cooled CCD camera (Photometrics-Quantix) and an optional image intensifier (Video Scope International VS4-1845). The camera has a resolution of 1536 × 1024 pixels with a depth of 12 bits per pixel. The 1536 pixels are aligned in the spatial direction to allow the greatest spatial resolution. During normal operation the wavelength resolution is 'binned' to 128 pixels, sufficient to resolve ~8 different spectra in a single excitation scan. Higher resolution can be employed for special applications.

A line of excitation light can be provided by a line generator when laser excitation is used or by a combination of slits and cylindrical lenses when using traditional lamps or burners (mercury or xenon). This line of light illuminates the sample in the same position that maps the resulting emission light

through the imaging spectrograph and onto the camera. Some advantages of illumination with a line of light include decreased sample bleaching, reduced background due to scattering, and efficient use of available excitation power. A traditional bandpass, a low-pass dichroic filter, or a linear variable filter (Raynard Corp.) may be employed to select or restrict the excitation wavelength during specific applications.

Linear Variable Filter (LVF)

The linear variable filter (LVF) (Raynard Corporation) can be used to replace the standard excitation filter cube to provide a capability for continuous excitation wavelength band selection. The LVF is $1'' \times 2.25''$ and is coated such that it continuously filters light from ~400 nm to ~800 nm along its length. Custom filters that span other wavelengths are available. The coating and therefore wavelength is uniform along a short distance, making it an ideal method for selecting an excitation wavelength band to paint across the slide, excite the slide's contents, and map the contents' emission into the slit of the imaging spectrograph. The bandwidth passed is about 21 nm wide. The LVF introduces ~50% attenuation of the intensity.

Spatial Resolution

The spatial resolution of a grating spectrograph Hyperspectral Imager is set by the size of the pixels of the CCD camera in the y- direction and the microscope system magnification. However, differing from the interferometric system, the spatial resolution in the x- direction depends on the spectrometer slit width and the microscope system magnification. As before, let the x- and y- dimensions of the CCD pixel be δx and δy, respectively, and the magnification be M. Let w_s be the slit width of the spectrometer, and note than the slit width is always going to be larger than a few δx. Then the spatial resolution in the y-direction is again $2\delta y/M$, but the spatial resolution in the x- direction is now $2w_s/M$. Again, for CCD pixel sizes of 10 microns square, binning together two pixels in the y-direction, and an overall magnification of 60, the y- resolution is 0.66 microns, as it was for the interferometer method. For a slit width of 50 microns, the x- resolution is 1.67 microns, independent of the number of pixels binned in the x-direction. The control software moves the stage the right number of steps to minimize the overlap or skipped areas. The slit width can be reduced, but at a loss of throughput or increased exposure time. The control software can compensate for different spatial resolution to display the image as 1:1.

Field of View

For N pixel rows (y- dimension) and C pixel columns (x- dimension), the field of view will be $N\delta y/M$ for the length of the area along the y-axis. If the spectrometer slit length is less than the height of the CCD, then the length is just h_s/M, where h_s is the slit length. We orient our CCD array so that the 1536-pixel dimension is along the y-axis. The y-view is thus 256 microns as in the interferometric example. To achieve the same field of view as the Sagnac method imager, we would need to take 103 stage movements and acquisitions. This highlights the difference in the two hyperspectral methods. The grating method collects the complete spectrum on each acquisition with no spectrometer adjustment but needs to step down the slide to produce the full spatial image. The interferometer method collects the complete spatial image on each acquisition with no position adjustment but needs to step the interferometer through a range of optical path differences to acquire multispectral content.

The sensitivity, dynamic range, and spectral response are set by the CCD camera optical components.

Spectral Resolution

Spectral resolution depends on spectrometer instrument function which includes the slit width, the dispersion of the grating, the CCD pixel size, and number of pixels binned together. The dispersion for normal operation was determined to be ~40 nm/mm or 0.4 nm/pixel in the 10 micron CCD pixel example. For example, binning of 8 pixels yields a spectral resolution of 3.2 nm at all wavelengths. To achieve this spectral resolution, the interferometer method would require 1000 OPD increments and acquisitions.

Analysis of the spectrum based on this resolution can be conducted to determine which dyes are present. Although the spatial resolutions differ considerably in the two methods, as long as the dye peaks are separated by the spectral resolution spacing, the spectral decomposition algorithms will find all dyes within the spatial resolution area. We have demonstrated that the analysis algorithms can resolve 5 dyes with peaks separated by more than 6 nm in various combinations and known quantity ratios against the dye standards. The program successfully identifies the dyes present with a 91% accuracy in the quantities.

Software

Software (*Hyper*Scope, a 'C' language program) controls all the hardware components for acquisition.

It includes features for analyzing and displaying the resultant $X-Y$ images and spectral information for the grating spectrometer Hyperspectral Imager. During a scan, individual pictures are taken in the $Y-\lambda$ plane, while the stage is incremented in the X-direction. A collection of such $Y-\lambda$ scan files, which can total from 50–1000, is merged to build an image cube (Figure 2). Another advantage of the single-line acquisition mode is that time-dependent features can be monitored continuously. The software was designed to permit repeated collection of a single line at variable time points. The utility of this feature has been demonstrated by capturing images of fluorescent objects moving through UV-transparent capillaries.

The software was designed to display the resulting $X-Y$ plane extracted in various ways from the image cube. A graph of the emission spectrum for any pixel within that image may be viewed by clicking on any pixel of interest in the $X-Y$ image (Figure 3c). A standard linear curve-fitting algorithm is used to determine the contribution of individual dyes to the measured emission spectrum. The software also features a windowing technique (integration of the emission spectra over a fixed window) which emulates standard filtering. An overlay feature within the software allows the curve fitting results to be displayed in false color and compared by viewing the composite for multiple fluorophores in a single image. Additionally, it permits the contribution of a fluorophore to be emphasized for visualization purposes by either displaying the contribution of a single fluorescent signature in the absence of the others that were present in the image or by scaling individual display intensity values up or down. Overlapping pseudo-colors assigned to represent each fluorophore (either by curve fitting or by windowing) may be displayed as added, averaged, maximum or minimum values. For each new fluorophore–excitation source combination, the characteristic emission spectra is acquired and added to a library of available spectra that can be used as components in the spectral decomposition. This permits the user to introduce new fluorophores at any time. Moreover, background spectra (defined as a region of interest by the user) can be acquired and used as one element of the decomposition. This background component can be turned off in the false color view (as any of the spectral components may be) resulting in enhanced noise reduction and visual contrast improvement.

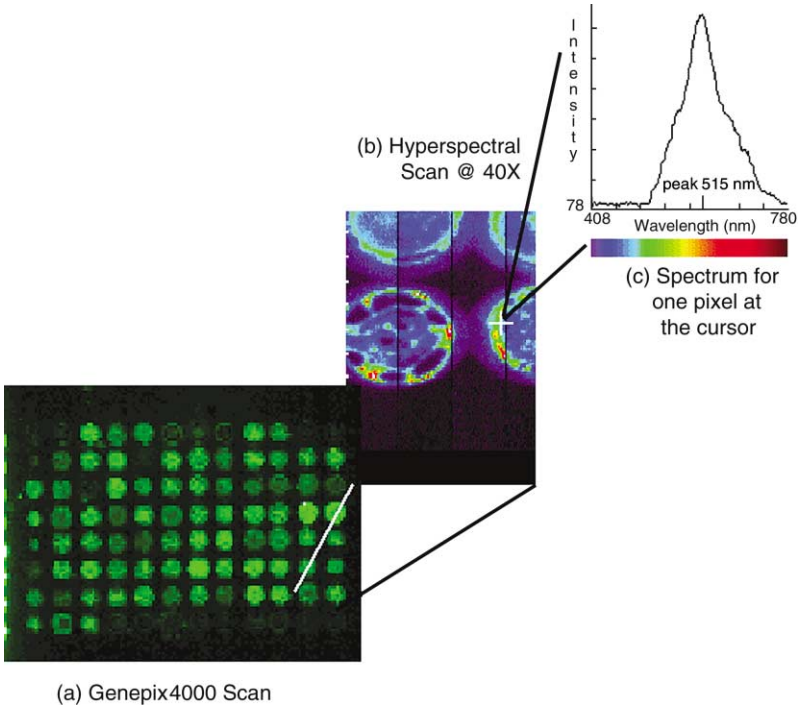

Figure 3 The benefit of spectral imaging is demonstrated in a spatial high-resolution scan of an expression microarray. (a) A portion of the scan of an expression microarray on a microscope slide using the Genepix4000 scanner. It records the intensity emitted by the Cy3 dye when excited with a 532 nm laser. (b) A portion of the scan of the same microarray with the Hyperspectral Imaging Microscope using a 40X objective and Hg excitation lamp. False color is displayed to indicate the intensity variations. (c) A *Hyper*Scope computer program display of the spectrum recorded when the cursor is placed over one pixel in a scan.

Description of Acquisition

In order to acquire a full image, a slide is placed on the microstage mover (Ludl Electronics) that allows for precise movement of the sample across the image acquisition plane. The user can position the stage via a joystick or via software to move to predetermined coordinates. The image is then scanned, with the number of scans being selected at the time of the image acquisition. Furthermore, the sample can be scanned at one magnification or resolution and then rescanned at another. Each $Y-\lambda$ image is saved as a single $Y-\lambda$ file for each increment along the sample. Thus, each image file corresponds to the excitation line of light and the emission collection region that maps through the imaging spectrograph to the CCD camera. Saving individual files permits unlimited $Y-\lambda$ image acquisition at the same Y coordinate, valuable for time-dependent studies. This feature also provides some robustness by enabling a partial $X-Y$ image to be displayed should acquisition of one or more Y scans fail for any reason. After acquiring each image, the stage is moved automatically, one or more steps in the X direction, to acquire emissions at the next line and generate the next $Y-\lambda$ file. Therefore, only the fluorescent probes in a line at a single X-location are examined at each acquisition time. Step sizes can be adjusted by the software to give: (i) the best resolution; (ii) the best 1:1 image; (iii) the minimum overlap; or (iv) the fast acquisition time.

After a variable number of rows of associated emission have been captured (typically 50–1000 scans), an image cube is loaded into memory comprising all the $Y-\lambda$ data files. A graph of the spectrum from any pixel (or bin) in the $X-Y$ plane may be displayed in a separate window by clicking on the cube (Figure 3c). A typical acquisition scan of 250 $Y-\lambda$ files, which are used to construct a $250 \times 768 \times 128$ ($\times 12$ bit) image cube, consists of approximately 100 Mb of information.

MicroArray Scanning and Customized Excitation

Another use of this technology is to analyze spotted microarrays. The Hyperspectral Imager has been compared to commercial two-color scanners with comparable sensitivity at approximately 0.5 fluors per square micron (Figure 3). Increased sensitivity (500–10 000 gain) can be provided by using a microchannel plate amplifier (Model VS4-1845, Videoscope International, Ltd.) installed between the CCD camera and the imaging spectrograph.

Since the hyperspectral imaging microscope collects images that reflect only the $Y-\lambda$ plane, it contains the potential to use a single line of light as a source for image illumination. Therefore, lights systems being developed, which are capable of generating a line of light composed of variable or complex wavelengths, could be employed to precisely control excitation. The incorporation of such an excitation source in hyperspectral imaging microscopy could be useful in many clinical and basic research applications.

Imaging Through Scattering Media

Introduction

We are often faced with the problem of seeing through scattering media such as smoke, fog, clothes, blood, tissues, ceramics, walls, etc. Tremendous effort has been made to introduce techniques which will allow us to overcome the intrinsic difficulty of selecting 'good' photons which are able to provide valuable information on structures which appear fuzzy or, for most of the time, completely hidden.

Although a number of concepts and techniques that we will discuss in this article could be applied to a large number of scattering samples, we will restrict ourselves to biological tissues.

Studying light propagation through biological tissues is becoming more and more popular among physicists, biologists, engineers, and doctors. Indeed this research domain appears to be growing rapidly as seen by the number of published articles, conferences, and international meetings. Optical techniques are attractive and are starting to compete with other well-established techniques (magnetic resonance imaging, X-ray imaging, ultrasonic imaging, positron emission tomography, etc.), because they are non-ionizing, nondestructive, they can reach high resolution and are usually much cheaper. Optical techniques reveal an optical contrast which is valuable in providing morphologic as well as functional information.

Most biological tissues are weakly absorbing in the deep red and near infrared region of the spectrum; the main difficulty in performing imaging arises from the high level of scattering. Figure 1 shows the picture of a small flash light bulb placed in the mouth: it appears fuzzy and red.

In Figure 2 we consider various photon trajectories between a short pulsed source S and a fast detector D.

Unscattered photons are called 'ballistic' photons, their number decreases exponentially, and they are completely damped after one or two millimeters.

Then there are scattered photons which propagate close to the ballistic trajectory reaching the detector; these are named 'snake-like' photons and can be used for imaging purposes.

Most of the energy which reaches D is related to the scattered photons which may exhibit very long trajectories (typically ~10 times the distance S–D).

The description of various experimental methods used to overcome the difficulty introduced by scattering will be associated with the various photon families that we have mentioned: ballistic, snake-like, and scattered photons. We will first give a few orders of magnitude of the parameters which will dictate the way light interacts with the tissues. Let us emphasize that these parameters also carry the information related to the contrast mechanism. The ultimate goal is to realize an 'optical biopsy', noninvasive but as close as possible to the regular biopsy followed by histopathology.

Figure 1 Biological tissues are highly scattering but the absorption is low in the red (as seen in this digital visible photography) and the near infrared.

Optical Parameters

Scattering Cross-Section

As shown in Figure 3, biological tissues are constituted of structures which exhibit various characteristic scales: from a few nanometers in membranes to about ten micrometers for an entire cell.

As we know from scattering theories these various scales correspond to various scattering properties. For small particles ('small' means much smaller than the optical wavelength λ) we are in the Rayleigh regime which is based on the evaluation of a time-varying dipole induced by a uniform time-varying (at the light frequency scale) electric field. This dipole radiates in the far field and its scattering cross-section, which is the ratio of the scattered power to the incoming irradiance for a sphere of radius r, is given by

$$\sigma = \frac{\langle P \rangle}{I} = \left(\frac{n^2 - 1}{n^2 + 2} \right)^2 \frac{8\pi}{3} r^6 k^4 \qquad [1]$$

n being the refractive index of the sphere divided by the index of the surrounding medium and $k = 2\pi/\lambda$. The scattering diagram for such particles is isotropic if we use unpolarized light. This cross-section is much smaller than the 'geometrical' section S of the particle; for instance, if $n = 1.5$, $a = 10$ nm, $\lambda = 0.6$ μm, $\sigma = 1510^{-8}$ μm^2, which is much smaller than the actual section (3×10^{-4} μm^2).

For larger particles the sphere (or the ellipse) interacting with a plane polarized wave is rather complicated because we are not restricted to the dipolar approximation (uniform field), but induced multipolar moments and their radiating fields have to be taken into account. This theory was proposed by Mie and can be found in optics textbooks. As an example, Figure 4 shows the scattering cross-section of a micron-size particle as a function of the

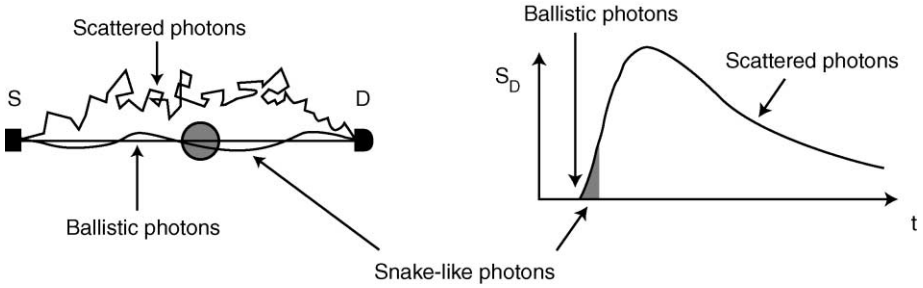

Figure 2 Between an ultrafast light source S and a detector D can be distinguished various classes of photons which can be used for imaging.

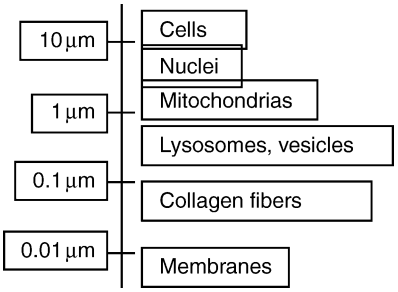

Figure 3 Various sizes of scatterers may be found in cell structures.

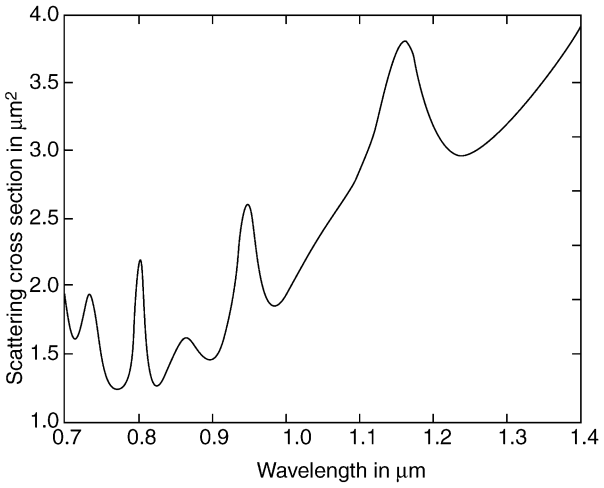

Figure 4 In the Mie scattering regime resonances are observed when varying the wavelength (here a 1 μm sphere, refractive index: 2).

wavelength: a number of 'resonances' can be observed.

The scattering diagram is no longer isotopic, it exhibits lobes, and forward scattering is much higher than back-scattering. Scattering is characterized by a scattering coefficient, μ_s, which is the inverse mean free path l_s of photons between scattering events:

$$l_s = 1/\mu_s = \sigma\rho \qquad [2]$$

where σ is the scattering cross-section and ρ the number of scatterers by unit volume.

The scattering coefficients μ_s of tissues are found within the range 100–1000 cm^{-1}. After a path length L, the number of ballistic photons will be damped by a factor $\exp(-L/l_s)$, so tissue imaging cannot rely only on ballistic photons as they survive only to a path length larger than about one mm. One needs to consider in more detail the scattering properties of the scatterers.

The dominant sizes of the scatterers in tissue (cells) demand consideration of the scattering in the Mie regime. Such a scattering event does not result in isotropic scattering angles. Instead, the scattering in tissue is biased in the forward direction.

Anisotropic scattering is quantified in a coefficient, g, which is defined as the mean cosine of the scattering angle θ, $p(\theta)$ being the probability of a particular scattering angle:

$$g \equiv \langle\cos(\theta)\rangle \equiv \frac{\int_0^\pi p(\theta)\cos(\theta)\sin(\theta)\mathrm{d}\theta}{\int_0^\pi p(\theta)\sin(\theta)\mathrm{d}\theta} \qquad [3]$$

For isotropic scattering, $g = 0$. For complete forward scattering, $g = 1$. In tissues, g varies from 0.7 to 0.95.

Photon migration, especially in the so-called diffusion regime, is often based on isotropic scattering such as for phonons (heat) or charge carriers scattering. For diffusion-like models, it has been shown that one may use an isotropic scattering model with a corrected scattering coefficient, μ_s', and obtain equivalent results using:

$$\mu_s' = \mu_s(1 - g) \qquad [4]$$

One can consider $l_s' = 1/\mu_s'$ as the length over which the incoming photon loses the memory of its initial direction, μ_s' is usually called the transport-corrected scattering coefficient.

Absorption Cross-Section

The absorption coefficient, μ_a (cm^{-1}) represents the inverse mean path length of photons before absorption. $1/\mu_a$ is also the distance in a medium at which intensity is attenuated by a factor of $1/e$ (Beer's Lambert law). Absorption in tissue is strongly wavelength dependent and is due to chromophores and water. Among the chromophores in tissue, the dominant component is the hemoglobin in blood. In the visible range, the blood absorption is relatively high, whereas it is much weaker in the near infrared. Water absorption is low in the visible and NIR region and increases above 1 μm, with tissues turning completely opaque above 2 μm. Thus, for greatest penetration of light in tissue, wavelengths in the 700–1300 nm spectrum are used. This region of the spectrum is called 'the therapeutic window'. Different spectra of chromophores allow one to separate the contribution of varying functional species in tissue such as quantification of oxy- and deoxy-hemoglobin to study tissue oxygenation.

Finally, when light is propagating in scattering media of thickness L, the damping of the incoming energy involves a combination of its absorption and

scattering properties, and is given by

$$\exp(-L/a) \qquad \text{with} \qquad a^2 = 1/3\mu_a(\mu_s' + \mu_a) \qquad [5]$$

This formula reflects the fact that the photon's pathlength is increased by scattering, leading to an increase of the damping, which is related to absorption.

These few examples provide a 'static' view of light behavior in scattering media. Studying in a more detailed way, the spatial and temporal distribution of light, is more difficult.

Photon Migration in Scattering Media

Photon migration models have been inspired by other fields, such as astrophysics, soft matter physics, and neutronics, where physical media are random in both space and time. To avoid difficulties linked to the microscopic complexity such investigations rely on a statistical basis.

The most widely used theory is the time-dependent diffusion approximation to the transport equation:

$$\vec{\nabla} \cdot (D\vec{\nabla}\Phi(\vec{r},t)) - \mu_a\Phi(\vec{r},t) = \frac{1}{c}\frac{\partial\Phi(\vec{r},t)}{\partial t} - S(\vec{r},t) \qquad [6]$$

where $\vec{r}$ and t are spatial and temporal coordinates, c is the speed of light in tissue, and D is the diffusion coefficient related to the absorption and scattering coefficients by the formula:

$$D = \frac{1}{3[\mu_a + \mu_s']} \qquad [7]$$

The quantity $\Phi(\vec{r},t)$ is called the fluence, defined as the power divided by the unit area. This equation does not reflect the scattering angular dependence; the use of μ_s' instead of μ_s ensures that isotropic scattering has been reached. Indeed, for the use of the diffusion theory which implies anisotropic scattering, the diffusion coefficient is expressed in terms of the transport-corrected scattering coefficient; $S(\vec{r},t)$ is the source term.

The diffusion equation has been solved analytically for different types of measurements such as reflection and transmission modes, assuming that the optical properties remain invariant throughout the tissue. To incorporate the finite boundaries, the method of images has been used.

The diffusion approximation equation in the frequency-domain is the Fourier transform of the time-domain equation. This leads to the equation:

$$\vec{\nabla} \cdot (D\vec{\nabla}\Phi(\vec{r},\omega)) - \left[\mu_a + \frac{i\omega}{c}\right]\Phi(\vec{r},\omega) + S(\vec{r},\omega) = 0 \qquad [8]$$

Here the time variable is replaced by the frequency ω which is the modulation angular frequency of the source. In this model, the fluence can be seen as a complex number describing the amplitude and phase of the so-called 'photon density wave' in addition to a DC component:

$$\begin{aligned}\Phi(\vec{r},\omega) &= \Phi_{AC}(\vec{r},\omega) + \Phi_{DC}(\vec{r},0) \\ &= I_{AC}\exp(i\theta) + \Phi_{DC}(\vec{r},0)\end{aligned} \qquad [9]$$

where θ is the phase shift of the diffusing wave whose wavelength is:

$$2\pi\sqrt{\frac{2c}{3\mu_s'\omega}} \qquad [10]$$

Although analytical techniques provide a rapid understanding of most phenomena involved in static or dynamic situations, real biological samples are much more complex than homogeneous isotropic media. In these cases, direct and inverse algorithms map the spatially varying optical properties.

Monte Carlo simulations are very popular nowadays; a number of useful programs are available on the websites of various groups. Results may include time or polarization dependence of the photons along their paths.

The other method used in tissue optics is the random walk theory (RWT) on a lattice. RWT models the diffusion-like motion of photons in turbid media in a probabilistic manner. Using RWT, an expression may be derived for the probability of a photon arriving at any point and time given a specific starting point and time.

Imaging in the Ballistic Regime: Taking Advantage of Various Coherence Properties

Shallow Tissue Imaging Through Selection of Ballistic Photons

When imaging thin (less than 2 mm) tissue samples, it is possible to use photons which have not been scattered, called the ballistic photons which can be used to form high-resolution images in the same manner as if no scattering had taken place.

Their number, however, decreases exponentially with propagation distance and this ballistic signal is usually hidden by multiply scattered photons that obscure the image. For relatively shallow tissue depths it is possible to use various spatial filtering techniques to block the multiply scattered photons and there is much current research that aims to

extend optical imaging and biopsy to depths of a few mm.

Confocal microscopy rejects much of the scattered light through spatial filtering and has been shown to form 3-D images at tissue depths of up to 200–300 μm, both *in vitro* and *in vivo*, which corresponds to about 50 dB of damping for the ballistic photons.

Two-photon fluorescence microscopy is particularly interesting in this regime since it ensures that all the detected fluorescence photons originate from the desired image plane. This technique also ensures a better penetration (using IR excitation) and a better resolution (nonlinear response) than single photon confocal microscopes.

Imaging to much greater tissue depths does not appear to be practical using optical microscopy and spatial filtering alone and more sophisticated techniques must also be employed to discriminate in favor of the ballistic photons. These techniques exploit either the fact that the ballistic signal photons retain spatial coherence of incident light or the fact that the ballistic photons keep the optical phase memory that multiply diffused photons have lost.

One of the most successful ballistic light-imaging techniques based on the latter filtering approach is optical coherence tomography (OCT) which uses coherence gating using low temporal coherence light and an interferometric detection. Coherent detection is used to discriminate against the multiply scattered photons that scatter back into the trajectories of ballistic photons. The ballistic light signal is measured by interference with a reference beam and the resulting pattern is detected with high sensitivity using homodyne or heterodyne detection. By using low coherence length sources and matching the time-of-flight of the reference beam signal to that of the desired ballistic light, OCT can acquire depth-resolved images in scattering media such as biological tissues. For powers in the mW range for tissue irradiation in the infrared, the unscattered ballistic (or more precisely single back scattered) component of the light will be limited by the shot noise detection limit after propagating through approximately 25 scattering mean free paths (MFP) of a scattering medium (or more than 100 dB). This corresponds to a 'typical' tissue thickness of about 1 mm tissue depth for the reflection geometry which is potentially useful for clinical applications such as screening for skin cancer, or for retinal examination.

OCT has proved clinically useful as a means of acquiring depth-resolved images in the eye and is being developed for application in strongly scattering biological tissue. Although the image acquisition requires pixel-by-pixel scanning, the use of new high-power superluminescent diodes in the 100 mW range or of ultrafast lasers to provide high average power, low coherence length radiation (sub-two cycle lasers) has resulted in an *in vivo* OCT system providing real-time imaging.

There are a number of other approaches to coherent imaging, including whole-field 2-D acquisition techniques which remove the need to scan transversely pixel by pixel.

Whole-field imaging using a temporally and spatially incoherent source and a well-balanced interferometric microscope intrinsically provides higher image acquisition rates and can take advantage of inexpensive spatially incoherent, broadband sources such as high-power LEDs, and white light thermal sources.

As an example, Figure 5 shows Linnik-type white light interferometer with optical path modulation and Figure 6 an image of an *ex-vivo* rat retina where one can recognize the main feature expected from histology.

Holography, which works in the Fourier space rather than in the object or image space, is also an interferometric technique able to discriminate between ballistic and scattered photons. Since the development of electronic holography, which takes advantage of available arrays of detectors with multimillion pixels, this approach is rapidly growing.

Real-time 3-D imaging systems based on photorefractive holography in multi-quantum-wells devices, which can potentially acquire depth-resolved images at thousands of frames per second, have been demonstrated.

These ballistic light techniques can extend the depth of tissue imaging to the mm range when

imaging in reflection. When it is necessary to image through cms, rather than mms of tissue, however, there will be no detectable ballistic light signal and one must extract useful information from the scattered photons.

Imaging in the Snake-Like Regime: Taking Advantage of Time (or Frequency) Gating

The first approach is to use time gating to select the earliest arriving scattered light, which will provide the most useful image information.

For moderate tissue depths one can exploit the fact that biological tissue is highly forward scattering, with most photons being only slightly deviated from their original direction upon each scattering event. After a few cm of tissue, there can be a significant number of photons that have followed reasonably well-defined 'snake-like' paths about the original direction through the tissue, arriving at the detector after the ballistic light but before the fully diffuse photons whose trajectories are effectively randomized. This early arriving light can be selectively gated using ultrafast lasers and a variety of detectors such as streak cameras, time-gated optical image intensifiers, and time-gated fast photon counting systems, which provide picoseconds time gates.

An alternative, sometimes cheaper, approach to temporal gating is the use of (high) frequency signal discrimination (which is the Fourier transform of the pulse experiment). The periodic solution of the diffusion equation with a periodic source term gives rise to the so-called 'photon density waves'. Such diffusive waves, like thermal waves, are used in the near-field regime (their amplitudes are damped by $\exp(-2\pi)$ after propagating over a single wavelength path) and they can reveal subsurface structures through their refractive and diffusive behavior. Coherence gating and polarization gating can be used when the early arriving light still retains some degree of coherence of the incident light. Indeed polarization discrimination has been used to select those photons which undergo few scattering events and therefore preserve a fraction of their initial polarization state, from the photons which experience multiple scattering resulting in a complete loss of memory of their initial polarization state.

As an example, Figure 7 shows the image of sub-mm light sources (LEDs) taken through 1 cm of polystyrene solution ($\mu_s' \sim \mu_s \sim 10\ \mathrm{cm}^{-1}$) by selecting photons which kept the memory of their initial circular polarization (here a few less than 1%). One can see the sources quite clearly.

For many important biomedical applications, such as mammography or imaging brain function, it is necessary to penetrate through 5–10 cm of tissue, after which all the detected signal is diffuse. Detecting earlier arriving photons can provide more information but, if the time window is too narrow, the detected signal becomes too weak to use with acceptable data acquisition times.

This problem is, however, being addressed with some success using statistical models of photon transport, with different degrees of approximation ranging from full Monte Carlo simulation of photon propagation to the diffusion equation. The approach is to address the inverse problem, i.e. to measure the scattered light signal as comprehensively as is practical and to calculate what distribution of absorption and scattering properties would have produced the measured signal. This provides a means to quantify the optical properties of biological tissue, averaged over a volume corresponding to a particular distribution of photon paths, and to form relatively low-resolution tomographic images.

Multiplying the number of sources and detectors and correlating the various intensity distributions over the whole structure under examination gives, as expected, better precision in localizing the size and position of the local structure to be identified.

Despite the multiple input and multiple output approaches, real-life situations with the previously

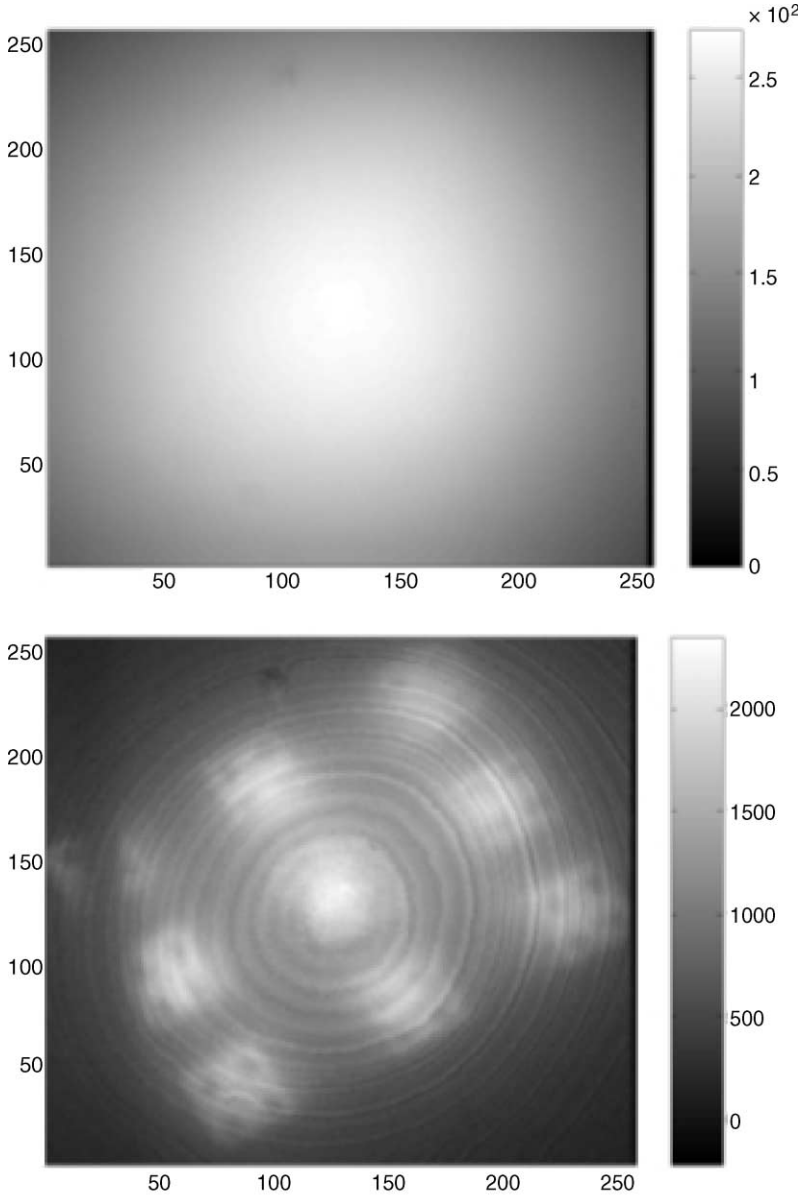

Figure 7 Polarization imaging: here the degree of circular polarization is measured in the upper image. The lower image shows the field without polarization filtering.

mentioned problem of the inhomogeneity of the optical properties of human tissues means that the results are still poor in term of resolution and sub-centimeter structures can hardly be observed in breast imaging, for instance.

One important exception to this limited success in finding precisely the position, the size, and the optical properties of hidden structures is the case of 'activation' studies. This corresponds to a 'differential' situation in which an unknown structure is locally changing with time. Here the goal is not to reach a full description of the unknown structure but only to characterize the local changes induced by the activation.

The main field of application of this approach is certainly in brain activation studies. A matrix of light emitters (usually at two wavelengths which differentiate oxy- and deoxy-hemoglobin, for instance 780 and 840 nm) is coupled to a matrix of light detectors. The signals are usually balanced and any local change which breaks the symmetry of the scattered photon paths induces a differential signal, easy to detect, because there is no background signal before activation takes place.

Moreover it has been demonstrated that for weak perturbations (weak variations of the optical parameters), the inverse problem can be rigorously solved. This geometrical selection provides a cheap and simple setup with rather spectacular results. Sometimes a modulation is added and the phase shift of the photon density wave is enhanced by the differential approach.

Imaging in the Multiple Scattering Regime: Taking Advantage of all the Photons

Light Only: Transillumination and Fluorescence Imaging

The optical systems used for CW measurements are rather simple and require only the alignment of a number of light sources and detectors. Compared to time-gated techniques due to multiple scattering a much stronger path length distribution is present in the signal and the result is a loss of localization and resolution. In the so-called transillumination geometry, collimated detection is used to isolate multiply scattered photons close to the normal emergence angle.

Direct imaging with the required resolution using CW techniques in very thick tissues, such as breast tissue, has not been established even with sophisticated multi-sources/multi-detectors combinations (typically a few tens of sources and detectors at three different wavelengths).

Despite rapid progress in the modeling of light behavior in scattering media it has not yet been demonstrated that CW imaging can provide images with suitable resolution in thick tissue and time-dependent measurement techniques discussed earlier are dominantly used.

For fluorescence imaging, one has to account for the strong attenuation of light as it passes through tissue. Fluorescent dyes (porphyrin, indo-cyanine, and more recently quantum dots) have been developed that are excited and re-emit in the 'biological window' at near-infrared (NIR) wavelengths, where scattering and absorption coefficients are lower, which is favorable for deep fluorescence imaging. Fluorescent intensity in deep tissues depends on the location, size, concentration, and intrinsic characteristics (e.g., lifetime, quantum efficiency) of the fluorophores, and on the scattering and absorption coefficients of the tissue at both the excitation and emission wavelengths. In order to extract intrinsic characteristics of fluorophores within tissue, it is necessary to describe the statistics of photon path lengths which depend on all these different parameters. The amount of light emitted at the site of the fluorophore is directly proportional to the total amount of light impinging on the fluorophore.

Using fluorescence contrast has the unique feature of carrying two spectroscopic contrasts related to both excitation and fluorescent photons.

The next two techniques take advantage of another way to handle the optical information by coupling optics and acoustics.

Coupling Light and Sound: Acousto-Optic and Photo-Acoustic

Although the two approaches that we will now describe are different in their basic principles as well as in the experimental setups, their names are similar – opto-acoustics (sometimes called photo-acoustics) and acousto-optics.

Opto- (or Photo-)Acoustics

In this technique a pulsed (or modulated) electromagnetic beam irradiates the structure under examination. Despite their tortuous paths (about 10 to 100 cm) photons propagate through the volume in a few nanoseconds. Local absorbing centers then absorb the electromagnetic energy, they experience a fast thermal expansion, and become sources of acoustic waves.

The optical problem of tomographic reconstruction is then transformed into a simpler problem of acoustic reconstruction of source distribution because the speed of the sound is much slower than the speed of the light. More precisely we can compute the signal generated by a short light pulse impinging on a scattering medium which contains an absorber (thickness e) as can be seen on Figure 8, when $e\mu_a \ll 1$.

The amount of power per unit surface which is deposited in the absorbing slice is $E\mu_a$ (E is the fluence in W/m^2). When the light pulse duration τ is short enough, despite the propagation in the scattering medium ($\tau \ll e/v$ where v is the speed of the sound),

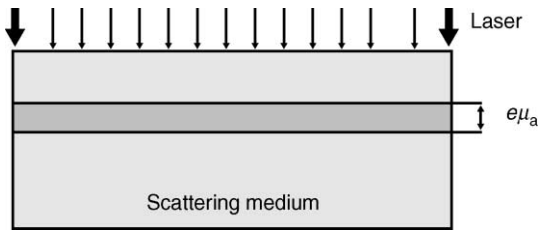

Figure 8 Photo acoustic signal generation: 1-D model.

we find a variation of the mass by volume unit:

$$\Delta\rho \sim \rho\beta\Delta T \sim \rho\frac{\beta E\mu_a e}{C_v e} \qquad [11]$$

The corresponding pressure is:

$$\Delta\rho = \frac{v^2}{\gamma}\Delta\rho \qquad \text{or} \qquad \Delta\rho \sim \rho\frac{v^2\beta E}{C_\rho}\mu_a \qquad [12]$$

Although this approach is new, compared to the purely optical transillumination approach, it has led to a large number of studies in which time gating brings new information to the accurate determination of the US emitter depth. It has been applied to breast tumor examination to complement standard imaging techniques such as echography and X-ray mammography. Recently this technique has demonstrated submillimeter resolution for *in vivo* blood distribution in rat brain imaging.

Acousto-Optic

Here a DC single frequency laser is used to illuminate the sample. For a typical biological sample a few cm thick the trajectories are distributed between the sample thickness value and more than ten times this value. Due to the good temporal coherence of the source all the scattered photons are likely to interfere when they emerge from the sample volume. These interferences are seen as a speckle field which can be observed at a suitable distance from the sample surface.

As seen in Figure 9, adding an ultrasonic field will mainly induce a small (smaller than the optical wavelength) displacement of the scatterers (it also induces local variation of the refractive index) which will cause a speckle modulation at the ultrasonic frequency.

If the zone irradiated by the ultrasonic field is optically absorbing, less photons will emerge from this zone than from a nonabsorbing one and thus less modulation will be seen when scanning across the sample volume. This modulation can be detected by selecting a single speckle grain and averaging over a number of uncorrelated speckle distributions to obtain a suitable average value (for instance with latex particles). This is not always possible, in particular because the overall geometry is rather stable in a semisolid tissue. Using a single detector which receives many speckle grains gives less contrast. A multiple detector and a parallel processing of many speckle grains improve greatly the speed and the signal-to-noise ratio: a typical image of absorbing spheres, embedded in a scattering phantom, is shown in Figure 10.

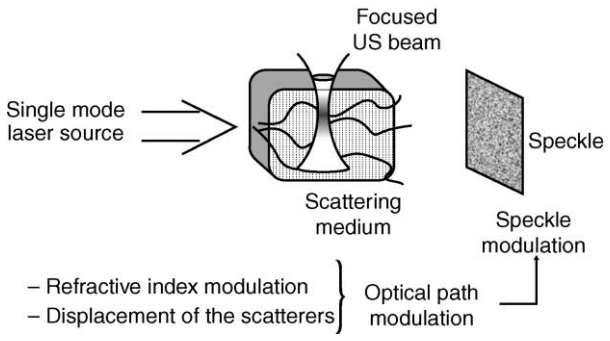

Figure 9 Acousto-optic imaging principle: photons are tagged by the acoustic field.

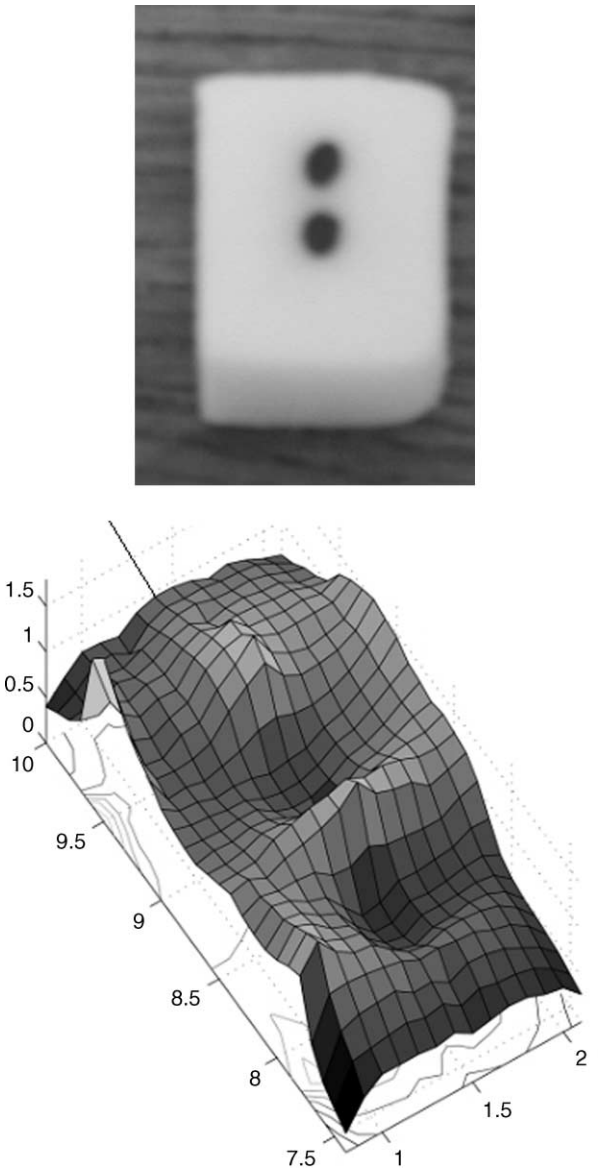

Figure 10 Acousto-optic imaging (lower image) of two absorbing spheres embedded in a scattering medium (upper image shows a section of the gel sample).

Conclusion

The complexity associated with multiple scattering in turbid media, such as tissues of the human body, prevents an easy use of light as a routine tool for in-depth examination, whereas superficial examinations have always been sources of diagnostics.

Optical techniques will obviously progress to better characterization of tissues' optical properties, improvement of laser properties and detection techniques, as well as new mathematical approaches of the inverse problem.

We believe that this field of research is still open to new ideas, and new experimental schemes leading to new breakthroughs in the delicate problem of using light in highly scattering media.

Introduction

All objects above 0 Kelvin emit electromagnetic radiation associated with the thermal activity on the surface of the object. For terrestrial temperatures (around 300 Kelvin), objects emit a good portion of the electromagnetic flux in the infrared part of the electromagnetic spectrum. The visible band spans wavelengths from 0.4 to 0.7 micrometers (infrared engineers typically use micrometer/μm for wavelength rather than the nanometer or wavenumber more commonly used in other fields). Infrared imaging devices convert energy in the infrared portion of the electromagnetic spectrum into images that can be created by the human eye. The unaided human eye cannot image infrared energy because the lens of the eye is opaque to infrared radiation.

The infrared spectrum begins at the red end of the visible spectrum where the eye can no longer sense energy. It spans from 0.7 μm to 100 μm. The infrared spectrum is, by common convention, broken into five different bands (this may vary according to the application). The bands are typically defined as: near infrared (NIR) from 0.7 to 1.0 μm; short wavelength infrared (SWIR) from 1.0 to 3.0 μm; mid-wavelength infrared (MWIR) from 3.0 to 5.0 μm; long wavelength infrared (LWIR) from 8.0 to 14.0 μm; and far infrared (FIR) from 14.0 to 100 μm. These bands are depicted graphically in Figure 1, which shows the atmospheric transmission for a 1-kilometer horizontal ground path for a 'standard' day in the United States. These types of transmission graphs can be tailored for any conditions, using sophisticated atmospheric models such as MODTRAN (from www.ontar.com). Note that

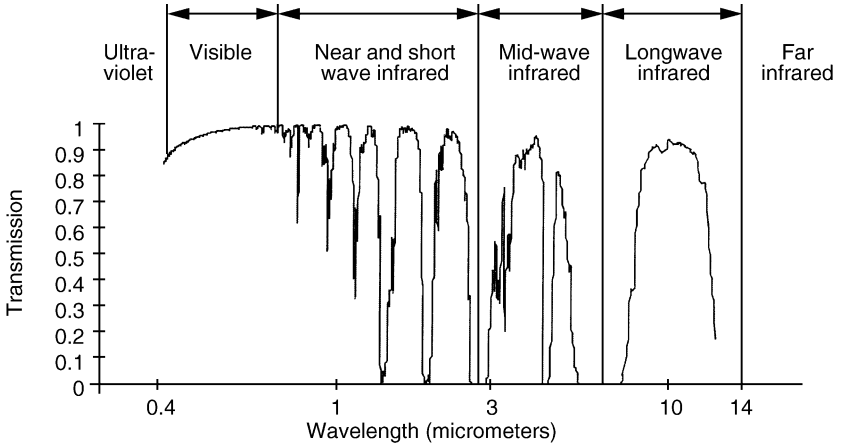

Figure 1 Visible and infrared spectra.

Figure 2 Visible image–reflected energy.

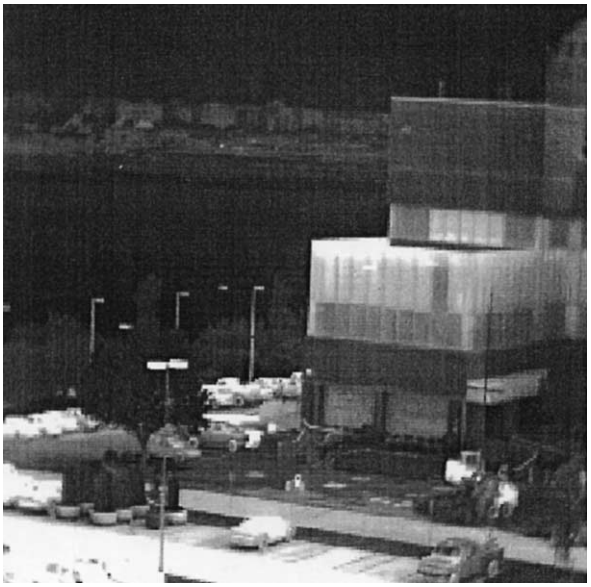

Figure 3 Infrared image–self-emitted energy.

there are many atmospheric 'windows', such that an imager designed with such a band selection can see through the atmosphere.

The primary difference between a visible spectrum camera and an infrared imager is the physical phenomonology of the radiation from the scene being imaged. The energy used by a visible camera is predominantly reflected solar, or some other illuminating energy, in the visible spectrum. The energy imaged by infrared imagers (Forward Looking Infrared, commonly known as FLIRs) in the MWIR and LWIR bands, is primarily self-emitted radiation. From Figure 1, the MWIR band has an atmospheric window in the 3 to 5 μm region and the LWIR band has an atmospheric window in the 8 to 12 μm region. The atmosphere is opaque in the 5 to 8 μm region, so it would be pointless to construct a camera that responds to this waveband.

Figures 2 and 3 are images that show the difference in the source of the radiation sensed by the two types of cameras. The visible image (Figure 2) is light that was provided by the Sun, propagated through Earth's atmosphere, reflected off the objects in the scene, traversed through a second atmospheric path to the sensor, and then imaged with a lens and a visible band detector. A key here is that the objects in the scene are represented by their reflectivity characteristics. The image characteristics can also change by any change in atmospheric path or source characteristic change. The atmospheric path characteristics from the Sun to the objects change frequently, because the Sun angle changes throughout the day and also weather and

cloud conditions change. The visible imager characterization model is therefore a multipath problem that is extremely difficult.

The LWIR image given in Figure 3 is obtained primarily by the emission of radiation by objects in the scene. The amount of electromagnetic flux depends on the temperature and emissivity of the objects. A higher temperature and a higher emissivity correspond to a higher flux. The image shown is 'white-hot' or the whiter a point in the image the higher the flux leaving the object. It is interesting to note that trees have a natural self-cooling process since a high temperature can damage foliage. Objects that have absorbed a large amount of solar energy are hot and are emitting large amounts of infrared radiation. This is sometimes called 'solar loading'.

The characteristics of the infrared radiation emitted by an object are described by Planck's black-body law in terms of spectral radiant emittance

$$M_\lambda = \varepsilon(\lambda)\frac{c_1}{\lambda^5(e^{c_2/\lambda T}-1)}\ \text{W/cm}^2\ \mu\text{m} \qquad [1]$$

where c_1 and c_2 are constants of 3.7418×10^4 W μm^4/cm^2 and 1.4388×10^4 μm K. The wavelength, λ, is provided in micrometers and $\varepsilon(\lambda)$ is the emissivity of the surface. A black-body source is defined as an object with an emissivity of 1.0, so it is a perfect emitter. Source emissions of black-bodies at typical terrestrial temperatures are shown in Figure 4. Often, in modeling, the terrestrial background temperature is assumed to be 300 K. The source emittance curves are shown for other temperatures for comparison purposes. One curve corresponds to an object colder than the background and two curves correspond to temperatures hotter than the background.

Planck's equation describes the spectral shape of the source as a function of wavelength. It is readily apparent that the peak shifts to the left (shorter wavelengths) as the body temperature increases. If the temperature of a black-body is increased to that of the Sun (5900 Kelvin), the peak of the spectral shape would decrease to 0.55 μm or green light. This peak wavelength is described by

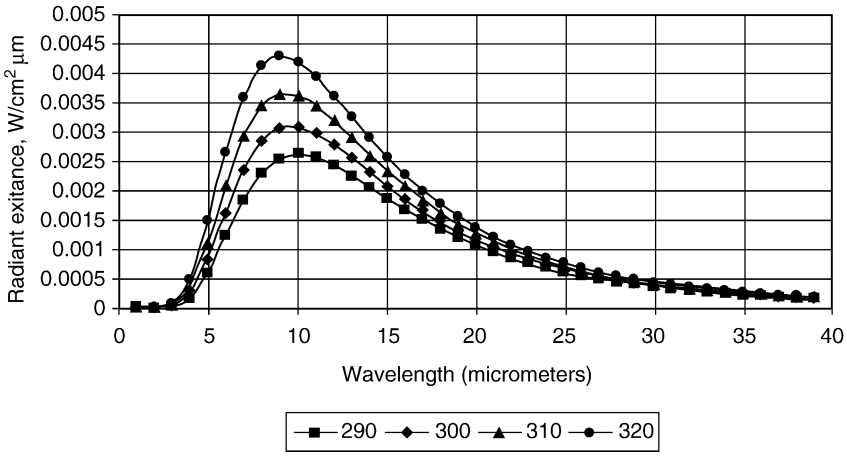

Figure 4 Planck's blackbody radiation curves for four temperatures from 290 K to 320 K.

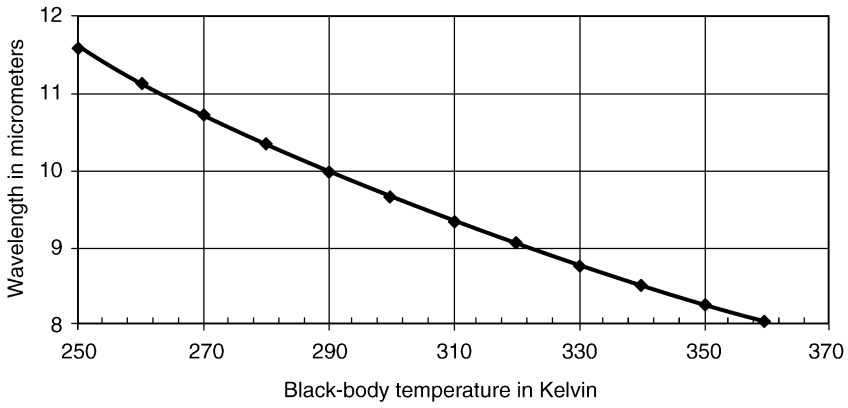

Figure 5 Location of peak of black-body radiation, Wien's Law.

Wien's displacement law

$$\lambda_{max} = 2898/T, \ \mu m \qquad [2]$$

Figure 5 shows the peak wavelength as a function of temperature through the longwave region. It is important to note that the difference between the black-body curves is the 'signal' in the infrared bands. For an infrared sensor, if the background is at 300 K and the target is at 302 K, the signal is the difference in flux between these curves. Signals in the infrared ride on very large amounts of background flux. However, in the visible band this is not the case. For example, consider the case of a white target on a black background. The black background is generating no signal, whereas the white target is generating a maximum signal (given that the sensor gain has been adjusted). Dynamic range may be fully utilized in a visible sensor. In the case of an IR sensor, a portion of the dynamic range is used by the large background flux radiated by everything in the scene. This flux never has a small value, hence sensitivity and dynamic range requirements are much more difficult to satisfy in IR sensors than in visible sensors. Table 1 summarizes this characteristic numerically for the 300 K background and targets shown in Figure 4.

A typical infrared imaging system scenario is depicted in Figure 6. The scene consists of two major components, the target and the background. In an IR scene, the majority of the energy is remitted from the constituents of the scene. This emitted energy is transmitted through the atmosphere to the sensor. As it propagates through the atmosphere it is degraded by absorption and scattering. Obscuration by intervening objects and additional energy emitted by the path also affect the target energy. All of these contributors, which are not the target of interest, essentially reduce one's ability to discriminate the target. So, at the entrance aperture for the sensor, the target signature is reduced from the values observed at the target. Then, the signal is degraded by the optics and scanner (as applicable) of the sensor. The energy is then sampled by the detector array and converted to electrical signals. Various electronics amplify and condition this signal before it is presented to either a display for human interpretation or an algorithm like an automatic target recognizer for machine interpretation. A linear systems approach to modeling allows the components' transfer functions to be treated separately as contributors to the overall system performance. This approach allows for straightforward modifications to a performance model for changes in the sensor or environment when performing trade-off analyses.

Table 1 Signal/dynamic range limitation in IR bands

Blackbody temperature	*Exitance in 8–12 μm band (w/cm^{-2})*	*Contrast*
290 ($-10\Delta T$ K target)	1.25E − 02	−8.48%
300 (background)	1.48E − 02	
310 ($+10\Delta T$ target)	1.74E − 02	7.97%
320 ($+20\Delta T$ target)	2.02E − 02	15.39%

History of Infrared Imaging

Night vision systems began to be developed extensively during World War II. Satisfying the requirement to image at night was approached with two different methodologies. The first method was image intensification (I^2). This method involves amplification of any small light that was available and displaying it directly to the eye. Typically I^2 devices are sensitive to visible light and a small portion of the short-wave IR (SWIR, 0.7–3.0 μm) band. They are often classified (along with visible band imagers) as electro-optical (EO) imagers. With an I^2 imager, there must be some source of illumination for them to function well (as little as starlight is sufficient

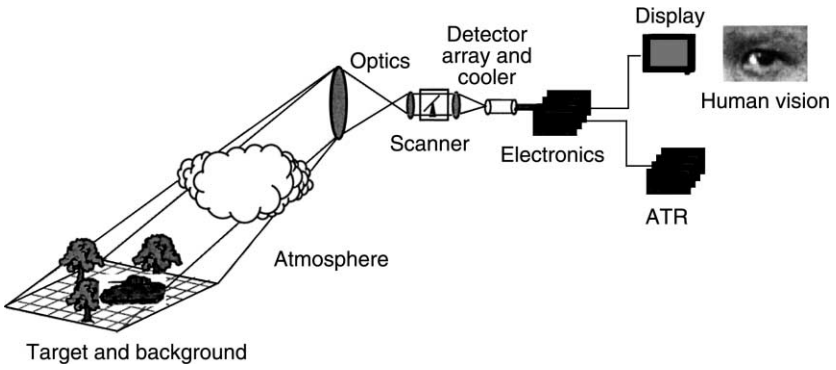

Figure 6 Typical infrared imaging scenario.

Table 2 Applications of infrared imaging

Category	*User*	*Application*
Military	Intelligence analyst	Intelligence surveillance and reconnaissance
	Pilot, driver	Navigation/pilotage
	Gunner, weapons officer	Targeting/fire control
	Air defense	Search and track
Commercial	*Civil government*	
	Police	Surveillance, fugitive tracking

	Doctors	Diagnostic imaging

for approx 20/40 acuity with current systems). The second type of night vision device is the infrared or thermal imager (also known as FLIRs). FLIRs are sensitive to the radiation in either the mid-wave IR (MWIR, 3–5 μm) or long-wave IR (LWIR, 8–14 μm) bands.

The first infrared cameras used photographic film that was sensitive to infrared wavelengths. Intelligence and reconnaissance imaging from aircraft drove the infrared system development as a night augmentation to existing visible cameras. These imagers used either continuous moving film or stationary film, like an ordinary camera. A slit aperture was used in the continuous moving film cameras and aircraft motion provided the scan of the scene along the film to build a continuous image. The introduction of television, as electronic imaging in the visible spectrum, led to the development of electronic imagers in the infrared band. Electronic infrared imagers were not restricted to looking down and using aircraft motion for scan, hence these devices came to be known as FLIRs (Forward Looking InfraRed). Today, an electronic infrared imager may be called a FLIR or a thermal imager, with the trend being to use FLIR to describe military applications.

Early FLIRs were often accompanied by illumination devices. They were not very sensitive compared to modern FLIRs so active illumination was necessary. Infrared searchlights or illuminators were used to get higher signal-to-noise ratios. These types of FLlRs are called 'active' IR imagers, while FLIRs that do not use illuminators are 'passive' imagers. Generally, active imagers are used in civil applications and are declining in military use. Broadly, applications for thermal imagers fall into two categories; military and commercial. Table 2 lists some of the purposes and users for modern thermal imagers. The design and performance criteria vary widely for some of the applications.

Types of Infrared Imagers

Infrared imagers are classified by different characteristics: scan type, detector material/cooling requirements, and detector physics. The scan type refers to the method used to construct the electronic image. The camera may use a single detector which is raster scanned over the input scene to build an image. Alternatively, a parallel scan uses a linear array of detectors scanned across a scene to build an image. The latest advances in materials have led to staring arrays of detectors. In a staring system, a detector is present in two dimensions to represent each image pixel and no mechanical motion of the focal plane is necessary to construct the image. There are some hybrid FLIR types that combine the different imaging techniques. Usually this combination leads to an improvement in signal-to-noise ratio or to reduce undersampling.

The second classification, by detector material/cooling requirements, usually describes FLIRs built using differing materials. For example, a typical LWIR FLIR material is mercury cadmium telluride (HgCdTe or MCT). In order to achieve high sensitivity, these devices are cooled to decrease dark current. Usually the cooling is based on liquid nitrogen or a cryogenic cooler, and the detectors operate at 77 K. Another common detector material is indium antimonide (InSb), which is used for MWIR FLIRs and is also cooled. A newer class of infrared cameras is not cooled, being referred to as 'uncooled' FLIRs. These uncooled FLIRs are microbolometers (resistive elements) or pyrometers (capacitive elements) and have less sensitivity than cooled imagers. Typically, the cooled imagers are comprised of photon detectors while the uncooled imagers are based on thermal detectors, the uncooled FLIRs being used in lower-performance applications.

Infrared Imager Performance

There are three general categories of infrared sensor performance characterizations. The first is sensitivity and the second is resolution. When end-to-end, or human-in-the-loop (HITL), performance is required, the third type of performance characterization

describes the visual acuity of an observer through a sensor. The former two are both related to the hardware and software that comprises the system, while the latter includes both the sensor and the observer. Sensitivity is determined through radiometric analysis of the scene/environment and the quantum electronic properties of the detectors. Resolution is determined by analysis of the physical optical properties, the detector array geometry, and other degrading components of the system in much the same manner as complex electronic circuit/signals analysis.

Sensitivity describes how the sensor performs with respect to input signal level. It relates noise characteristics, responsivity of the detector, light gathering of the optics, and the dynamic range/quantization of the sensor. Radiometry describes how much light leaves the object and background and is collected by the detector. Optical design and detector characteristics are of considerable importance in sensor sensitivity analysis. In infrared systems, noise equivalent temperature difference (NETD) is often a first-order description of the system sensitivity. The 3D noise model describes more detailed representations of sensitivity parameters (see Further Reading).

The second type of measure is resolution. Resolution is the ability of the sensor to image small targets and to resolve fine detail in large targets. Modulation transfer function (MTF) is the most widely used resolution descriptor in infrared systems. Alternatively, it may be specified by a number of descriptive metrics such as the optical Rayleigh criterion or the instantaneous field-of-view of the detector. Where these metrics are component-level descriptions, the system MTF is an all-encompassing function that describes the system resolution.

Sensitivity and resolution can be competing system characteristics and they are the most important issues in initial studies for a design. For example, given a fixed sensor aperture diameter, an increase in focal length can provide an increase in resolution, but may decrease sensitivity. Typically, visible band systems have plenty of sensitivity and are resolution-limited, whereas infrared imagers have been more sensitivity-limited. With staring infrared sensors, the sensitivity has seen significant improvements.

Often metrics, such as NETD and MTF, are considered to be separable. However, in an actual sensor, sensitivity and resolution performance are not independent. As a result, minimum resolvable temperature difference (MRT or MRTD) has become the primary performance metric for infrared systems. MRT is a quantitative performance measure in terms of both sensitivity and resolution and a simple MRT curve is shown in Figure 7. The performance is bounded by the sensor's limits and the observer's limits. The temperature difference (or thermal contrast) required to image smaller details in a scene increases with detail size. The inclusion of observer performance yields a single sensor performance characterization, MRT. It describes sensitivity as a function of resolution, and includes the human visual system.

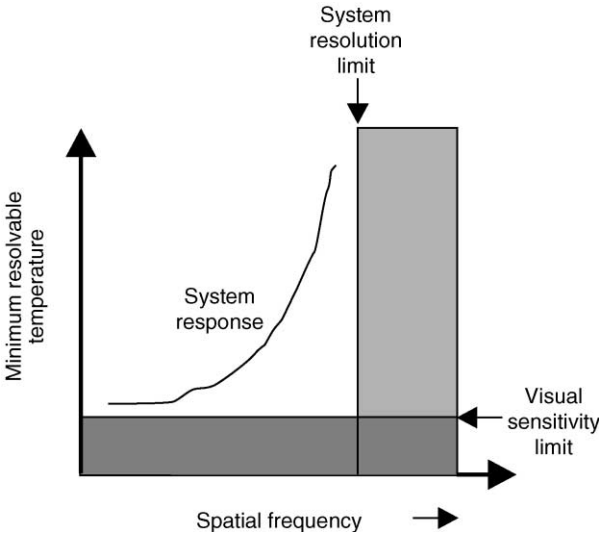

Figure 7 IR imager performance.

Many different sensor characteristics may be considered to increase the fidelity of a sensor model. A list of typical infrared imaging system parameters is given in Figure 8. When considering performance in the system sense, the groupings are often blocks in the system diagram, each with separate transfer functions. This approach works well unless the linear shift invariance assumption is not valid.

General Characteristics of Infrared Imagers

There are a number of imaging characteristics that make infrared systems a little different than conventional visible imaging systems. These include source flux levels, detector charge storage and sensitivity, detector size, diffraction blur, sampling, and uniformity characteristics.

First, we consider the source flux levels. The daytime and night-time flux levels (in photons per second per square centimeter) on Earth in the visible (0.3 to 0.7 μm) is 1.5×10^{17} and around 1×10^{10}, respectively. In the mid-wave (3 to 5 μm), the daytime and night-time flux levels are 4×10^{15} and 2×10^{15} μm where the flux is a combination of

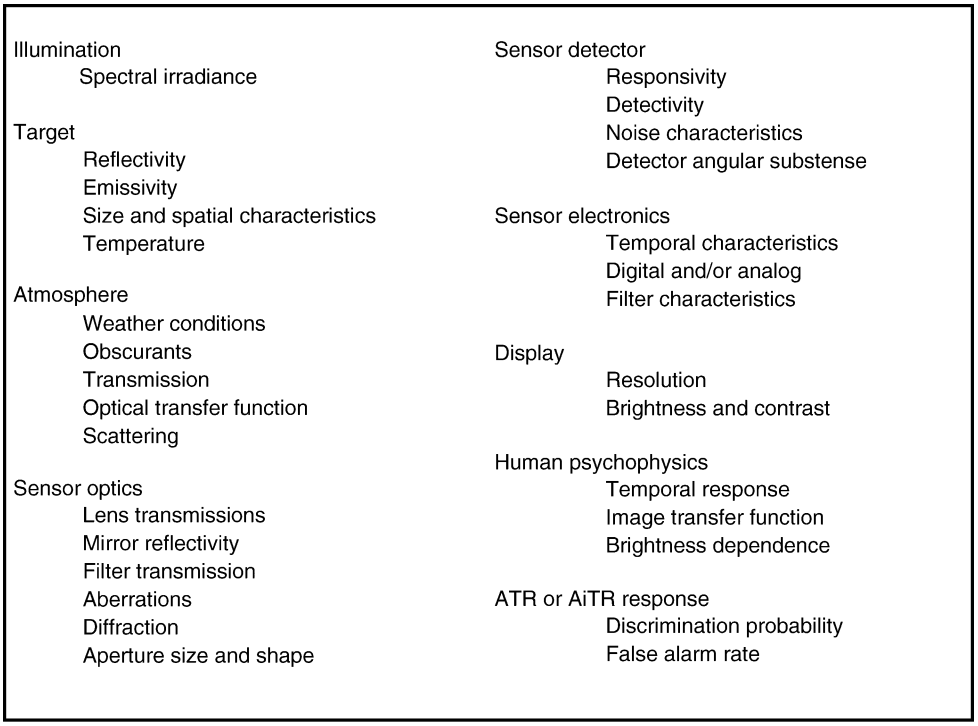

Figure 8 Factors in infrared sensor modeling.

emitted and solar reflected flux. In the longwave, the flux is primarily emitted where both day and night yield a 2×10^{17} μm frequency, the AMOP drops rapidly to zero. The effect is to extend the prediction of the MRT beyond the half sample rate and introduce a parameter called minimum temperature difference perceived (MTDP) to replace MRT in the range performance estimate and also in the lab to characterize an undersampled system.

The concept of MTDP follows from observation of standard 4-bar images as the pattern frequency passes the imager half sample rate. The image changes from four bars to three, two, and finally one (can be perceived). The phase of the target image on the detector array may need to be adjusted to observe this progression. The standard MRT measurement requires that all four bars be resolvable by the observer during the measurement process. For use in the lab, the MTDP is defined as the minimum temperature difference at which two, three, or four bars can be resolved in the image of the standard 4-bar test pattern by an observer, with the test pattern positioned at optimum phase. The optimum phase is the phase at which two, three, or four bars are 'best perceived'. TRM3 uses the standard definition of MRT as for adequately sampled imagers. The TRM3 Approach Model is implemented if the imager is considered undersampled as defined when the prefilter MTF at the half-sample frequency is larger than 10%. The MTDP equation is given by

$$\mathrm{MTDP}(f) = \frac{\frac{\pi}{2}\mathrm{SNR}_{\mathrm{th}}\Psi(f)}{\mathrm{AMOP}(f)} \qquad [3]$$

where $\mathrm{SNR}_{\mathrm{th}}$ is a threshold signal-to-noise ratio and Ψ is the total system filtered noise. MTDP is used in the same manner as MRTD in range calculations.

Another approach is the triangle orientation discrimination (TOD) threshold. In the TOD, the test pattern is a (nonperiodic) equilateral triangle in four possible orientations (apex up, down, left, or right), and the measurement procedure is a robust 4AFC (four alternative forced-choice) psychophysical procedure. In this procedure, the observer has to indicate which triangle orientation he sees, even if he is not sure. Variation of triangle contrast and/or size leads to a variation in the percentage correct between 25% (complete guess) and 100%, and by interpolation the exact 75% correct threshold can be obtained. A complete TOD curve (comparable to an MRTD curve) is obtained by plotting the contrast thresholds as a function of the reciprocal of the triangle angular size (Figure 9).

The TOD method has a large number of theoretical and practical advantages: it is suitable for undersampled and well-sampled electro-optical and optical

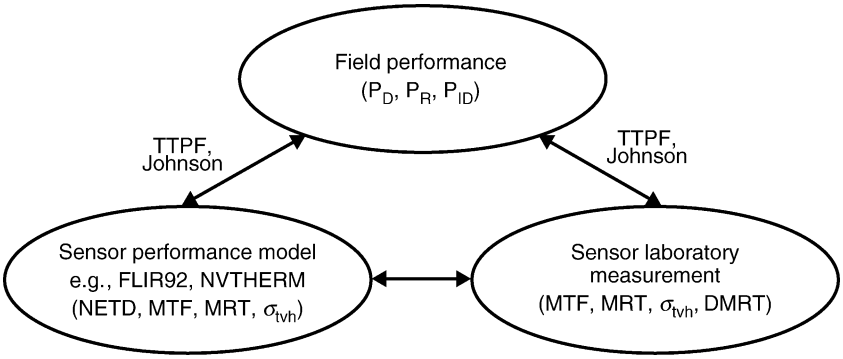

Figure 9 Modeling, testing and performance triangle.

imaging systems in both the thermal and visual domains, it has a close relationship to real target acquisition, and the observer task is easy. The results are free from observer bias and allow statistical significance tests. The method may be implemented in current MRTD test equipment with little effort, and the TOD curve can be used easily in a target acquisition (TA) model such as ACQUIRE. Two validation studies with real targets show that the TOD curve predicts TA performance for under-sampled and well-sampled imaging systems very well. Currently, a theoretical sensor model to predict the TOD (comparable to NVTherm or TRM3) is under development. The lab measurement and field performance appear sound, but the model is not yet available.

Testing Infrared Imagers: NETD, MTF, and MRTD (Sensitivity, Resolution and Acuity)

In general, imager sensitivity is a measure of the smallest signal that is detectable by a sensor. Sensitivity is determined using the principles of radiometry and the characteristics of the detector. For infrared imaging systems, noise equivalent temperature difference (NETD) is a measure of sensitivity. The system intensity transfer function (SITF) can be used to estimate the NETD, which is the system noise rms voltage over the noise differential output. NETD is the smallest measurable signal produced by a large target (extended source).

Equation [4] describes NETD as a function of noise voltage and the system intensity transfer function. The measured values are determined from a line of video stripped from the image of a test target, as depicted in Figure 10. A square test target is placed before a black-body source. The delta T is the difference between the black-body temperature and the mask. This target is then placed at the focal point of an off-axis parabolic mirror. The mirror serves the purpose of a long optical path length to the target, yet relieves the tester from concerns over atmospheric losses to the temperature difference. The image of the target is shown in Figure 10b. The SITF slope for the scan line in Figure 10c is the $\Delta S/\Delta T$ where ΔS is the signal measured for a given ΔT. The N_{rms} is the background signal on the same line.

$$\text{NETD} = \frac{N_{rms}[\text{volts}]}{\text{SITF\_Slope}[\text{volts/K}]} \qquad [4]$$

Resolution is a general term that describes the size of resolvable features in an imager's output. With infrared imaging systems, the resolution is described by the system modulation transfer function (MTF). Consider Figure 11 for the determination of MTF, from either point spread function or edge spread function (psf or esf). In Figure 11a, a test target is placed at the focal point of a collimator. The target may be a point, edge, or line as shown in Figure 11b. The IR system images this target. The output of a detector scan, or a line of detectors in the staring array case, is taken for analysis, in Figure 11c. For the edge spread function, the spatial derivative is taken to get the psf. The Fourier transform is then calculated to give the system MTF as shown in Figure 11d. The point spread function is really the impulse response of the system, so a smaller psf is desirable, where a wide MTF is desirable. Such a psf/MTF combination gives a higher resolution.

The MRTD of an infrared system is defined as the differential temperature of a four bar target that makes the target just resolvable by a particular observer. It is a measure of observer visual acuity when a typical observer is using the infrared imager. It results in a descriptor, which is a function not just of a single value. It is a plot of sensitivity as a function of spatial frequency.

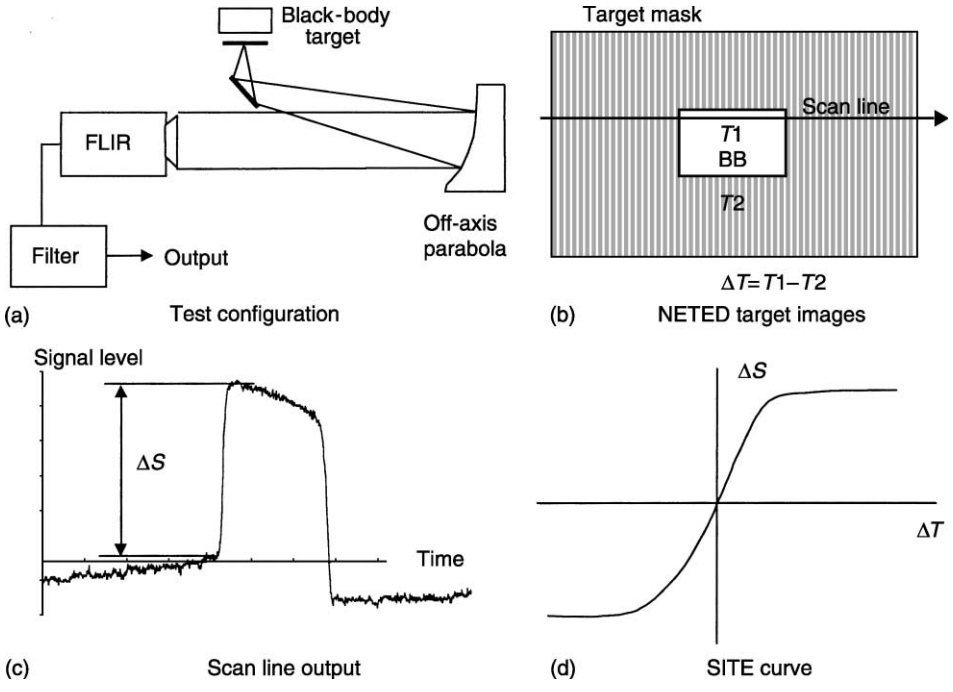

Figure 10 NETD measurement.

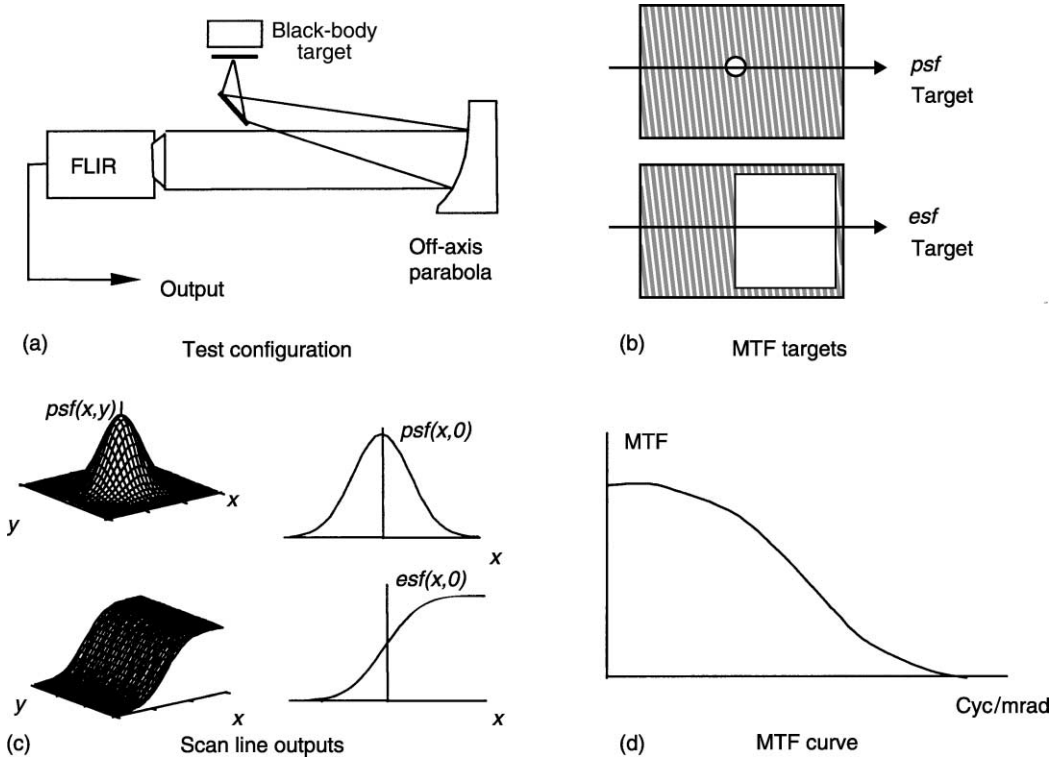

Figure 11 MTF measurement.

This parameter can be extended to field performance using Johnson's criteria.

As a laboratory measurement, it uses a 7:1 aspect ratio bar target. The procedure is shown in Figure 12. A bar target mask, with a black-body illuminator, is placed at the focal plane of a collimator (Figure 12a and 12b). The temperature is increased from a small value until the bars are just resolvable to a trained

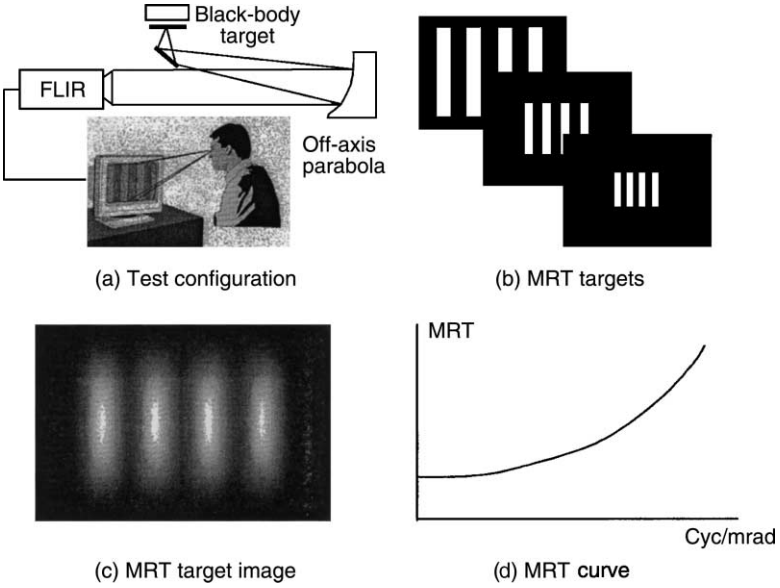

Figure 12 MRTD measurement.

observer (Figure 12c). Then the temperature difference is decreased until the bars are no longer visible. These are averaged for a particular target. The same procedure is performed with a negative contrast bar target. The average of the positive and negative values is the MRT for a particular spatial frequency. These data points are plotted and a curve may be fitted to interpolate/extrapolate performance at other than the discrete spatial frequencies of the targets, as in Figure 12d.

Summary

We have provided a general description of infrared imaging systems in terms of characteristics, modeling, field performance, and performance measurement. The characteristics of infrared imagers continue to change. Significant changes have occurred in the past five years, to include the development of higher performance uncooled imagers and ultra-narrow field of view photon systems. Large format detector arrays are commercially available in the mid-wave and are becoming more available in the longwave. Still in the research phase are dual-band focal plane level. At first sight, it appears that the longwave flux characteristics are as good as a daytime visible system; however, there are two other factors limiting performance. First, the energy bandgaps of infrared photons are much smaller than those photons in the visible, so the detectors suffer from higher dark current. The detectors are usually cooled to reduce this effect. Second, the reflected light in the visible is modulated with target and background reflectivities that typically range from 7 to 20%. In the infrared, all terrestrial objects are emitting with an emission temperature of around 300 Kelvin. Typically, a two-degree equivalent black-body difference in photon flux is considered a high contrast target to background flux. The flux difference between two black-bodies of 302 K compared to 300 K can be calculated in a manner similar to that shown in Figure 4. This is the difference in signal that provides an image, so note the difference in signal compared to the ambient background flux. In the longwave, the signal is three percent of the mean flux and in the mid-wave, it is six percent of the mean flux. This means that there is a large flux pedestal associated imaging in the infrared. Unfortunately, there are two problems accompanying this large pedestal. First, photon noise is the dominant noise and is determined by the mean of the pedestal and is compared to the small signal differences. Second, the charge well storage in infrared detectors is limited to around 10^7 charge carriers. A longwave system in a hot desert background would generate 10^{10} charge carriers in a 33 millisecond integration time. Smaller F-numbers, spectral bandwidths, and integration times are used so that the charge well does not saturate. This results in SNR of 10 to 30 times below the ideal. It has been suggested that some on-chip compression may be a solution to the well pedestal problem. In many scanning FLIR systems, the pedestal is eliminated by AC-coupling the detector signals. Infrared focal plane array (IRFPA) readout circuits have been previously designed and fabricated to perform charge skimming and charge partitioning.

Another major difference in infrared systems, from that of visible systems, is the size of the detector and diffraction blur. For infrared photon detectors, typical sizes range from 25 to 50 μm, where visible systems can be fabricated with 3 μm detectors. Also, the diffraction blur for the longwave is more than ten times larger than the visible blur and mid-wave blur is eight times larger than visible blur. Therefore, the image blur, due to diffraction and detector size, is much larger in an infrared system than a visible system. Also, it is common for infrared staring arrays to be sampling limited where the sample spacing is larger than the diffraction blur and the detector size. Dither and microscanning are frequently used to enhance performance.

Finally, both infrared photon and thermal detectors in staring arrays have responsivities that vary dramatically and it is current practice to correct for the resulting nonuniformity (nonuniformity correction or NUC). The nonuniformity can cause fixed pattern noise in the image that can limit the performance of the system even more than temporal noise (especially in static imaging or stabilized target acquisition imaging).

Modeling Infrared Imagers

Otto Schade Sr. developed the earliest imaging system models and performance measures. His work describing television in the 1950s and 1960s, pioneered the way for the characterizations of imaging sensors used by engineers today. His performance measure for still pictures, moving pictures and television systems was based on an observer resolving a three bar periodic target.

John Johnson developed the technique of relating the acquisition of military targets in the field to laboratory measurements of resolvable bar targets. He divided the discrimination tasks into four categories: detection, orientation, recognition, and identification. This technique was termed an 'equivalent bar pattern approach'. It related performance on a simple test target to performance with complex object targets. Johnson viewed scale models and bar targets in the laboratory against a bland background. The smallest discernible barchart target yielded the maximum resolvable bar pattern frequency. These results, tabulated in Table 3 as cycles across the minimum dimension, were the basis for the discrimination methodology in widespread use today. Note that detection took only one cycle, but as the tasks got more specific or difficult, the requirement went as high as 8 cycles across the target minimum dimension.

Recognizing that typical vehicle aspect ratios were somewhat limited, Johnson and Lawson conducted further experiments. Paul Moser conducted some of his own, reanalyzed Johnson and Lawson's, and developed the concept that this task was related to the average or critical dimension instead of the minimum dimension. This led to the conversion of line pairs to resolution elements, introducing the second dimension. Additionally, he performed a similar experiment on marine targets, which is summarized in Table 4. Lloyd and Sendall developed the MRT metric, which combines both resolution and sensitivity characteristics. This measurement of MRT is described in detail in a following article, but there is a theoretical model that is used to evaluate new sensor designs and concepts. It relates the minimum temperature difference between bar pairs at which they are just resolvable as a function of spatial frequency. MRT describes the infrared imager sensitivity as a function of resolution. More specifically, MRT is a measure of thermal contrast sensitivity as a function of spatial frequency.

Ratches *et al.* developed the NVL (US Army Night Vision and Electronic Sensors Directorate formerly known as the Night Vision Laboratory) Static Performance Model, which predicted the end-to-end performance. It started with the target signature and carried through to the observer. The MRT, a laboratory measurement or a modeled value, was related to the probabilities of discrimination through the target transfer probability function, cumulative percentages related to Johnson's criteria.

Table 3 Johnson's criteria

Target	*Resolution per minimum dimension*			
Broadside view	*Detection*	*Orientation*	*Recognition*	*Identification*
Truck	0.9	1.25	4.5	8
M-48 Tank	0.75	1.2	3.5	7
Stalin Tank	0.75	1.2	3.5	6
Centurion Tank	0.75	1.2	3.5	6
Half-track	1	1.5	4	5

Command car	1.2	1.5	4.3	5.5
Soldier (standing)	1.5	4.8	3.8	8
105 howitzer	1	1.5	4.8	6
Average	1 ± 0.25	1.4 ± 0.35	4.0 ± 0.8	6.4 ± 1.5

Table 4 Moser's data

Discrimination task	Line pairs/critical dimension
Detect ship	Aperiodic treatment
Classify as combatant	4
Recognize type	10

D'Agostino and Webb created the 3D noise model, both spatial and temporal considerations, for analyzing system noise. This technique divided the noise components into manageable and understandable components. It also simplified the integration of these effects into models.

The introduction of focal plane array (FPA) imagers has created a requirement to improve the model performance to account for the difference between scanning arrays and staring arrays. This change has made sampling an important area for improvement. A new model called NVTHERM is a result of the NVESD model improvement effort, which addresses undersampled imaging system performance.

Sensor characterization is seen in three ways: theoretical models, field performance, and laboratory measurements (**Figure 9**). Theoretical models are developed that describe sensor sensitivity, resolution, and human performance for the purpose of evaluating new conceptual sensors. Acquisition models, and other models, are developed to relate the theoretical models to field performance. This link allows theoretical models to be converted to field performance quantities (e.g., probabilities of detection, recognition, and identification). Field performance is measured in the field so that the theoretical models can be refined and become more accurate with advanced sensor developments. Since field performance activities are so expensive, methods for the direct measurement of sensor performance are developed for the laboratory. Field performance testing of every infrared sensor built, including buy-off, acceptance, and life-cycle testing, is ridiculous and out of the question. Laboratory measurements of sensor performance are developed such that, given these measurements, the field performance of a system can be predicted. Sensor characterization programs require accurate sensor models, field performance estimates with acquisition models, and repeatable laboratory measurements.

There are a few alternatives to the US NVTherm model. One candidate approach to undersampled imager modeling is Germany's TRM3, or the MDTP approach. The impact of undersampling in the image of a 4-bar target can readily be seen by simply observing the change in the image as a function of spatial frequency and phase. The spatial frequency is defined as line pairs per angular extent of the target, and the phase specifies the relative location of the target image to the detector array raster. These effects are obviously not independent of each other, but for each target there can be found an optimal phase where the observer can see the maximum amplitude modulation in the image of the target. MRT measurements in the past have utilized this variation with phase by allowing the observer to optimize the displayed image through target or system line-of-sight changes during the measurement process. For undersampled imagers, TRM3 addresses the problem of the MRT calculation's inability to predict beyond the half sample rate of the sensor, by replacing the MTF in the denominator of the MRT equation with an appropriately scaled term called the average modulation at optimum phase (AMOP). AMOP is the average signal difference in the image of the 4-bar standard pattern, with the test pattern positioned at optimum phase. AMOP oscillates between the presample MTF and the bar modulation. Beyond a frequency of 0.8 times the sample rate or 1.6 times the half sample arrays and quantum well detector systems. These systems will find their place in applications to include both military and commercial sectors.

Interferometric Imaging

D L Marks, University of Illinois at Urbana-Champaign, Urbana, IL, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Interferometric imaging is image formation by measuring the interference between electromagnetic signals from incoherently emitting or illuminated sources. To learn about interferometric image formation using coherent light, *see* **Holography, Techniques:** Overview. To understand what optical coherence is, *see* **Coherence:** Overview. To learn what kinds of sources produce incoherent light, *see* **Incoherent Sources:** Lamps. To learn about interferometric instruments, *see* **Interferometry:** Overview. To learn about interferometric instruments utilizing incoherent light, *see* **Interferometry:** White Light Interferometry. To better understand the effect of the coherence of light sources on image formation, *see* **Coherence:** Coherence and Imaging.

Interferometric imaging attempts to improve the resolution of images by interferometrically combining the signals from several apertures. By doing so, a resolution can be achieved that is superior to that achievable through standard image formation by any of the individual apertures. This is especially useful in astronomy, where resolving more distant and smaller stellar objects is always desirable. It is also finding increasing use in microscopy. It has several advantages over conventional noninterferometric imaging methods. The method can combine the light gathered from several imaging instruments to form an image superior to that which can be formed by any one of the instruments. It can also obviate the need to produce a single very large aperture to achieve the equivalent resolution, which in many cases is of impractical size. In addition, because it can produce a phase-resolved measurement, the data can be processed more flexibly to form a computed image estimate. There are also considerable disadvantages to interferometric imaging compared to conventional imaging methods. The amount of signal gathered is far less than could be gathered with an equivalent single aperture. It is difficult to mechanically or feedback stabilize the time delay between two widely separated apertures to obtain an accurate phase measurement. Often only a small bandwidth of the source light can be utilized, further reducing the available signal. The interference component of the combined signal can be very small. Typically an interferometric image must be computed from the data, rather than being directly measured on photographic film or an electronic focal plane array. Even with these disadvantages, interferometric imaging is frequently more feasible than building a single large aperture to achieve the highest available resolution images.

In contrast to interferometric imaging, a standard image forming instrument such as a telescope has a resolution limited by the telescope mirror aperture in the absence of aberrations and atmospheric turbulence. As telescope mirrors become very large, they become bulky, extremely heavy, and difficult to manipulate, as well as deform under their own weight and temperature gradients. However, adaptive optics is being more frequently utilized to dynamically correct for instrument aberrations as well as atmospheric turbulence. The images captured by telescopes are typically intensity-only images, which are amenable to image processing and deconvolution, but nevertheless lack phase information. Interferometric imaging is an alternative, where the resolution of a large aperture can be attained by measuring the interference between individual points of the electromagnetic field within an area equivalent to the large aperture extent. The interferometric combining of light from sub-apertures to achieve the resolution of a larger aperture is called aperture synthesis.

Unlike image formation by a lens, interferometric images are never physically formed. Conventional images are formed when diverging spherical waves emanating from sources are focused by a lens to converging spherical waves on a photographic film or an electronic sensor. In this case, the image information is directly contained in the exposure at each position on the sensor. Interferometric measurements contain the image information as statistical correlations between the electromagnetic fields at pairs of spatial points. The statistical properties of electromagnetic waves are modeled by optical coherence theory. Interferometric imaging works by measuring the statistical correlations between various pairs of points in the electromagnetic field, and then uses optical coherence theory to infer what the image of the source of the radiation is.

The light that emanates from most natural and many artificial sources is incoherent. Incoherent radiation is optical random noise. It is analogous to the sound of static heard on a radio receiving no signal. Because it is random, the fluctuations of the electromagnetic field produced by an incoherent source are completely unrelated to the fluctuations of any other source. The origin of the randomness is

usually from microscopic processes such as the thermal motions of electrons or the spontaneous emission of an excited atom. Because these microscopic processes tend to act independently of one another, the light produced by different sources tends to be mutually incoherent. Because incoherent sources do not radiate a deterministic field, the average amount of power they radiate is usually specified rather than the field itself, which is random.

However, as the fields propagate away from their sources, the fields can become partially coherent. To see this, consider the light waves propagating away from a single point-like incoherent source. The field produced at the source point consists of random fluctuations in time, but these fluctuations travel outward in a spherical wave at the speed of light. The fluctuations of the field of any two points an equal distance from the source will be the same, or perfectly correlated, because they arrive from the source at the same time. This is illustrated in Figure 1a, where a random wave is emanated from a point incoherent source. Because of the complete correlation, we can say that these two points are fully spatially coherent.

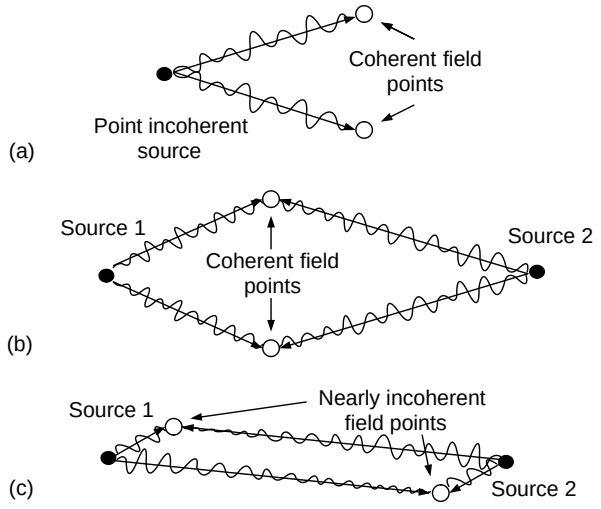

Figure 1 The distance between incoherent sources and two field points determines the coherence between the field points. (a) Because there is only one source, the field everywhere is determined by the radiation of that source. Therefore, the same fluctuations of the wave arrive at two points an equal distance from the source at the same time, and produce identical fields at both points, and so are completely coherent. (b) Two field points are now the same distance from two incoherent sources. Because both sources contribute identical fields to both points (because the fluctuations of the wave from both sources arrive at both points at the same time), the superposition of the fields from both sources at both field points are identical, and so the fields are coherent. (c) Two field points are now near two sources. Because each field point receives radiation mostly from its nearby source and very little from the other source, the fields at each field point are almost completely mutually incoherent.

So while the source itself produces random noise, the fluctuations of the field at points distant from the source become correlated because they originate from the same source.

Partially coherent waves occur when the measured field contains a superposition of the fields from more than one incoherent source. If there are now two point sources instead of one, each field point in space will receive radiation from both sources. The amount of the contribution from each source to each point in space depends on the distance between the field point and the source. In general, because both sources can be different distances from the two field points, the fluctuations at the field points will not be the same. For example, two field points that are the same distances from both sources will be perfectly correlated, or coherent, because they receive the same combination of fields from both sources. This situation is illustrated in Figure 1b. However, if one considers two points that are near both respective sources, the points will usually receive light from the nearby source. Because the sources are incoherent, and each point is mostly receiving radiation from its closer source, these points will be nearly uncorrelated, as shown in Figure 1c.

A spatial distribution of incoherent sources radiating various amounts of power will create a pattern of correlations in the field remote from the source. By using interferometry, the correlation between pairs of field points remote from the sources can be measured. The interference between two points in the electromagnetic field is achieved by relaying the two fields (e.g., with mirrors) to a common location that has an equal travel time for the fields from both points, where the fields are superimposed. The power of the superimposed beams is then detected, by a photocathode, for example. If the two signals being combined are incoherent, then no interference will take place, and the total power measured on the photodetector is simply the sum of the power of the two signals. However, if the two signals are partially coherent, there will be a deviation in the measured power from the sum of the power of the two signals. The magnitude of this deviation relative to the power of the constituent signals indicates the degree of partial coherence of the signal.

An interferometer, such as depicted in Figure 2, gathers the light from two areas of the electromagnetic field remote from an object and combines them together at the same point to form an interferogram. In this example, two telescopes of a known separation gather light from a star. The primary mirror of each telescope is of insufficient size to resolve the star as anything but a point. However, a telescope is used in practice to collect enough light to produce a

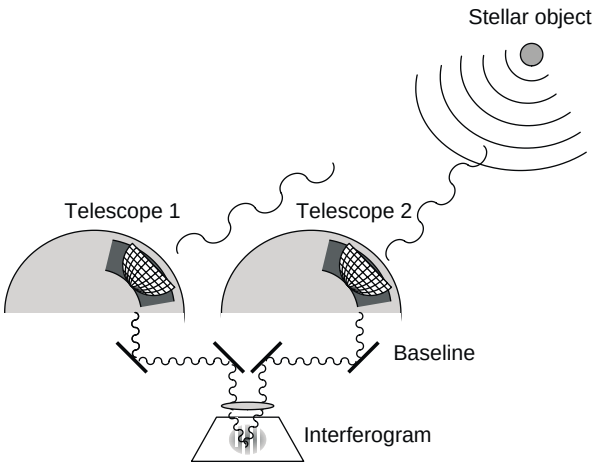

Figure 2 Two telescopes receive radiation from a stellar object. The light is collimated and directed down the baseline to a point halfway between the telescopes, where the two images are interfered together onto a focal plane.

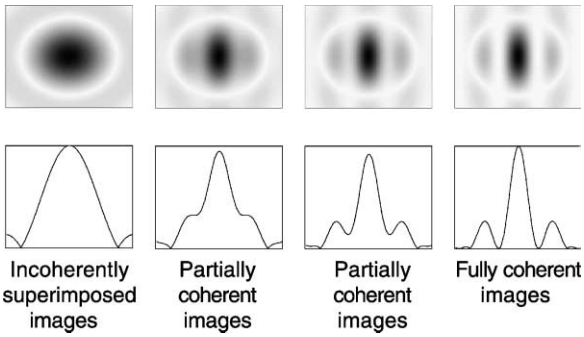

Figure 3 The image of two interfering wavefronts from a point object with various states of coherence.

measurable interference signal. Each telescope primary mirror forms a point image of the star. At the image plane of each telescope a mirror directs the point image to a measurement plane equidistant between the two telescopes. This line that joins the two telescopes is called the baseline, and it is the baseline length rather than the individual telescope mirror size that determines the minimally resolvable size. The image from each telescope is superimposed by mirrors (or perhaps beamsplitters) and imaged onto a focal plane, to get an image similar to that of Figure 3. If the light arriving from one telescope is blocked, then the image formed looks like an Airy ring pattern formed by an image, a point-like object, which is the incoherent image of Figure 3. However, when both signals are allowed to interfere, the image will have vertical stripes superimposed on it. If these stripes are very prominent, so that the image is fully darkened inside the stripes, then an image similar to the rightmost image of Figure 3 is obtained, complete intereference is occurring and the two field points at which the telescopes are situated are coherent or completely correlated. If the stripes disappear, then no interference is occurring and the two field points at which the telescopes reside are incoherent. These examples are shown in Figure 3, with images of two superimposed points with varying degrees of coherence on the top row, and a line plot of the measured field through the center of the images in the bottom row. The degree to which the contrast of the stripes is enhanced by coherence is referred to as the 'modulation' and indicates the degree or magnitude of partial coherence.

In addition to having a degree of coherence, the correlation between two electromagnetic field points also has a relative phase shift. This phase shift is given by the relative position of the interference maxima, as shown in Figure 4. As the relative phase between the

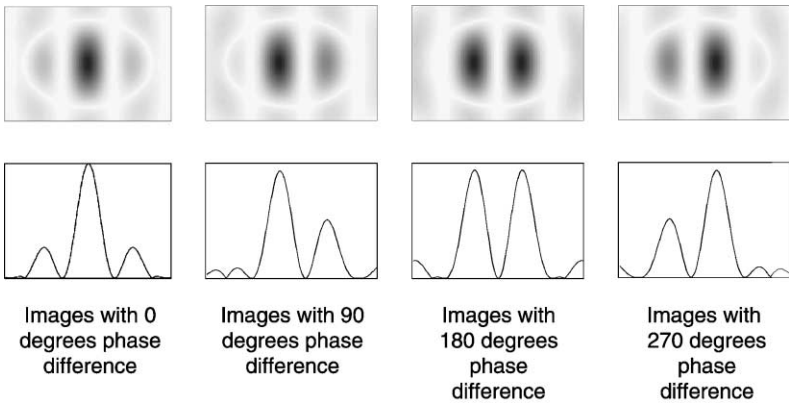

Figure 4 The image of two interfering wavefronts from a point object with various phase differences between the two wavefronts.

fields collected by the telescopes changes (which is a function of the path length difference between the light arriving at the two telescopes), the peaks of the interferogram between the two telescope images shift position. By observing the depth of the formed interference fringes and the position of the fringes, both the amplitude and the phase of the correlation between the two field points can be simultaneously measured. The amplitude of the modulation and the phase of the interference are used to compute the complex degree of coherence that is used in the computation of interferometric images.

In practice, the phase of the complex degree of coherence is much more difficult to measure than its magnitude. This is because while the amplitude tends to change very slowly as the positions of the two correlated points change, the phase is sensitive to changes in relative path length on the order of an optical wavelength. Even though a long baseline produces better resolution, the baseline length must be known to a small fraction of a wavelength to obtain a meaningful phase measurement. Minute vibrations in the positions of the mirrors on the baseline can easily cause fluctuations in the path length greater than a wavelength. This is observed as wild oscillations in the position of the fringes on the image plane. In addition, atmospheric turbulence can also produce large random phase shifts. Achieving a stable phase measurement is one of the most challenging engineering aspects of interferometric imaging.

To model realistic sources, we must determine the coherence produced by sources of a finite size. Finite size incoherent radiators can be regarded as an arrangement of an infinite number of point-like incoherent sources radiating various amounts of power. When an interferogram is made of a field which has two superimposed incoherent sources, the power of the interferograms that each would make alone is added together, rather than the fields of the interferograms. This is because when the fields of the two sources interfere, the phases of both sources are varying randomly over time. The two fields will randomly vary between constructively and destructively interfering with each other. Over a long time, the constructive and destructive interference averages out to no interference. We can then calculate what the interferogram of many incoherent sources combined is by computing the interferogram of a point source and adding the power of many such interferograms together.

To figure out what the power of an interferogram of an arbitrary object is, first consider what the interferogram of a single point source is. Consider a situation depicted in Figure 5, but with a single point

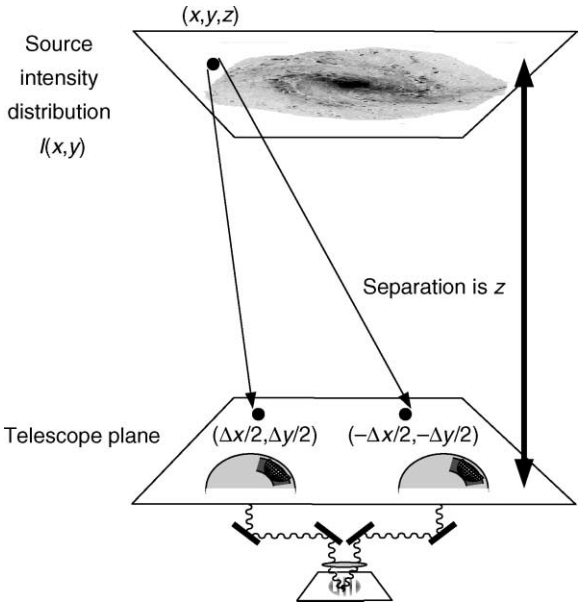

Figure 5 Diagram of source and telescope plane used for derivation of Van Cittert–Zernike theorem. A source at a distance z from the telescope plane has a power density $I(x,y)$. The telescope plane has two movable apertures symmetric about the origin of the telescope plane separated by $(\Delta x,\Delta y)$. The light from both apertures is directed to the center of the baseline at the origin of the telescope plane, where it is interfered on the sensor.

illuminator at the source plane positioned at (x,y,z) with radiant power I. We will have a receiving plane at a distance z from the source plane with two telescopes located symmetrically about the origin at $(\Delta x/2,\Delta y/2,0)$ and $(-\Delta x/2,-\Delta y/2,0)$. The fields received at the telescopes from the point will be interfered together at the center of the baseline, which is at the origin. We will assume that the point source produces a narrow band of radiation centered at wavelength λ. The point source produces a spherical wave that is received at both telescopes. The interference power is proportional to the two intensities measured at each telescope with the relative phase at the two telescopes causing constructive or destructive interference:

$$P \propto I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\phi \qquad [1]$$

where I_1 and I_2 are the intensities of the field at each telescope, and ϕ is the phase difference between the two fields at each telescope. We will assume that the point (x,y,z) is very far away from the telescopes, and so the intensities at the two telescopes are equal and proportional to the point intensity I, so that $P \propto I(1+\cos\phi)$. The phase ϕ is given by the difference in distance from the the source point at (x,y,z) to the receivers at $(\Delta x/2,\Delta y/2,0)$ and $(-\Delta x/2,-\Delta y/2,0)$. The phase is given by the difference in the Euclidean

distances:

$$\phi = \frac{2\pi}{\lambda}\left(\sqrt{z^2 + (x + \Delta x/2)^2 + (y + \Delta y/2)^2} - \sqrt{z^2 + (x - \Delta x/2)^2 + (y - \Delta y/2)^2}\right) \approx \frac{2\pi(x\Delta x + y\Delta y)}{z\lambda} \quad [2]$$

where the second term gives the difference in the distance to a first-order approximation in x and y. The interference intensity relation is then $P \propto I(1 + \cos(2\pi(x\Delta x + y\Delta y)/z\lambda))$.

If the source is now of a finite site, we can regard it as radiating an intensity (power per unit area) $I(x, y)$. To compute the total intensity of the interferogram, we integrate over all the sources in the source plane:

$$P(\Delta x,\Delta y) \propto \int I(x,y)(1+\cos(2\pi(x\Delta x+y\Delta y)/z\lambda))\mathrm{d}x\mathrm{d}y = \int I(x,y)\mathrm{d}x\mathrm{d}y + \int I(x,y)\cos(2\pi(x\Delta x+y\Delta y)/z\lambda)\mathrm{d}x\mathrm{d}y \quad [3]$$

This result can be interpreted as follows. The intensity of the interference when the two telescopes are separated by a distance $(\Delta x,\Delta y)$ is proportional to the real part of the two-dimensional Fourier transform of the intensity distribution $I(x,y)$ evaluated at spatial frequencies $(\Delta x/z\lambda,\Delta y/z\lambda)$, plus a constant intensity. This result, related to the Van Cittert–Zernike theorem, is a commonly used result in interferometric imaging. It is covered in more detail in **Coherence:** Overview.

By moving the telescopes to various horizontal and vertical separations and measuring the interference intensity, the real part of the Fourier transform of the intensity is inferred. In practice the imaginary part can also be found by varying the baseline optical path length difference by a quarter wavelength. With these samples of the Fourier transform, the inverse Fourier transform computes the image intensity distribution $I(x,y)$. This is how simple computational image formation occurs with interferometric data.

One application of the Van Cittert–Zernike theorem and interferometric imaging is the measurement of the diameter of stars. When observing coherence, the correlations between field points tend to decrease as the separation between the points grows. By observing this decrease of the coherence, the angular size of a star can be measured. This method was pioneered by Albert Michelson in 1890 with the invention of the Michelson Stellar Interferometer. It is needed because the aperture size required to measure the angular diameter of most nearby stars in the Milky Way is larger than the size of most telescope apertures. Stars usually have a circular profile that produces a circularly symmetric pattern of correlations. The coherence between field points as the distance between them is increased does not decrease monotonically, but disappears at certain separations, and has many revivals. The first separation distance at which interference disappears (and the degree of coherence is zero) for a circular profile object is $d_0 = 0.61\lambda/\alpha$, where λ is the wavelength of the light measured from the star, α is the angular diameter (in radians), and d_0 is the first separation from zero at which the interference disappears. In practice, each wavelength produces a null in interference at a different separation, so all but a small bandwidth of the star's light is filtered out before measurement to achieve a suitably strong interference null. For example, for the star Sirius, which has an angular diameter of 0.0068 arc seconds viewed from the Earth, measuring at a wavelength of $\lambda = 500$ nm (blue-green in the visible spectrum), the first separation distance at which no interference will be observed is at 18.5 m. This is larger than the largest available telescope aperture, and therefore an image cannot be directly formed that can resolve the size of Sirius.

Modern examples of stellar interferometry include the European Southern Observatory in Paranal, Chile, the CHARA Array at Mt Wilson, California, USA, and the NASA Jet Propulsion Laboratory Keck Interferometer in Hawaii, USA. The ESO main telescope system is the Very Large Telescope Interferometer (VLTI) consisting of four 8.2 m diameter telescopes as well as several smaller ones that can be moved independently, and will achieve milliarcsecond resolution through the interferometric combination of the telescopes. These telescopes are connected by underground tunnels through which the collected light from each telescope is combined. To measure the phase of the interference, extreme positioning precision is required in the relative delay between the light collected by the telescopes along the baseline, of 50 nm over 120 m, or 1 part in 2400 million, equivalent to 1.6 cm over the circumference of the Earth. Achieving this requires combinations of electronic and mechanical feedback systems with laser stabilized interferometric position measurement. The CHARA array has a very large 330-meter baseline, with 1-meter telescope apertures. The Keck Interferometer consists of two 10 m diameter telescopes with a baseline separation of 85 m. One of the main goals of achieving such high

resolution is to be able to observe planets and planet formation around distant stars, to identify possible signs of life in other solar systems.

A similar principle is used for interferometric image formation in radio astronomy. The chief differences are the methods used to collect, detect, and correlate the electromagnetic radiation. Radio astronomical observatories, such as the Very Large Array in New Mexico, USA, and MERLIN at the Jodrell Bank Observatory in Cheshire, UK, use collection dishes and radio antennas to directly measure the electric field, which is not feasible at optical frequencies. These fields are converted to electrical voltages, which can then be directly correlated using electronic mixers, rather than detecting the correlation indirectly through interference. Because the wavelength is much larger, the stability requirements are greatly relaxed. Radio and optical frequency interferometric images are formed in essentially the same way, using the Van Cittert–Zernike theorem.

Interferometric imaging methods have also become of interest for microscopy applications. Aperture synthesis is not needed in microscopy, because the objects of interest are very small and therefore single apertures can be used to achieve diffraction-limited resolution. However, interferometric detection of partially coherent light affords greater flexibility because an image may be computed from the data rather than being directly detected. Typically this is achieved by creating an incoherent hologram of the object, typically through shearing interferometry. For example, by using a Rotational Shearing Interferometer, one can measure an incoherent hologram that can be used to produce a representation of an object with a greatly increased depth-of-field. In addition, direct detection of the partial coherence of sources can allow the methods of computed tomography to be used to produce three-dimensional images of volumes of incoherently emitting objects. Because of the versatility that interferometric detection can provide, interferometric imaging will surely be increasingly used outside of astronomy.

Introduction

Light detection and ranging (LIDAR) refers to an optical system that measures any or all of a variety of target parameters including range, velocity, and chemical constituents. Usually a LIDAR system consists of a transmitting laser source, transmitter optics, receiver optics, and a detector. Several configurations of LIDAR systems are possible, based on the type of laser source and detection scheme selected. Basically, sources can be continuous wave (CW), pulsed, or chirped. Sources that are CW are most often used to measure velocity or chemical constituents. Pulsed and chirped sources

provide the additional capability of measuring range. LIDAR receivers are either incoherent (direct detection – amplitude only) or coherent (heterodyne detection – amplitude and frequency). Generally, for velocity detection, a coherent receiver with a local oscillator (LO) laser is required. A coherent receiver is also needed if a chirped laser source is used, for instance, in frequency modulation continuous wave (FM-CW) LIDAR.

For the special case of imaging LIDAR, the detector has multiple elements. In an imaging LIDAR system, the detector, or focal plane array (FPA), and the receiver optics are designed to image independent volumes in object space onto individual elements in the FPA. Each detector element, therefore, contains information for a specific volume in space and can be thought of as an independent LIDAR system. The advantage of an imaging LIDAR system is that multiple measurements can be made on extended target(s) at the same time. Thus, characterization of rapidly changing events (like wake vortices), speckle reduction by spatial averaging, synthetic aperture radar, multiple target tracking, and target identification are all possible without the sophisticated algorithms and hardware platforms required in single channel scanning systems. In addition because the multiple pixels allow parallel image capture, a true imaging LIDAR can acquire data much more rapidly than a scanning system.

In this chapter, for clarity, the emphasis will be on imaging LIDAR systems applied to hard body targets for the measurement of range and velocity. The basic configurations presented here, though, are extensible to distributed targets and measurements of wind profiles and atmospheric constituents. Also, since general textbooks are available that cover LIDAR systems and incoherent imaging systems, the concentration will be on architectures, optics, detectors, and design considerations that are specifically applicable to coherent imaging LIDAR.

Frequency Modulated Continuous Wave (FM-CW) LIDAR

One LIDAR technique, which is particularly suited for imaging due to the simplicity of the processing, is FM-CW LIDAR. FM-CW LIDAR simultaneously measures range and velocity (Doppler shift) by using a frequency chirped waveform. Referring to Figure 1, assume that a continuous wave (CW) laser frequency is linearly modulated (chirped) by a triangular wave about an offset frequency, such that the modulated signal is given as:

$$f(t) = f_o + \alpha\tau \qquad [1]$$

where f_o is the subcarrier offset frequency and α is the linear modulation rate in frequency/second, and τ is a time variable. The transmitted beam is focused by the optical system onto the target surface, reflected (or absorbed or scattered) and arrives at the receiver after τ seconds, where

$$\tau = 2\frac{R}{c} \qquad [2]$$

and R is the distance to the target surface, and c is the speed of light. The returning signal is optically mixed with the LO on the detector and produces a sum/difference beat frequency (Δf). Figure 1 shows the incident wave with its linear or chirped frequency characteristics and the delayed version returned from the target. Only the difference frequency can be optically detected since only it falls within the detector's bandwidth. Assuming the target is not moving, the result is

$$\Delta f = f(t+\tau) - f(t) = f_o + \alpha(t+\tau) - (f_o + \alpha t) = \alpha\tau \qquad [3]$$

where $\alpha = B/T$, the chirp rate of the modulator in units of Hz/s, B is the modulation bandwidth, and T is the period of the chirp. Substituting into eqn [3] for

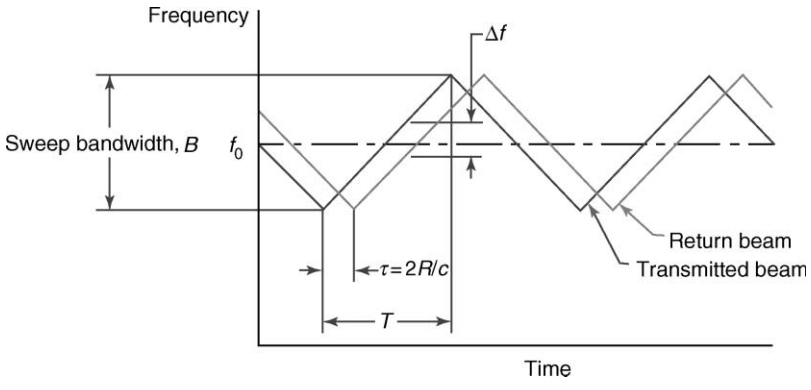

Figure 1 Triangular-wave modulation Envelope on the transmitted beam (black) and return beam (gray).

τ and α we have

$$\Delta f = \frac{B}{T}\left(2\frac{R}{c}\right) \quad [4]$$

Finally, one can solve for the distance to the target, R, as a function of the beat frequency and chirp rate:

$$R = \frac{cT}{2B}\Delta f \quad [5]$$

The difference frequency, Δf, is the same for the up and down ramp of the modulation signal. Figure 2 demonstrates the return signal for the case of a target moving toward the LIDAR system. The difference frequency now contains a component proportional to the target induced Doppler shift given by

$$f_d = 2\frac{v}{\lambda} \quad [6]$$

where v is the line-of-sight target velocity and λ is the laser wavelength. From Figure 2, the Doppler shift causes the difference frequency on the up ramp to be less than the range induced frequency shift given by eqn [5] and the net difference frequency is greater on the down slope. In this case, the difference frequency is given by

$$\Delta f = \frac{B}{T}\left(2\frac{R}{c}\right) + f_d \quad [7]$$

The range and Doppler contributions to the difference frequency may be separated by measuring the frequency difference over both the up and down chirp of the waveform. The Doppler frequency $f_d = \Delta f(\text{up}) - \Delta f(\text{down})$ and the range is given by the average of $\Delta f(\text{up})$ and $\Delta f(\text{down})$ over a complete cycle of the modulating triangular wave. Therefore, substituting in eqns [5] and [6], the range may be determined from the equation

$$R = \frac{cT}{2B}\left\{\Delta f(\text{up}) - \Delta f(\text{down})\right\} \quad [8]$$

and the line-of-sight (LOS) velocity is

$$v = \frac{\lambda}{2}\left\{\frac{\Delta f(\text{up}) + \Delta f(\text{down})}{2}\right\} \quad [9]$$

The range resolution of a FM-CW LIDAR system is the range for which the difference frequency equals 1 cycle in the sweep time interval of T or $\Delta f = 1/T$. Then, from eqn [5], the range resolution, ΔR, is given by

$$\Delta R = \frac{cT}{2B}\frac{1}{T} = \frac{c}{2B} \quad [10]$$

Therefore, the range resolution is only a function of the sweep bandwidth and not the laser wavelength. However, the Doppler shift is dependent on the laser frequency. The accuracy with which the difference frequency may be determined is a function of the number of cycles over which the measurement is made. The number of cycles is maximized for the case of $\tau = T/2$ or T should be set for twice the time delay for the maximum range of interest.

Numerical Example

A range resolution of 30 cm requires a chirp bandwidth, B, of 500 MHz. For a total range of interest of 10 km, the chirp time, T, should be 133.33 μs or the chirp rate should be 3750 Hz (1 up and 1 down ramp per cycle). The difference frequency for a 10 km range target will be 250 MHz, which demonstrates the need for wideband detectors to capture high-resolution range images (Table 1).

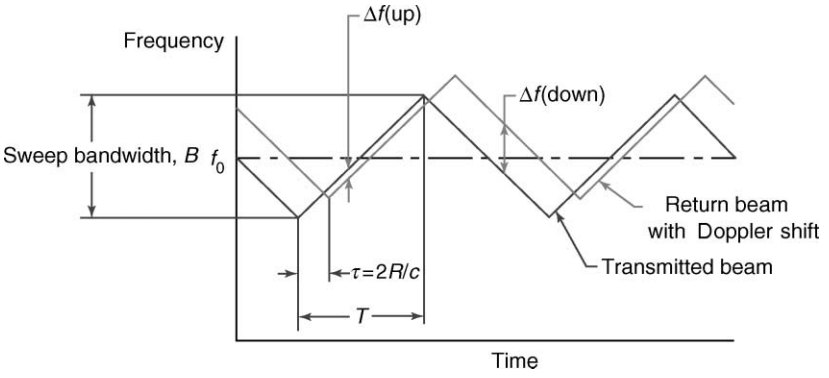

Figure 2 Lidar return with Doppler shift proportional to target velocity.

Table 1 Summary of FM-CW LIDAR characteristics

Parameter	*Value*
Range resolution (m)	0.3
Chirp rate (Hz)	3750
Chirp bandwidth (Hz)	500×10^6
Maximum range (km)	10

Optical Configuration for Imaging LIDAR

Imaging LIDAR systems can be constructed for virtually any wavelength range with appropriate sources, optical components, and detectors. The design of an optical receiver system capable of recording coherent images requires additional considerations over those necessary for a video camera or single-channel receiver. First, the collection optics must have resolution capabilities consistent with both the detector grid dimensions and the coherence properties of the source. Next, the local oscillator (LO) power must be applied to each array element. For a typical infrared (HgCdTe) detector, one to ten milliwatts of LO power might be required to reach the shot noise limit. For large arrays, this may result in unacceptable heat loads, even for momentary application. Thus, detector arrays with substantial spacing between detector elements benefit from the application of individual LO 'beamlets' to shield the insensitive portions of the array substrate. These beamlets can be generated by illuminating a mask containing an array of holes with the LO Gaussian laser beam. This scheme is illustrated in Figure 3.

In the configuration shown in the figure, the signal beam (from the target) and the LO beamlets are combined at the beamsplitter prior to being focused onto the detector plane by the objective lens. The detector plane coincides with the far-field image plane of the objective lens, and any additional optical elements utilized to enhance the camera's resolution are not shown. An expanded LO beam illuminates an aperture array located at the far-field object plane of the ancillary lens. For instance, if the objective lens and the ancillary lens are identical, the LO mask is imaged onto the detector plane with unity magnification. The detector surface is assumed to be flat with uniform video and heterodyne quantum efficiency.

Several aspects of this design are discussed below. We first discuss how the optical parameters may be adjusted to give nearly-Gaussian LO profiles at each detector position. The receiver antenna array is then shown to consist of nonoverlapping sub-beams spaced with the detector array geometry. Signal considerations for both incoherent and coherent sources are then discussed, and it is found that optimal detector size and array-spacing is dependent on the coherence properties of the intended object field.

Aperture Array

As an alternative to holographic LO beam array generation, the LO mask design presented here consists of an array of apertures with size and spacing equal to the detector dimensions. The LO is expanded to coherently illuminate the entire mask with approximately uniform intensity. The mask is located at the front focal plane of the ancillary lens and its image is located at the back focal plane (detector plane) of the objective lens. The coherent image of the mask formed at the detector plane by the ancillary-objective lens combination can be described by a two-stage Fraunhofer diffraction process.

Finite dimensions of the ancillary pupil results in spatial filtering which can affect the image profile of the LO mask. If desired, the ancillary pupil may be chosen to provide nearly-Gaussian LO beamlet profiles with beam waists at each detector location.

It is useful to first consider the coherent image of a single aperture uniformly illuminated with plane LO wavefronts. In one dimension, this wave train diffracts from the aperture to form a far-field diffraction pattern at the Fraunhofer plane of the ancillary lens given by

$$E_{\mathrm{F}}(\beta) = E_{\mathrm{F}} \frac{\sin(\beta)}{\beta} \qquad [11]$$

where $\beta = \frac{1}{2} kb \sin(\theta)$, $k = 2\pi/\lambda$, λ is the wavelength, b is the aperture width, and θ is measured from the optical axis. For small θ, $\beta = \pi b \nu/(\lambda f)$ where ν measures a point on the Fraunhofer plane and f is the focal length of the ancillary lens. The finite diameter D (determined by an aperture stop in the Fraunhofer plane) of the ancillary lens spatially filters the diffraction pattern and this limits the range of β values in eqn [11]. We define an aperture-limited pupil as one which limits β to the range $-\pi < \beta < \pi$; this will be the case when $f/D = b/2\lambda$.

Consider now a linear aperture array consisting of N individual apertures of width b and separation $a > b$. Assume that each aperture is illuminated by plane, uniform, mutually coherent LO wavefronts of equal intensity. In this case, the LO profile at the Fraunhofer plane is characterized by the diffraction pattern for a coherently illuminated linear diffraction grating:

$$E_{\mathrm{F}}(\theta) = E_0 \mathrm{sinc}\,(\beta) \frac{\sin(N\alpha)}{N \sin(\alpha)} \qquad [12]$$

where $\alpha = \frac{1}{2} ka \sin\theta$ and where β, θ, and k are defined above.

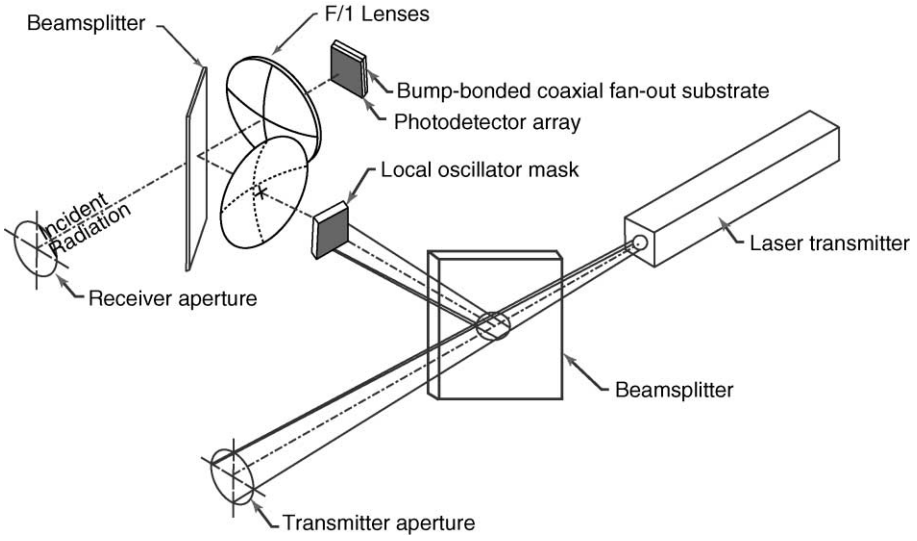

Figure 3 The individual beamlets are generated by the local oscillator or aperture mask. Reproduced with permission from Simpson ML, Bennett CA, Emery MS, *et al.* (1997) Coherent imaging with two-dimensional focal-plane arrays: design and applications. *Applied Optics* 36: 6913–6920.

Propagation of the LO from the ancillary lens Fraunhofer plane to the detector plane can be described by applying the Fraunhofer diffraction integral to eqn [12] with integration limits appropriate to the ancillary pupil dimensions. The larger pupil gives increased illumination at the detector edges while the aperture-limited pupil gives a nearly Gaussian LO profile with $1/e$ points close to the detector edges.

Receiver Antenna Array

The requirement of wavefront matching between the LO field and the signal field leads to the notion of an 'antenna beam' or equivalently, 'backward propagating LO' (BPLO) to define the field of view of an individual heterodyne receiver element. This beam is formed by allowing a reverse projection of the local oscillator field to diffract from the detector surface, through all collection optics in the signal beam path to a point on the object field of the imaging system. A receiver array will produce an array of such BPLO beams which must maintain the detector array geometry in the object field if the LO and signal beams are to mix efficiently.

As above, spatial filtering by the receiver pupil (assumed to be located at the Fraunhofer plane of the objective lens) will affect the BPLO profile. In the Fraunhofer plane of the objective lens, the uniformly illuminated single-detector BPLO profile is given by eqn [11], and we define an aperture-limited detector as one which limits the range of β to $\pm\pi$. Similarly, eqn [12] characterizes the BPLO profile resulting from a detector array uniformly illuminated with an extended uniform LO wavefront. The uniform illumination BPLO profiles in the object field differ from the detector plane profiles only in horizontal scale which now is consistent with the magnified detector dimensions.

For our purposes, we may define the far field of the objective lens according to the condition for maximum Gaussian beam collimation:

$$\omega_d \omega_0 = \frac{f\lambda}{\pi} \qquad [13]$$

where ω_0 is an effective BPLO Gaussian beam waist at the Fraunhofer plane and ω_d is an effective BPLO beam waist at the detector. Under this circumstance, the BPLO Rayleigh range is $Z_D = \pi\omega_0^2/\lambda = f(\omega_0/\omega_d)$. Identifying ω_0/ω_d as the magnification (notice that for the BPLO, the magnification is greater than unity) gives $d_o = (d_i/f)Z_D \sim Z_D$ where d_o is the object distance and d_i is the image distance. Thus the far-field of the objective lens is at least one BPLO Rayleigh range away.

The object field BPLO profiles for an aperture-limited detector array consists of nearly Gaussian sub-beams with $1/e$ points located approximately at the magnified detector edge locations. Since the far-field object distance exceeds Z_D, the divergence of each BPLO sub-beam is constant and remains distinct and nonoverlapping for all $d_o > Z_D$.

Imaging Applications Involving Incoherent Sources

For an object plane in the far field of aperture-limited collection optics, the nearly Gaussian-profile BPLO propagates from the receiver aperture according to

the condition for maximum Gaussian beam collimation. The waist is at the Fraunhofer plane where the BPLO wavefront is nearly plane, while at the object field the BPLO wavefronts are spherical with radius equal to

$$R(d_o) = d_o\left[1 + \left(\frac{Z_D}{d_o}\right)^2\right] \qquad [14]$$

where we have set $d_o - f \approx d_o$.

It will generally be the case that an imaging system will be used to analyze extended objects whose size exceeds the resolution limit. Following convention, we define a spatially coherent source as one which is illuminated with spatially coherent light with appreciable structure and roughness of depth within the coherence length of the illuminating light, and where the target motion does not appreciably perturb the speckle field during the measurement process. The speckle effects, which so seriously degrade the information content in images formed of spatially coherent objects, are not present in images formed of incoherent objects such as thermal emitters. Speckle may be reduced by time-averaging speckle fluctuations resulting from target motion, atmospheric effects, and independent transmitter pulses, and in the limit such objects become incoherent pseudothermal sources. Similar remarks apply to spatial averages over detector subarrays.

Independent radiators on the object field produce disturbances which can diffract to illuminate the entire receiver aperture as well as a finite coherence area in the image field A_{ci} given by

$$A_{ci} \gg \frac{\lambda^2}{\Omega_{ci}} \qquad [15]$$

where Ω_{ci} is the solid angle subtended by the receiver aperture at the image field. Alternatively, we may interpret A_{ci} as the area of an aperture in the object plane which, if illuminated with wavefronts characterized by eqn [14] (reciprocal illumination), would just fill the receiver aperture with a central diffraction order. Thus the combination of independent disturbances within the detector's field of view on the object plane, combine to form a spatially coherent disturbance over the receiver aperture and within A_{ci}.

According to the Van Cittert–Zernike theorem, the complex degree of spatial coherence μ_s is a unity amplitude wavetrain that propagates exactly as a signal beam resulting from the reciprocal coherent illumination of an object-field aperture of area A_{ci}. Thus, μ_s and the BPLO are Helmholtz-reciprocal pairs whose overlap determines the mixing efficiency with which heterodyne signal is generated from radiation collected from an extended incoherent source. Following convention, we refer to the overlap of μ_s and the BPLO as the effective receiver aperture.

Detectors larger than the aperture-limit, whose area exceeds A_{ci}, exhibit reduced receiver apertures and a corresponding decrease in heterodyne mixing efficiency. For example, varying the receiver pupil, while maintaining constant LO illumination, results in a heterodyne signal proportional to the received power for detector diameters much less than the aperture-limit, while detector diameters much greater than the aperture-limit produce heterodyne signal only in proportion to the square-root of the received power. Thus, for constant LO illumination and incoherent sources, increasing the entendue past the aperture limit will always increase the heterodyne signal, but less than for direct detection.

Optimal Detector Size

As noted above, an aperture-limited system is one where detectors of diameter d are matched with an objective lens with $f/D = d/2\lambda$. Commercially available detectors for use at 10 μm are commonly 100 μm wide suggesting the use of a $f/5$ lens, however aspheric lenses as fast as $f/1$ are also commercially available. Apart from aberrations, it would be advantageous to utilize a 5×5 subarray of 20 μm detectors with an $f/1$ lens in place of a single 100 μm detector for applications involving coherent sources. Applications involving incoherent thermal sources would generally favor a wide detector/fast lens combination since thermal sources provide weak heterodyne signals.

Noise Analysis and Performance

Radar Range Equation

The laser power requirements for the LIDAR system depend on the signal-to-noise ratio of the FPA, the i.f. amplifier performance, atmospheric transmission, and the optics system design. The following calculations are used to determine the performance of the LIDAR system for a single pixel of the FPA. The radar range equation is

$$P_r = P_t\left(\frac{G_t}{4\pi R^2}\right)\left(\frac{\sigma_{pt}}{4\pi R^2}\right)\left(\frac{\pi D^2}{4}\right)\eta_{atm}\eta_{sys} \qquad [16]$$

where P_r = received power; P_t = transmitted power; G_t = antenna gain; σ_{pt} = radar cross-section; R = range; D = transmitting and receiving aperture diameter; η_{atm} = atmospheric transmission; and η_{sys} = optical system efficiency.

The beam divergence of the transceiver is

$$\theta_t = \left[\left(\frac{D}{R}\right)^2 + \left(\frac{\lambda}{D}\right)^2\right]^{0.5} \quad [17]$$

where λ = wavelength and the antenna gain is

$$G_t = \frac{4\pi}{\theta_t^2} \quad [18]$$

The radar cross-section for a lambertian diffuse point target is $\sigma_{pt} = 4\rho_t dA$. The target reflectivity is ρ_t and dA is the target area, which is effectively the size of a pixel of the FPA projected onto the target. For purposes of the following calculations, a surface reflectivity of 0.1 is assumed. The pixel size at the target (assuming Gaussian beam optics) is given by

$$dA = \pi\left(\frac{D}{3}\right)^2\left[1 + \left[\frac{\lambda R}{\pi}\left(\frac{3}{D}\right)^2\right]^2\right] \quad [19]$$

where D = transmitter and receiver mirror diameter and it is assumed that the target is larger than dA.

Finally, the signal-to-noise (SNR) ratio for a coherent receiver is given by

$$SNR = \frac{\eta P_r}{h\nu B_{if}} \quad [20]$$

where η = detector quantum efficiency; P_r = received power from eqn [16]; h = Planck's constant; ν = frequency of laser; and B_{if} = post-detection bandwidth of signal processor.

Numerical example

Assuming an atmospheric transmission efficiency, η_{atm}, of 98%, an optical system efficiency, η_{sys}, of 30%, and a detector efficiency, η, of 10%, the SNR was calculated as a function of the transmitting/receiving telescope (assumed to be a mirror) diameter, D, with target range as a parameter and plotted in Figure 4. This calculation assumed

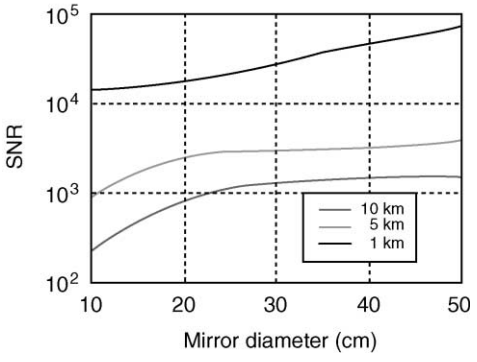

Figure 4 The SNR saturates for a mirror diameter greater than 30 cm at long range.

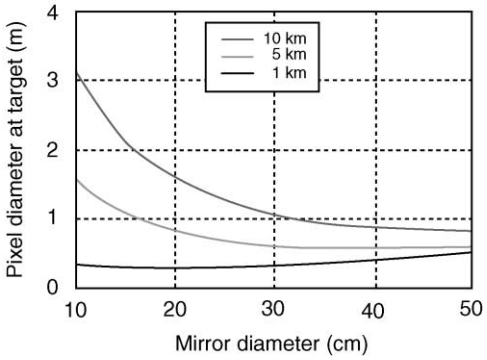

Figure 5 The pixel size determines the target cross-range image resolution.

that the pixel field-of-view (FOV) at the target was illuminated with 1 watt of power. Even at a range of 10 km, the 32 × 32 element imaging LIDAR receiver with a SNR of 100 for each pixel will require only 75 watts (approximately 74-milliwatts per pixel) of total transmitted power for a mirror diameter of 30 cm. From Figure 4, it appears that the telescope mirror size could be reduced to a diameter of 20 cm and still maintain an excellent SNR. However, the SNR is not the only consideration on the transmitting telescope diameter. The cross-range target resolution is determined by the projected pixel size at the target. This target pixel size is plotted versus the telescope mirror diameter in Figure 5. Diffraction from the transmitting and receiving optic sets the limiting resolution that can be achieved with the LIDAR system and is only a function of the diameter and wavelength. A transmit/receive telescope aperture of 30 cm seems to represent a good trade-off between cross-range resolution and SNR.

Applications and Future Directions

The remote sensing community has recognized the advantages of coherent receivers over conventional direct IR detection with respect to increased measurement sensitivity and multidimensional information capability. These advantages, however, come at a price of added system complexity, power, size, weight, and cost. In addition, choices of components, particularly in the long wavelength infrared (LWIR) region of the spectrum, have been limited to liquid nitrogen-cooled nonimaging detectors and table-top-sized gas lasers. Thus, implementations of imaging LIDAR systems have been primarily single detector, single source scanning systems which require high pulse repetition frequency lasers, complex tracking systems, and platforms, and augmentation of automated target recognition input to compensate for multiple, simultaneous measurements on the

same target. New technology developments in quantum well infrared photodetector (QWIP) detectors and arrays, and in HgCdZnTe technology are now paving the way toward thermo-electrically cooled LWIR imaging array detectors. Also waveguide, folded cavity, laser resonator designs are providing compact, lightweight packages for CO_2 lasers. Coherent receivers, that use the new focal plane arrays and compact sources, provide the capability of making parallel LIDAR measurements without the added hardware and software overhead of scanning systems. In the following section, several examples are provided that demonstrate the versatility of imaging LIDAR systems that use detector arrays for measurement applications such as chemical plumes, velocity gradients, and speckle reduction.

Wideband heterodyne receivers are useful in measuring chemical species whose absorption peaks are not well aligned with the laser source line. If the species absorption peak corresponds directly with the laser line, an absorption measurement can be made using direct detection (amplitude only). For off-line (off-resonance) measurements, heterodyning is needed, where the bandwidth of the heterodyne receiver dictates how far away from the laser line an absorption peak can be measured. For example, the CO_2 laser line spacing in the 9 to 12 micron region of the spectrum averages around 50 GHz. With the new QWIP detectors theoretically having heterodyne bandwidths of 30 GHz or more, full high-resolution spectral coverage for the long-wave IR is within grasp. For chemical detection with heterodyne receivers, there are two modes of operation. The first is termed passive heterodyne radiometry where the source is a black-body radiator and the absorption is measured for chemical species located between the blackbody and the receiver. The second mode of operation is thermoluminescence where a laser transmitter is used to excite a chemical species in the atmosphere and the resulting emission (luminescence) is measured with the heterodyne receiver. The advantage of imaging in both cases is the ability to capture chemical plumes in the presence of wind and other anomalies.

To illustrate the ability of heterodyne imaging receivers to spectroscopically resolve chemical plumes, **Figure 6** shows a series of 10×10 pixel images of a small bottle of concentrated ammonium hydroxide against a 212 °C blackbody recorded in both passive heterodyne radiometry and direct detection modes. **Figure 6a** shows a heterodyne image of the bottle with the top in place where, in **Figure 6b** the top is removed and the absorbing plume is clearly imaged. The heterodyne images in **Figures 6a** and **6b** were recorded with the LO adjusted to emit the 9R(30) line which is known to

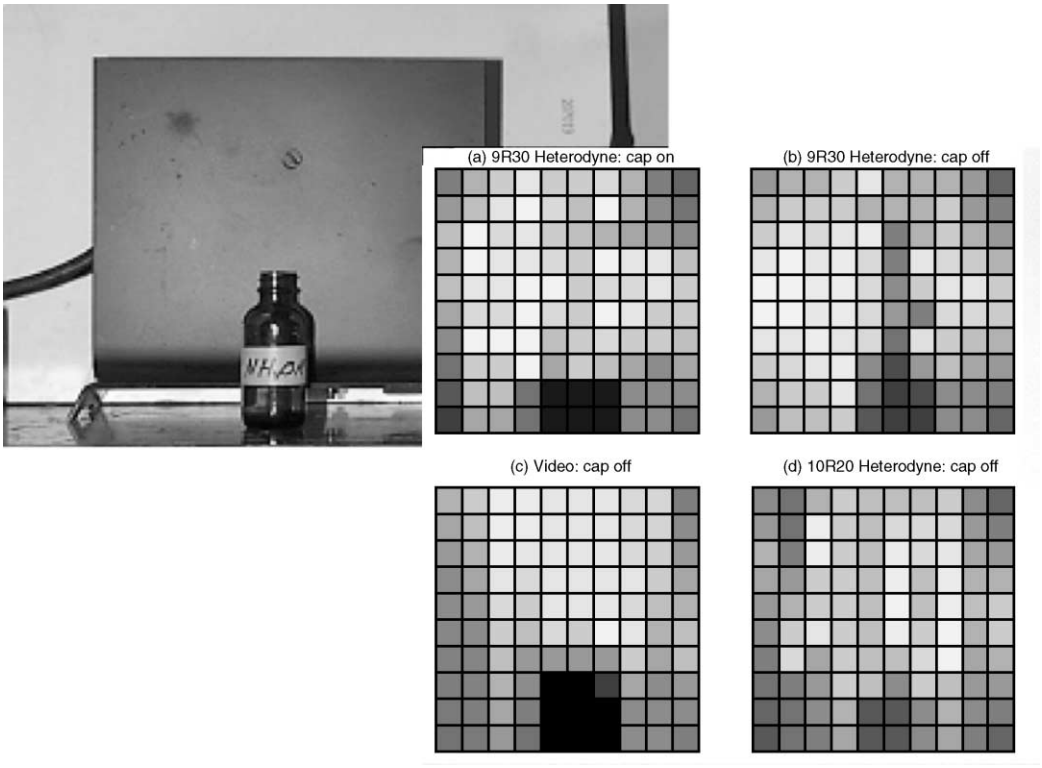

Figure 6 Ammonia plume characterization.

be absorbed strongly by NH_3. In Figure 6c, the same image was recorded by direct detection and fails to detect the ammonia plume. Similarly, in Figure 6d, the LO was adjusted to emit a nearby line known not to be absorbed by NH_3 and the plume is again not detected. Both the objective and ancillary lens were $f/1$ 38 mm, and the object field was about three meters away. The top of the bottle was approximately 2 cm in diameter and is located at the bottom of the field of view. Measurements utilizing hot ammonium hydroxide imaged against a cold background resulted in similar images (albeit at substantially reduced signal to noise ratios) where the plume was bright and the background was dark.

Another use of imaging LIDAR is the measurement of velocity profiles. Applications include wake vortex measurements for aircraft, wind shear detection, and vibration signature measurements for identification. In another experiment, active mode images were recorded by illuminating the target with a portion of the LO laser beam which had been shifted in frequency by 40 MHz using an acousto-optic modulator. The resulting Doppler image is recorded using an 8×8 HgCdTe array with discrete electronics for each pixel element in the array. Figure 7 shows the active image of a vertical squirrel cage fan where each pixel is rendered to represent the peak Doppler shift measured with the detector at the corresponding location in the image plane. The moving target scatters incoherently and thus speckle effects do not degrade the image. The measured Doppler shifts are consistent with the known rotational velocity of the target.

Speckle effects associated with coherent mixing of laser light reflected from an extended target (constructive and destructive interference) are a major source of noise in LIDAR measurements. These speckle effects can be reduced by signal averaging. For single detector LIDAR, averaging over many transmitter pulses can reduce speckle but this technique also reduces temporal resolution. The alternative considered here is to sacrifice spatial resolution by averaging over an array of detectors, all of which record the signal returned from a single transmitter pulse. Detectors separated by a coherence area diameter will record signals that approach statistical independence, and in this case speckle effects can be reduced by an amount approaching the square-root of the number of detectors in the subarray.

The following laboratory experiment demonstrates speckle reduction by spatial averaging with a fixed focal plane array. The receiver used in this experiment consists of a 3×3 array of HgCdTe detectors. The 50-micron diameter detectors are arranged in a square pattern, with 100 micron center-to-center spacing. Custom electronics multiplex the output of each detector for subsequent processing. As with the velocity profile experiment, LIDAR illumination is produced by frequency shifting a portion of the LO beam by 40 MHz with an acousto-optic modulator prior to illuminating the object field. Polarization of the illumination beam in the experiment is parallel to the LO prior to scattering from the target. The measured receiver bandwidth, limited mostly by the dewar design, is about 100 MHz, which permits the acquisition of the 40 MHz heterodyne signal. The collection optic consists of a 38 mm $f/2$ asphere which produces a 2 mm diameter pixel image at a 3 m object distance.

The target for this experiment is a 30 cm diameter disk coated with an aluminum powder. The particle size of this powder ranges from 1 to 100 microns as determined by electron microscopy. The disk is attached to a stepper motor that is incremented between frames to provide statistically independent speckle fields. Figure 8 shows the distribution of

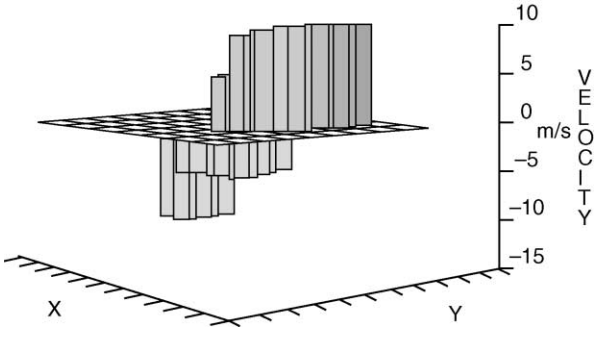

Figure 7 Doppler image of a rotating squirrel cage fan.

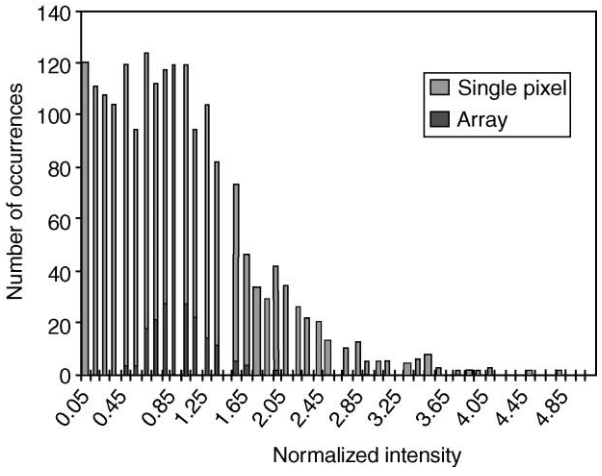

Figure 8 Speckle reduction using spatial averaging over a coherent array.

measurements taken with a single pixel superimposed on the distribution taken by averaging over the focal plane array. A reduction in speckle noise by a factor of the square root of the number of averaged pixels is obtained as predicted.

In this chapter, an overview of imaging LIDAR systems has been presented. Imaging LIDAR system design, performance, and application were discussed. With new technology developments in wide-bandwidth QWIP detector arrays, thermo-electrically cooled detectors, and compact sources, substantial potential exists for imaging LIDAR systems in the next generation in remote sensing. Due to the parallel, multifunction measurement capability of these new receivers a single sensor system can provide three-dimensional information, including range, shape, velocity, and chemical composition. In addition to the sensor fusion advantages, snapshot imaging allows the capture of high-speed, rapidly evolving events that elude present scanning systems.

Introduction

The ability to project an image onto a screen in a darkened room has been known since antiquity and Leonardo da Vinci (1515) precisely described principles of the Camera oscura. When one exposes a paper sheet directly to sunlight, it is uniformly lighted. However, if one pierces a little hole through the paper sheet then an image of the sun can be displayed on a screen beyond the hole (Figure 1). Similarly, the shape of the light spot we can see in a dark room, from the rays passing through a small aperture of a closed shutter, is not that of the aperture. Generally, the spot has a circular shape, as an image of the sun. Actually, it is neither a shadow of the hole nor an image of the sun but a combination of both. Light incident on an aperture contains the entire information about the light distribution of the object, but this information has to be 'deblurred', or decoded. The aperture acts as an elementary spatial 2D-filter that selects and preserves the direction and intensity of light rays coming from each point of the scene. The projection on the screen of each pencil of light passing through the hole is a small light spot, the geometry of which is the same as the aperture, and

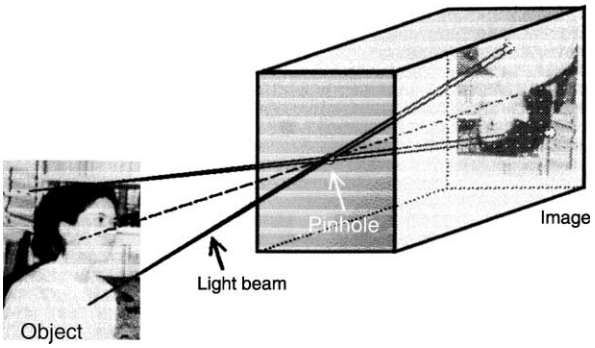

Figure 1 Principle of darkroom.

the intensity is proportional to that of the emitting point. The smaller the hole, the more detail the image exhibits, but with less luminosity. Thus, we must adopt a compromise between the resolution and the illumination of the image.

Now, if the mask has several holes, the amount of light reaching the screen, being proportional to the whole aperture area, is extensively increased. On the other hand, as each hole displays an image on the screen, the overlapping of these multiple images gives a new but blurred image. However, the information exists and we should be able to retrieve it if we know the characteristics of the complex aperture. This is the basic concept of multiplex imaging. The crucial question is: what is a good aperture design and a good way to reconstruct images having high resolution and with high illumination levels? The suitable masks with this aim are named synthetic apertures.

Porta (1589) and Kepler (1611) found the perfect solution, by setting up a lens in front of a large hole. Indeed, one can regard a lens as a wide aperture made of continuously juxtaposed microprisms (**Figure 2**). The lens obtains such refractive properties that the image displayed by each of these microprisms is moved toward a center. Moreover, as the angle of the microprisms varies continuously, it focuses on a single point, all the rays coming from a given object point. Thus, the blurring is suppressed and the illumination is increased. The way was opened toward the invention of optical instruments and photography and the 'pinhole' has fallen into oblivion for a long time.

Two new problems awake interest in synthetic apertures, around 1960. First, the domain of imaging has extended out of visible light: infrared and ultraviolet light, γ-rays, X-rays, ultrasound waves, and others. Materials suitable for making lenses or mirrors, operating with such waves, are expensive or often do not exist. For example, most of the transparent materials have a refractive index close to 1 for γ-rays and X-rays. However, some are opaque enough to enable the use of masks.

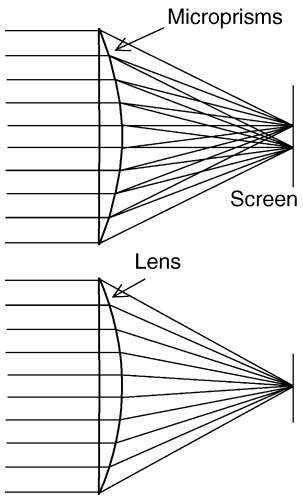

Figure 2 A lens can be modeled as a juxtaposition of microprisms with continously variable angles.

The second challenge appeared with progress in astronomy. In order to explore the universe more, further from Earth and closes to the Big Bang, astrophysicists needed telescopes providing very high luminosity and high resolution, since distant stars, nebulae, and other galaxies are extremely weak and small luminous objects. This exploration can be achieved by increasing the diameter of the primary mirror of telescopes. Indeed, due to diffraction of light by the pupil of the primary mirror, the theoretical limit of resolution of a telescope (i.e., the smaller distance between two points that one can discriminate), is inversely proportional to the diameter of the mirror. In addition, the illumination is proportional to its area. However, the working of large mirrors is a technical prowess that is very expensive and has high risks. Defect of a fraction of micrometer when polishing the surface can have dramatic consequences, e.g., Hubble. Also, such mirrors, being heavy, can bend out of shape under their own weight. Nevertheless, outstandingly large telescopes have been implemented, based on Adaptive optics: the deformations of the mirror are measured in real time by an interference method and compensated by activating a mosaic of jacks (New Technology Telescope – NTT – European program, 1989). Another way consists in replacing the solid-state mirror by a mosaic of 36 mirrors accurately directed (Keck telescope, USA). However, in either case, the mirror diameter does not exceed 8 to 10 meters. Synthetic apertures could be a solution to that difficulty, as earlier demonstrated by Fizeau (1868) and Michelson (1890).

In the first part of this article, any fundamentals are briefly recalled about properties of light and imaging.

The second part describes recent experimental methods and results obtained in synthetic aperture imaging. The last part reports the important programs in progress today relating to stellar interferometry.

Background

Electromagnetic Waves Propagation

Light power, which is involved in image formation, is carried by the electric field of an electromagnetic wave (Figure 3). The electric field $\vec{E}$ has properties of a vector orthogonal to the direction of propagation $\vec{N}$ of the light ray. It is characterized by its amplitude $\vec{E}_0$, the angular time frequency of vibration ω, and the wavevector $\vec{k}$, which specifies the propagating direction of the ray. Let $P(\vec{d})$ be a current point on a plane wavefront, defined by the position vector $\vec{d}$ from the origin of the reference frame. The electric field propagation of a monochromatic wave is expressed as:

$$\vec{E}(\vec{d},t) = \vec{E}_0 \exp[\mathrm{i}(\vec{k}\cdot\vec{d} - \omega t)] \qquad [1]$$

The light power carried by the electromagnetic field is proportional to $I = \|\vec{E}_0\|^2 = \vec{E}\cdot\vec{E}^*$ where $\vec{E}^*$ is the complex conjugate of $\vec{E}$. The time frequency $\nu = \omega/2\pi$, or the wavelength $\lambda = c/\nu$, where c is the electromagnetic wave celerity, characterize the hue of the light. The wavevector $\vec{k} = \vec{N}\omega/c$, where $\|\vec{N}\| = 1$ is an angular space frequency vector, as $\vec{n} = \vec{N}/\lambda = \vec{N}\nu/c$ is a space frequency vector. We have $\vec{k} = 2\pi\vec{n}$. As λ is a constant for a given monochromatic light, $\vec{n}$ defines the direction of propagation of a ray.

Spatially Coherent Light

Consider a very small source stated as the point source S_1, emitting uniform lightwaves in any direction (Figure 4). The wave reaching a farfield point, P, from S_1, propagates along a direction defined by the wavevector $\vec{k}_1$. The vectors $\vec{k}_1$ and $\vec{d}_1 = \overrightarrow{S_1P}$ are collinear. Another point source, S_2 is characterized from P by the wavevector $\vec{k}_2$, such that $\vec{k}_2$ and $\vec{d}_2 = \overrightarrow{S_2P}$ are collinear. When the distances d_1 and d_2 are close to each other, the amplitudes $\vec{E}_{01}$ and $\vec{E}_{02}$ of the waves at P are proportional to those of the corresponding emitting sources, S_1 and S_2. According to the principle of superposition, the resulting field at the point P, $\vec{E} = \vec{E}_1 + \vec{E}_2$, and the instant wavevector $\vec{k}$, are unique vectors.

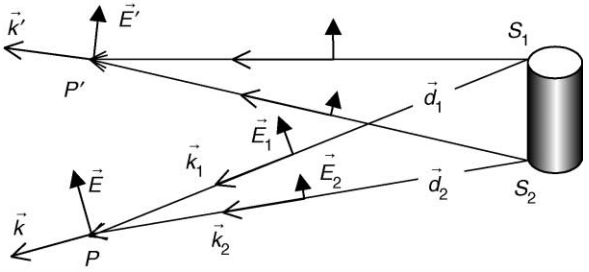

Figure 4 Spatially coherent light.

If S_1 and S_2 are two synchronous sources, the amplitude $\vec{E}_0$ of $\vec{E}$ and the wavevector $\vec{k}$ are constant versus time at any point P. This is still the case when an extended object is made of an arrangement of synchronous points. That situation defines a spatially coherent object. Thus, one cannot recover multiple data about the object's distribution, from the field framework at a single point P, since the relationship between the two is multi-unequivocal. Nevertheless, due to diffraction, one can retrieve them by knowing the complex amplitude distribution of light on a set of wavevectors available over an extensive area of a screen. Let $\vec{E}_0(\vec{r})$ be the amplitude of the electric field at the object point $M(\vec{r})$ and let $\vec{E}_0(\vec{n})$ be the one diffracted by the object to farfield toward the direction corresponding to the space frequency $\vec{n}$. Fourier transforms give the connection between $\vec{E}_0(\vec{r})$, and $\vec{E}_0(\vec{n})$:

$$\left\{\begin{array}{l} \vec{E}_0(\vec{n}) = \int \vec{E}_0(\vec{r}\,)\exp[\mathrm{i}2\pi\vec{n}\cdot\vec{r}]\mathrm{d}\vec{r}, \\ \vec{E}_0(\vec{r}) = \int \vec{E}_0(\vec{n}\,)\exp[-\mathrm{i}2\pi\vec{n}\cdot\vec{r}\,]\mathrm{d}\vec{n}. \end{array}\right\} \qquad [2]$$

This is the situation encountered when an object is illuminated by a laser or by a point source such as a single star.

Spatially Incoherent Light

When the point sources S_1 and S_2 are independent – spatially incoherent – both wavevectors $\vec{k}_1$ and $\vec{k}_2$

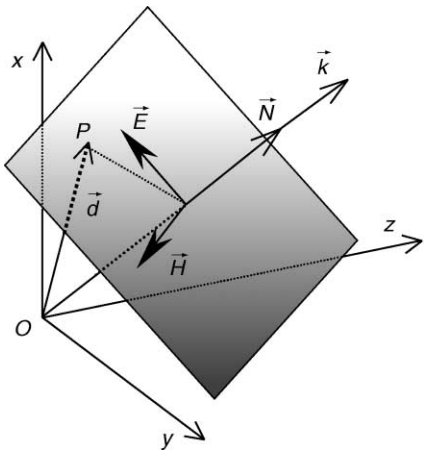

Figure 3 Electromagnetic wave propagation.

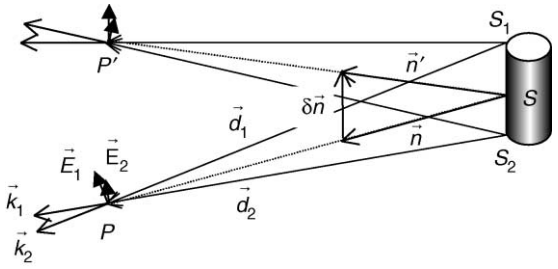

Figure 5 Spatially incoherent light.

coexist at the point P, each characterizing the angular position of S_1 and S_2 (Figure 5). If S_1 and S_2 are part of an extended intensity distribution $I_0(\vec{r})$, fans of wavevectors and fields are mixed at P, each coming from an independent point source S. Together, they carry the whole data on the object distribution. Those data are partially uncorrelated at any two points P and P' on a screen, related to the different optical paths from any point S to P and P' and to the finite time of coherence of light. The correlation between data available to farfield in two directions $\vec{n}$ and $\vec{n}'$ from the object, is given by the mutual intensity function, $\Gamma(\delta\vec{n}) = \int \vec{E}(\vec{n})\cdot\vec{E}^*(\vec{n}+\delta\vec{n})\mathrm{d}\vec{n}$, where $\delta\vec{n} = \vec{n}' - \vec{n}$. Fourier transforms give the relation between $I_0(\vec{r})$ and $\Gamma(\delta\vec{n})$:

$$\left\{\begin{array}{l} \Gamma(\delta\vec{n}) = \int I(\vec{r})\exp[\mathrm{i}2\pi\delta\vec{n}\cdot\vec{r}]\mathrm{d}\vec{r}, \\ I(\vec{r}) = \int \Gamma(\delta\vec{n})\exp[-\mathrm{i}2\pi\delta\vec{n}\cdot\vec{r}\,]\mathrm{d}\delta\vec{n} \end{array}\right\} \quad [3]$$

Therefore, by drawing a map of $\Gamma(\delta\vec{n})$, one can recover the object distribution $I_0(\vec{r})$ by a Fourier transformation. Most of time, one uses the spatial degree of coherence function, $\gamma(\delta\vec{n}) = \Gamma(\delta\vec{n})/\Gamma(\vec{0})$. When the object illuminates a screen, at a large distance d, the degree of coherence of light between two points P and P' on the screen is $\gamma(\delta\vec{\rho}/\lambda d)$, with $\delta\vec{\rho} = \overrightarrow{PP'}$. The 2D extension of $\gamma(\delta\vec{\rho}/\lambda d)$ defines the area of coherence of light on the screen. The width of the area of coherence, $\Delta\rho$, and that of the object distribution, Δr, are inversely proportional:

$$\Delta\rho\cdot\Delta r \sim \lambda d \quad [4]$$

If a mask perforated by two pinholes, separated by a distance $\delta\vec{\rho}$, replaces the screen, one can observe Young fringes of interference beyond the mask, the visibility of them being precisely $\gamma(\delta\vec{\rho}/\lambda d)$. Therefore, one can built a map of $\gamma(\delta\vec{\rho}/\lambda d)$ versus $\delta\vec{\rho}$ from a set of 2D measurements of visibilities of fringes, then reconstruct the object distribution by a Fourier transformation.

Notice that the entire data of the object distribution is available from a single coherence area. That is, a pinhole covering exactly one area of coherence would select the entire available data from the object and would display to farfield the most accurate image possible. Generally, such a pinhole is so small that practically no light passes through it. However, we can regard each area of coherence as an independent channel of information. Then an imaging device based on a juxtaposition of such reduntant channels can be considered as a multiplex imaging device.

Self-luminous objects such as extended or double stars, and artificial thermic sources are spatially incoherent sources.

Multiplex Imaging

Methods of multiplex – or lensless – imaging are performed either with coherent of incoherent light. The very different properties of the two types of light leads to completely different methods, even if all are related to holography. Holography with coherent light is an interference method for local recording of both the direction and modulus of the wavevectors and the amplitude of the field contained in many juxtaposed grains of speckle, scattered by the object. Each grain is an independent channel of imaging.

Synthetic Apertures with Spatially Incoherent Objects

As interferences are impossible by this method with incoherent light, we must improve other methods of imaging. Synthetic aperture is a concept consisting of using a redundant multichannel system to increase the luminosity of images without loss of resolution. The basic principle is that of a multiple holes darkroom. The processing is in two steps: recording and reading the image. The recording step consists in illuminating a photosensitive receptor with the object through a mask (Figure 6). Generally, the receptor is a

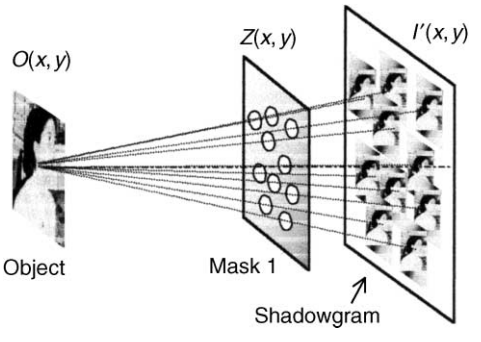

Figure 6 Principle of synthetic aperture: recording.

photographic plate. Obviously, the light distribution on the plate is blurred. Indeed, any elementary transparencies on the mask project on the receptor inverted images of the object located the shadow of the mask. Such a distribution is expressed by a convolution. Let $O(x, y)$ be the conical projection of the object on the receptor and $Z(x, y)$ that of the mask. The shadows distribution on the receptor is (the variable being normalized):

$$I'(x', y') = Z(x, y) * O(x, y) = \int Z(x, y)O(x' - x, y' - y)\mathrm{d}x\ \mathrm{d}y \quad [5]$$

The reading step is a decorrelation processing from the recorded intensity (Figure 7). It consists in achieving a new correlation of I' with an arbitrary function T:

$$I''(x, y) = T(x, y) * [Z(x, y) * O(x, y)] = [T(x, y) * Z(x, y)] * O(x, y) \quad [6]$$

$R[x, y] = [T(x, y) * Z(x, y)]$ is the system point spread function (SPSF) of the processing. It expresses the image distribution of a single-point. The perfect image is obtained when $R(x, y)$ is a 2D *Dirac* – or *delta*– distribution, $\delta(x, y)$:

$$R(x, y) = \delta(x, y), \quad \text{as} \quad \int \delta(x, y)O(x' - x, y' - y) \times \mathrm{d}x\ \mathrm{d}y = O(x', y') \quad [7]$$

Fresnel zone plates

First Mertz and Young used Fresnel zone plate (FZP) as a synthetic aperture for X-ray imaging purposes. FZPs are made of alternate transparent and opaque concentric crowns of equal area. The radius of the nth circle is $r_1\sqrt{n}$, r_1 being the smallest. When illuminated by a cylindrical light beam, the FZP is a multiple foci diffractive lens (Figure 8).

The reading step is either analogical or numerical. Through the analogical method, we consider the recorded plate as a pseudohologram (Figure 9). When the 'shadowgram' is lighted with a parallel beam of laser light, the FZPs recorded around each point concentrates the light on its foci. Then an image of the object is reconstructed on the focal planes; a method that is simple and elegant. Nevertheless, the processing is not linear since we record an intensity distribution at the recording step, while the reading step by diffraction involves amplitude. Moreover, the S/N ratio decreases as the amount of data increases, recorded on the photographic plate because of its finite dynamic.

Mertz and Young had the idea of using a second FZP to perform the deconvolution processing by optical methods. In this case, the SPSF, $R(x, y)$, is the autocorrelation function of the FZP transparency (Figure 10). It presents a narrow central peak, emerging from a pyramidal ground (Figure 11). The optical setup is the same as the recording step.

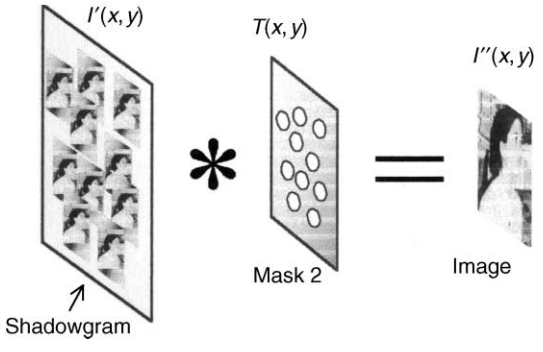

Figure 7 Synthetic aperture: reading.

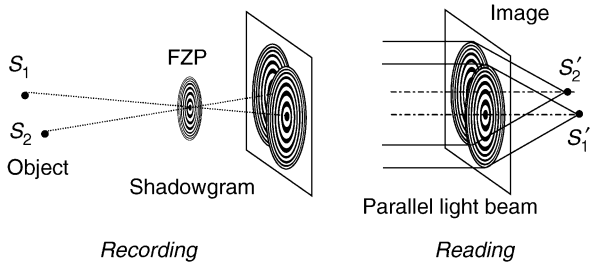

Figure 9 Recording and analogical reading with a FZP.

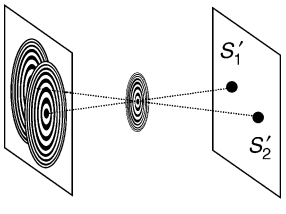

Figure 10 Optical decorrelation.

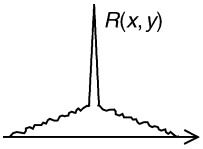

Figure 11 System point spread function with a Fresnel zone plate.

The FZP scale factor only must be adjusted to compensate for the magnification ratio generated by the conical projection at the recording step.

In either digital or analogical deconvolution, the image reconstructed is accurate, with good sharpness, if the number of zones is sufficient. Ceglio *et al.* obtained relevant images of 8 μm targets with FZP having 100 zones. Nevertheless, the multiple foci of FZP induces decreasing of the S/N ratio which is an important limitation. Besides, we pointed out above that the larger the object, the more the decrease in the S/N ratio.

Random and uniformly redundant arrays

Dicke and Ables substituted a random array to the FZP. The mask is made of randomly distributed holes and the expected advantage is doubled. First, one can reduce the transparent area of the mask by less than 50% in order to increase the S/N ratio when the object is wide. Second, the autocorrelation function of such an array is theoretically a Dirac distribution when its width is infinite. Thus, one can hope to narrow the system point response. However, when the width is finite, the pyramidal ground of the point response mentioned above is present and the advantage is not clearly demonstrated. In order to correct this effect, Chris Brown used a 'mismatched' function, for the postprocessing deconvolution. This function is calculated, first by achieving the complement of the recording mask function, then subtracting from it. Thus, the 1 transparencies result in +1 while the 0 transparencies are changed by −1. Brown shows images digitally reconstructed of X-ray sources, 30 sec. of arc wide. Fenimore and Cannon conceived a uniformly redundant array. The center random motif of the mask is half replicated on each side with only the center area being used for the recording step. The deconvolution is calculated by taking into account the whole area in a mismatched way. The result is an exact delta function. The authors show images of 200 μm-wide microspheres with a similar resolution but a signal 7100 times stronger than with a comparable pinhole camera.

Theta Rotating Interferometer

The theta shearing interferometer enables us to record complete data from the Fourier transform of a spatially incoherent object (Figure 12). The source can be any natural one, but monochromatic. This is easily practicable using a good filter or monochromator.

The device is based on a Michelson interferometer, the plane mirrors being replaced by two roof prisms. One of the roof prisms is fixed so the other can rotate around the axis of the interferometer. As a result, we have two images of the object. Let θ be the angle between the two edges of the prisms. The angle between the images is 2θ. Since the original object is noncoherent, and two homologous points being mutually coherent, the light they emit interferes, resulting in fringes.

The intensity, space frequency, and direction of the fringes characterize the intensity and the position of the point source. One shows that the farfield visibility distribution of fringes $V(\delta\vec{n})$ and the object distribution $O(\vec{r})$ are related by Fourier transforms:

$$\left\{\begin{aligned} V(\delta\vec{n}) &= \int O(\vec{r}\,)\exp\left[\mathrm{i}2\pi\frac{\delta\vec{n}\cdot\vec{r}}{2\sin\theta}\right]\frac{\mathrm{d}\vec{r}}{2\sin\theta}, \\ O(\vec{r}\,) &= \int V(\delta\vec{n})\exp\left[-\mathrm{i}2\pi\frac{\delta\vec{n}\cdot\vec{r}}{2\sin\theta}\right]\mathrm{d}\delta\vec{n} \end{aligned}\right\} \quad [8]$$

Then, one can see that the visibility of the interference pattern is an image of the degree of coherence $\gamma(\delta\vec{n})$, with a scale factor 1/2 sin θ.

Such a pattern recorded on a photographic plate is a Fourier hologram of the noncoherent object. An image can be reconstructed by diffraction at infinity or near a focus (see Figure 13, examples performed in 1972 by the author). The technique was successfully applied to the determination of the modulation transfer function of optical systems. C Roddier and F Roddier applied the method to astronomy.

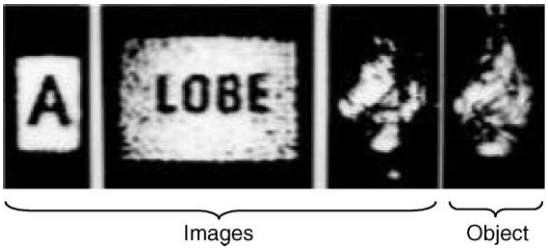

Figure 13 Incoherent light holograms.

For instance, they examined Alpha Orionis and discovered the evolution of its dust envelope and the possible existence of a companion.

High Resolution Imaging in Astronomy

In astronomy, the limit of resolution depends chiefly on two factors. The first is a technical one. Adaptive optics and very large telescopes (VLT) brought spectacular progress to clarity and resolution of telescopes. The 8.2 m VLT of Kueyen set up in 1989, shows images easily resolved of HIC 69495 Centauri, separated by 0.12 sec. of arc. Nevertheless, working of large mirrors for telescopes reaches its limits. Therefore, their clarity remains too weak. On the other hand, atmospheric turbulences make the refractive index of air unstable and the position of the images in the focal plane of telescopes unsettled. Thus, the point response is a granular spot named 'speckle'. Short exposure times relieve that inconvenience, but they prohibit the observation of weak stars. In 1970, Labeyrie proposed a method of speckle interferometry consisting of a statistical analysis of a set of speckles. The result is a display of a diffraction-limited image. He resolved many tens of single and double stars. Only Hubble, above the atmosphere, is able to do it by direct imaging. However, the primary mirror of Hubble being only 2.40 m wide, has clarity much lower. Stellar interferometry is a very promising alternative solution.

Principles of Stellar Interferometry

Stellar interferometry is based on eqn [3]. The light emitted by double or wide stars is noncoherent, so that one can access an image of them trough 2D measurements of the degree of coherence of light. We showed above that one could achieve this by using interference devices such as Young holes. Eqn [3] shows that if we measure the visibility of Young fringes at increasing distances $\delta\rho$ between the pinholes, the distance $\Delta\rho$ from which the visibility is zero gives the angular width of the star, $\Delta\alpha$, under the formula:

$$\Delta\rho \cdot \Delta\alpha \sim \lambda \qquad [9]$$

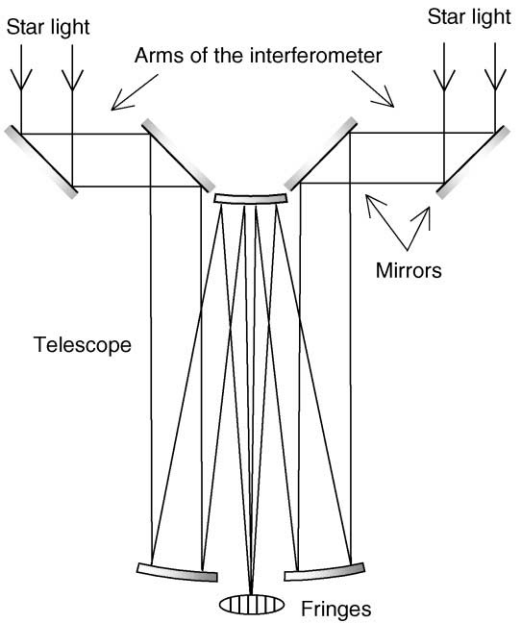

Figure 14 Stellar interferometer of Michelson.

where $\Delta\alpha = \Delta r/d$. In the case of a double star, the visibility varies periodically versus $\delta\rho$ when the pinholes are aligned along the axis of two stars. Let $\Delta\alpha$ be the angular distance between the stars: the smallest distance $\Delta\rho$ for which the visibility is zero is given by:

$$\Delta\rho \cdot \Delta\alpha = \lambda/2 \qquad [10]$$

The larger the uttermost distance between the holes, the more the limit of resolution of the processing is potentially sharp.

In order to exploit this idea, Stephan placed and rotated a mask with two holes in front of the objective of a refractive telescope. He established that the diameter of the stars he observed was much less than 0.16 sec. of arc. Then, Michelson built up, on top of a 30 cm refractive telescope, a stellar interferometer consisting of two arms catching the light at 7 m of distance from each other (Figure 14). He measured correctly the diameter of the satellites of Jupiter. Hale carried the distance of the base up to 15 m in 1920.

The Two Telescopes Interferometer of Labeyrie

In 1975, Labeyrie improved the idea by setting up two separate 25 cm diameter Cassegrain-coudé telescopes on a 12 m baseline, oriented north–south (Figure 15). The setting and mechanical stability of the device are extremely sensitive. The tolerances do not exceed any μm. A mobile table near the common focal plane of the two telescopes compensates for the optical path differences due to stars tracking. In spite

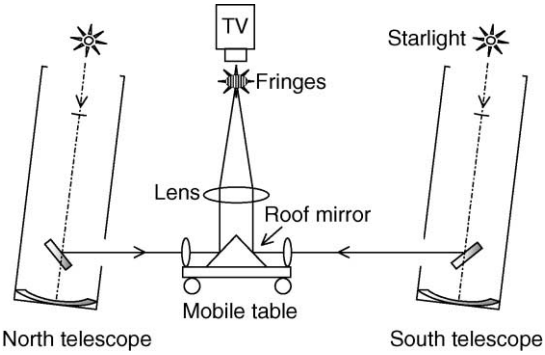

Figure 15 The two telescopes interferometer of Labeyrie.

of the acute difficulties, he succeeded in observing fringes on Vega. He obtained a resolution of 0.01 sec. of arc versus 0.5 sec. with a single 25 cm telescope. Later, one telescope was rendered mobile bringing the base width variable between 4 and 67 m. The resolution reaches up to 0.00015 sec. of arc. Note that the rotation of Earth also enables east–west analysis with resolution of 0.005 sec., and today, the 25 cm telescopes are replaced by 1.5 m ones.

The Very Large Telescope Interferometer (VLTI)

The two telescopes interferometer of Labeyrie is a first step toward a very ambitious project: the telescope at synthetic aperture and very large base. Proofs of reliability of such a principle was already given by the very large array (VLA) experimented in radio astronomy. Labeyrie with Lena, and the team of the ESO (Ecole Supérieure d'Optique, Paris), imagined a very large telescope interferometer (VLTI) made of 6 telescopes of 2 m, in a 2D structure on a base of 100 m. The European VLTI was built at Cerro Paranal. It is made of four 8.2 m telescopes corrected in real time by adaptive optics (NTT technology) and three 1.8 m telescopes. The fourth 8.2 m telescope was put in service in 2001. Some days, each of the 8.2 m telescopes used separately gives a resolution close to that of Hubble. However, the clarity is much better because of the larger primary mirror diameter (8.2 m against 2.4 m). In May 2003, the team of J-G Cuby observed a galaxy the farthest away ever seen, only 900 millions years old since the Big Bang. Obviously, a drastic gain of resolution (by a factor 10) is expected from the interference configuration.

Photon Density Wave Imaging

V Toronov, University of Illinois at Urbana-Champaign, Urbana, IL, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Photon density wave imaging (PDWI) employs diffused light, usually in the near-infrared band, for imaging inhomogeneous structures in a highly scattering medium. The other names for PDWI are diffuse optical tomography and photon migration imaging. The term photon density wave (PDW) refers to the wave of light density spreading in the highly scattering medium from the source whose power changes in time. Therefore, rigorously speaking, photon density wave imaging uses intensity-modulated light sources, such as pulsed lasers, or sources whose power is harmonically modulated. However, many applications employ steady-state light sources. Most applications of PDWI are in the field of imaging of biological tissues, including medicine and cognitive neuroscience.

As in the other imaging methods, such as x-ray, computed tomography (CT) or ultrasound imaging, the problem of PDWI consists in the reconstruction of the internal structure of the medium from the measurements made outside the medium (on its surface). In the case of PDWI the internal structure of the medium is represented by the spatial distribution of its optical properties. The reconstruction procedure is essentially an iterative mathematical algorithm, which includes the modeling of the light propagation inside the medium assuming a certain distribution of the optical properties, and the

correction of this distribution to match the model prediction with the actual measurement. The modeling part of the imaging problem is usually referred to as the forward problem, and the correction procedure is known as an inverse problem.

Forward Problem: Photon Density Waves

Unlike optically transparent media, in a highly scattering medium the coherence of light from the coherent source very rapidly decays with distance. This happens due to the interference of many randomly and multiply scattered light waves at every point of the medium that is distanced from the source much farther than the photon mean free path l, which is the mean distance at which a light wave undergoes a single scattering event. For biological tissues, where light scattering occurs on cell membranes and other heterogeneities of the index of refraction, l is typically about 1 mm. Although high scattering eliminates the coherence of the electromagnetic waves at the short time intervals corresponding to oscillation at optical frequencies ($\sim 10^{-15}$ s), in the case of an intensity-modulated light source, the macroscopic wave of the density of light energy, called 'photon density wave', forms in the highly scattering medium. The properties of PDW depend on the type of the source modulation and on the local optical properties of the medium, which are the scattering coefficient μ_s [cm^{-1}] and the absorption coefficient μ_a [cm^{-1}].

Because of the complexity and incoherence of the macroscopic electromagnetic field in highly scattering media, i.e. media with $\mu_a \ll \mu_s$, the fundamental Maxwell equations of electrodynamics do not provide a convenient approach to the solution of the problem of light propagation in such media at distances much larger than l. Therefore, statistical approaches have been developed, such as the photon transport model and its diffusion approximation. In the photon transport model the light is characterized by the radiance $L(\mathbf{r}, \hat{\Omega}, t)$ [W cm^{-2} steradian^{-1}] (where the steradian is the unit solid angle), which is the power of radiation near the point $\mathbf{r}$ propagating within a small solid angle around the direction $\hat{\Omega}$ at time t. The photon transport model accounts for the possible nonisotropy of the radiation flux. For the given spatio-temporal distribution of the optical properties, μ_a and μ_s, and for the given spatial and angular distribution of light source power $S(\mathbf{r}, \hat{\Omega}, t)$ [W cm^{-3} steradian^{-1}] the radiance $L(\mathbf{r}, \hat{\Omega}, t)$ can be found from the linear radiation transfer equation, also called the photon transport equation, or simply the transport equation (TE):

$$\frac{1}{v}\frac{\partial L(\mathbf{r}, \hat{\Omega}, t)}{\partial t} + \nabla \cdot L(\mathbf{r}, \hat{\Omega}, t)\hat{\Omega} + (\mu_s + \mu_a)L(\mathbf{r}, \hat{\Omega}, t) = \mu_s \int L(\mathbf{r}, \hat{\Omega}', t) f(\hat{\Omega}, \hat{\Omega}') d\hat{\Omega}' + S(\mathbf{r}, \hat{\Omega}, t) \quad [1]$$

where $f(\hat{\Omega}, \hat{\Omega}')$ is the phase function, which represents the portion of light energy scattered from the direction $\hat{\Omega}$ to the direction $\hat{\Omega}'$, and v is the speed of light in the medium. TE is equivalent to the Boltzmann transport equation describing the transport of particles undergoing scattering.

Equation [1] is difficult to solve even numerically. Therefore, a hierarchy of approximations to the PTM was developed. This hierarchy, known as the P_N approximation, is based on the expansion of the radiance in a series of spherical harmonics $Y_{nm}(\hat{\Omega})$ truncated at $n = N$. In the P_1 approximation the coefficients of the series are proportional to the radiation fluence

$$\Phi(\mathbf{r}, t) = \int L(\mathbf{r}, \hat{\Omega}, t) d\hat{\Omega}, \quad [2]$$

and the flux

$$J(\mathbf{r}, t) = \int L(\mathbf{r}, \hat{\Omega}, t)\hat{\Omega} d\hat{\Omega}, \quad [3]$$

both having units of [W cm^{-2}]. By substituting the P_1 series for $L(\mathbf{r}, \hat{\Omega}, t)$ and $S(\mathbf{r}, \hat{\Omega}, t)$ into eqn [1] and assuming isotropic light sources and sufficiently slow change of source intensity, one can obtain the equation that includes only $\Phi(\mathbf{r}, t)$ as the unknown. Usually, this equation

$$v\mu_a U(\mathbf{r}, t) + \frac{\partial U(\mathbf{r}, t)}{\partial t} - D\Delta U(\mathbf{r}, t) = Q(\mathbf{r}, t) \quad [4]$$

is written in terms of the value $U(\mathbf{r}, t) = \frac{1}{v}\Phi(\mathbf{r}, t)$ [J cm^{-3}], which has units of energy density, and is called the photon density. In eqn [4] $D = v/(3\mu_a + 3\mu_s')$ [cm^2/s] is the light diffusion coefficient, and $\mu_s' = \mu_s(1 - g_1)$ [cm^{-1}] is the reduced scattering coefficient; g_1 is the average cosine of the scattering angle. The source term $Q(\mathbf{r}, t)$ [J cm^{-3} s^{-1}] in the right-hand side of the equation [4] describes the spatial distribution of light sources (in the isotropic approximation, i.e., neglecting the dipole and higher momenta of $S(\mathbf{r}, \hat{\Omega}, t)$) and the temporal modulation of source intensity.

Equation [4] is mathematically equivalent to the equation describing the density of the medium consisting of the particles undergoing linear diffusion. Therefore, it is called the diffusion equation (DE), and the P_1 approximation is also known as the diffusion

approximation. The diffusion approximation is valid under the following three conditions: (a) the light sources are isotropic or the distance between the source and the detector is much larger than l; (b) characteristic source modulation frequencies ν are low enough that $\nu\mu_s'/(2\pi\nu) \gg 1$; and (c) $\mu_a \ll \mu_s'$. In the biomedical applications of PDWI the condition (a) is fulfilled when the source–detector distance is larger than 1 cm. The condition (b) is valid when the characteristic modulation frequencies of the light source are less than 1 GHz. The condition (c) is fulfilled in most biological tissues, for which the scattering is highly isotropic, i.e. $g_1 \ll 1$. Thus, the forward problem of PDWI, i.e., the modeling of light propagation, can be solved using the diffusion approximation in a large variety of situations.

PDWs described by equation [4] are the scalar damped traveling waves, characterized by the coherent changes of light energy (photon density) in different locations on time intervals from microseconds to nanoseconds. Usually pulsed or harmonically modulated light sources are used to generate PDWs. The properties of the PDWs from a harmonic source are fundamental, because the PDW from the source of any type of modulation can be considered as a superposition of harmonic waves from sources having different frequencies using the Fourier transform.

In order to get an idea of the basic properties of PDW, one can consider the analytical solution of [4] for the case of a harmonically modulated point-like source placed in an infinite homogeneous scattering medium. This solution is

$$U(r,t) = U_{dc}(r) + U_{ac}(r)\exp[-i\omega t + i\phi(r)] \qquad [5]$$

where U_{ac}, U_{dc}, and ϕ are the ac, dc and phase, respectively, of the wave measured at the distance r from the source, and $\omega = 2\pi\nu$. U_{ac}, U_{dc}, and ϕ depend on the medium optical properties, source intensity Q_0, modulation amplitude A_0, and initial phase ψ_0 as

$$U_{ac}(r) = \frac{Q_0 A_0}{4\pi D} \times \frac{\exp\left[-r\left(\frac{\nu\mu_a}{2D}\right)^{1/2}((1+x^2)^{1/2}+1)^{1/2}\right]}{r} \qquad [6a]$$

$$U_{dc}(r) = \frac{Q_0}{4\pi D}\,\frac{\exp\left[-r\left(\frac{\nu\mu_a}{D}\right)^{1/2}\right]}{r} \qquad [6b]$$

$$\phi(r) = r\left(\frac{\nu\mu_a}{2D}\right)^{1/2}\sqrt{(1+x^2)^{1/2}-1} \qquad [6c]$$

where $x = \omega/(\nu\mu_a)$. Equations [5]–[6] describe a spherical wave whose wavelength at $\mu_a = 0.1\ \mathrm{cm}^{-1}$ and $\mu_s' = 8\ \mathrm{cm}^{-1}$ (typical for biological tissues) and at modulation frequency $\nu = 100$ MHz, is close to 35 cm, so that the phase of the wave changes approximately by 10° per cm. In the same time, the wave decays exponentially at a distance of about 3 cm, so that PDWs are strongly damped. A similar analytical solution in the form of a spherical wave can be obtained for the case of a semi-infinite homogeneous medium and point source placed on the surface of the medium (see Figure 1). These analytical solutions are employed to measure μ_a and μ_s' of the homogeneous medium. The method is based on fitting measured ac, dc, and phase of the PDW as functions of source–detector distance by the analytical solution.

Inhomogeneities in the optical properties of a turbid medium cause distortion of the PDW from sphericity (see Figure 1). PDWs in homogeneous media of limited size or with strong surface curvature also usually have complex structure. For a limited number of configurations one can obtain solutions to the DE using analytical methods of mathematical physics, such as the method of Green's functions. However, in practice the complexity of the inhomogeneities and surfaces usually requires numerical solution of the DE. This can be achieved using numerical methods for the solution of partial differential equations, such as the finite element method and the finite difference method. The finite difference method can also be used to solve the TE. This may be necessary in situations when the DE is not valid, for example to accurately account for the influence of the cerebrospinal fluid (which has relatively low scattering) on light transport in the human skull. However, the solution of the TE requires formidable computational resources, which increase proportionally to the volume of the medium. Therefore, hybrid DE-TE methods were developed, in

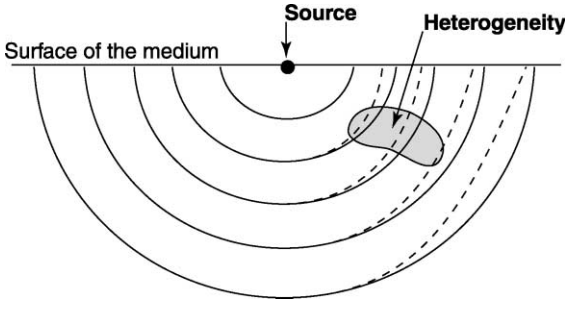

Figure 1 Equiphase surfaces of the PDW induced by a point source in a semi-infinite homogeneous medium (solid lines) and in a medium including heterogeneity (dashed lines).

which DE is used to describe light propagation in most of the medium except small low-scattering areas described by the TE.

One should note that although the term 'photon' suggests quantum properties of light, no consistent application of quantum theory to problems related to PDWI has been developed so far. Also, it should be noted that the notion of a photon as a particle of light having certain energy, momentum, and localization at the same time is not completely consistent with quantum electrodynamics. However, since the theoretical models of light transport in a scattering medium (such as TE and DE) are mathematically equivalent to the models describing systems of randomly moving particles, the notion of a photon as a 'particle of light' may be accepted as adequate and is widely used in the limits of PDWI.

Inverse Problem and Imaging Algorithm

Mathematically the forward problem can be expressed in the form of a general nonlinear operator F:

$$G = F[\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}] \qquad [7]$$

where G is the set of measured values (ac, dc, and phase), $\mathbf{r}$ is the coordinate vector of a medium element (voxel), and $\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}$ denotes the set of tissue optical properties corresponding to whole collection of voxels. The problem of finding the spatial distribution of medium optical properties can be formalized as

$$\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\} = F^{-1}[G] \qquad [8]$$

Neither the transport model nor the diffusion model allow inversion in a closed analytical form for a general boundary configuration and spatial distribution of optical properties. The basic reason for the complexity of the inverse problem is in the complexity of the light paths in the highly scattering medium. This situation is opposite to that in CT, where the x-ray radiation propagates through the medium along straight lines almost without scattering, which significantly simplifies the forward problem and allows its analytical inversion. From the mathematical point of view, the complexity of the inverse problem of PDWI is due to its nonlinearity and ill-posedness. Only approximate methods of inversion have been developed so far.

The simplest method is called backprojection by analogy with the method of the same name used in CT. The method attempts to reconstruct the actual spatial distribution of the optical properties μ_a and/or μ_s' from the 'measured' bulk values μ_a^m and $\mu_s'^m$ obtained at a variety of locations assuming homogeneity of the medium. The measured values are considered as a result of the volumetric 'projection'

$$\{\mu_a^m(\mathbf{r}), \mu_s'^m(\mathbf{r})\} = \int \{\mu_a(\mathbf{r}'), \mu_s'(\mathbf{r}')\} h(\mathbf{r} - \mathbf{r}') d^3\mathbf{r}' \qquad [9]$$

of the actual distribution, where $\mathbf{r}$ and $\mathbf{r}'$ are the locations of the measurement and reconstruction, respectively. A weight function $h(\mathbf{r})$ accounts for the contribution of the particular region to a measured value and should be derived from the forward model. Different versions of the backprojection method use different weight functions $h(\mathbf{r})$. In the backprojection method the values of μ_a and/or μ_s' are obtained by inverting the convolution [9]. In practice the convolution integral is usually estimated by a sum over a limited number of voxels for a limited number of measurements. Therefore, the inversion of the convolution reduces to the solution of the set of algebraic equations corresponding to [9]. The advantage of the method is high speed, which allows real-time imaging of the dynamic processes, for example, functional hemodynamic changes in the brain. However, the backprojection method provides a phenomenological rather than a self-consistent inversion of the forward problem, and its quantitative accuracy is low.

A more consistent method is based on the perturbation approach to the solution of the inverse problem [8]. If we have an estimate $\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e$ that is close to the ideal solution, then $G_e = F[\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e]$ (see eqn [7]) is close to S. Then the difference $G - G_e$ can be written as a Taylor series:

$$G - G_e = J[\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e]\{\Delta\mu_a(\mathbf{r}), \Delta\mu_s'(\mathbf{r})\} + \ldots \qquad [10]$$

where $J[\ldots]$ is the Jacobian, and $\{\Delta\mu_a(\mathbf{r}), \Delta\mu_s'(\mathbf{r})\} = \{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\} - \{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e$. Neglecting terms after the first one in [10], the problem of finding the correction $\{\Delta\mu_a(\mathbf{r}), \Delta\mu_s'(\mathbf{r})\}$ to the estimate $\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e$ reduces to the calculation of the Jacobian and to the solution of a linear algebraic equation.

This approach provides a basis for the PDWI algorithm, which is the following. First one makes an initial guess at the optical properties of the medium. Then one calculates the ac, dc, and phase of the PDW using a model of light propagation through the tissue and the geometry of the source–detector configuration. The calculated values are compared with the measured ones. If the error is above a set tolerance level, one calculates corrections to the current values of μ_a and μ_s' by solving eqn [10]. The algorithm is completed when the required error level is achieved. Thus, the PDWI algorithm iteratively applies both

the forward and inverse problems. Since at each of many iterations one should solve the forward problem, which in the simplest case is a partial differential equation, the algorithm typically requires considerable computational resources.

One should note that the success of the method is largely dependent on the closeness of the initial guess to the actual values of the optical properties. In many studies the 'first guess' of the tissue optical properties was obtained by measuring the bulk absorption and reduced scattering coefficients. However, because of the ill-posedness of the inverse problem, homogeneous initial conditions did not always lead to the correct reconstruction. A more productive approach to the problem of the initial conditions is to assign approximate initial values of the optical properties known for example from *in vitro* measurements to different structures revealed by nonoptical imaging techniques, such as magnetic resonance imaging (MRI) or CT.

Applications

PDWI was proposed and developed as a noninvasive biomedical imaging technique. Although the spatial resolution of PDWI cannot compete with that of CT or MRI, PDWI has the advantages of low cost, high temporal resolution, and high biochemical specificity. The latter is based on the optical spectroscopic approach. Biological tissues are relatively transparent to light in the near-infrared band between 700 and 1000 nm (a near-infrared window). The major biological chromophores in this window are oxy- and deoxyhemoglobin, and water. One can separate contributions of these chromophores into light absorption by employing light sources at different wavelengths. Multi-wavelength PDWI can also be used to measure the redox state of the cytochrome oxidase, which is the terminal electron acceptor of the mitochondrial electron transport chain and responsible for 90% of cellular oxygen consumption.

One of the hot topics in cognitive neuroscience is the hemodynamic mechanism of the oxygen supply to neurons and removal of products of cerebral metabolism. High temporal resolution and biochemical specificity make PDWI a unique noninvasive tool for studies of functional cerebral hemodynamics, although light can penetrate no deeper than the very surface of the adult brain. Figure 2 displays a typical arrangement of light sources and detectors used in PDWI of functional cerebral hemodynamics, and the images of the activated area in the brain.

Because of its low cost, noninvasiveness, and compact size of the optical sensors, PDWI is also considered to be a promising tool for mammography and structural imaging of anomalies in the brain. PDWI is an especially promising tool for neonatology, because the infant tissues have low absorption.

PDWI instruments employ lasers, light-emitting diodes and gas-discharge tubes as sources of light. Among the detectors there are photomultiplier

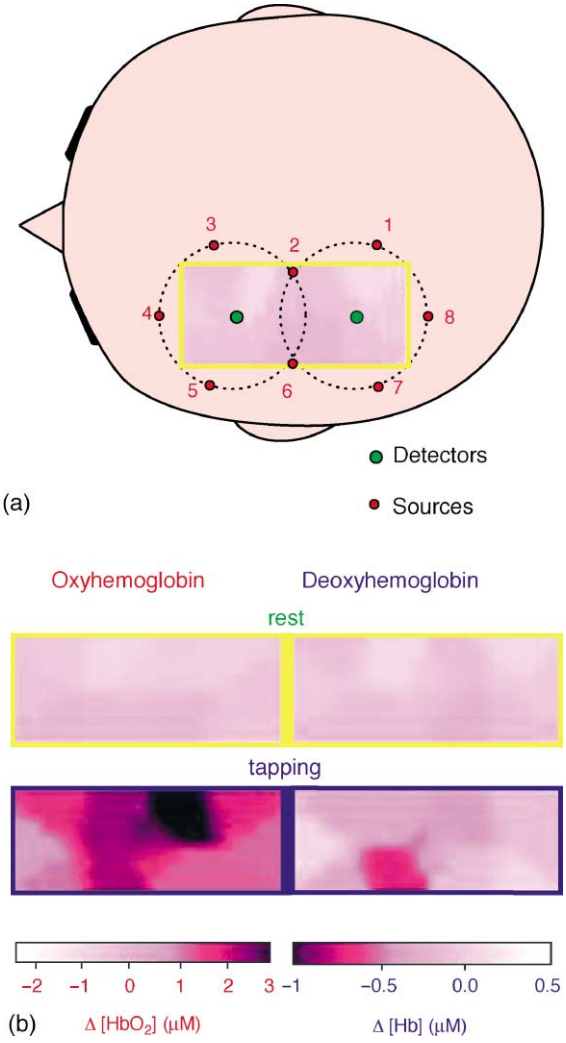

Figure 2 (a) Geometrical arrangement of the 16 sources and two detectors on the head of a human subject. Each one of the eight small red circles (numbered 1–8) represents one pair of source fibers at 758 and 830 nm. Two larger green circles represent detector fiber bundles. The rectangle inside the head outline is the 4×9 cm^2 imaged area. (b) Maps of oxyhemoglobin ([HbO_2], left panels) and deoxyhemoglobin ([Hb] right panels) concentration changes at rest (top) and at the time of maximum response during the third tapping period (bottom). The measurement protocol involved hand-tapping with the right hand (contralateral to the imaged brain area). Adapted with permission from Franceschini MA, Toronov V, Filiaci M, Gratton E, Fantini S (2000) On-line optical imaging of the human brain with 160-ms temporal resolution. *Optics Express* **6**(3), 49–57 (Figures 1 and 4).

tubes, avalanche photodiodes, and CCD cameras. Both sources and detectors can be coupled with the tissue by means of optical fibers. A number of commercially produced near-infrared instruments for PDWI are available on the market. According to the type of source modulation, there are three groups of instruments: frequency domain (harmonically modulated sources), time domain (pulsed sources), and steady state. Steady-state instruments are simpler and cheaper than frequency-domain and time-domain ones, but their capabilities are much lower. Time-domain instruments can theoretically provide a maximum of information about the tissue structure, but technically it is difficult to build a time-domain instrument with high temporal resolution and high signal-to-noise ratio. Frequency-domain instruments provide temporal resolution up to several milliseconds and have high quantitative accuracy in the determination of optical properties.

Nomenclature

Absorption coefficient, μ_a [cm^{-1}]
Alternating part of PDW, alternating current (ac)
Average cosine of the scattering angle, g_1
Circular modulation frequency, ω [s^{-1}]
Computed tomography (CT)
Difference between the estimate and actual optical properties, $\{\Delta\mu_a(\mathbf{r}), \Delta\mu_s'(\mathbf{r})\} = \{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\} - \{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e$ [cm^{-1}]
Diffusion coefficient, $D = v/(3\mu_a + 3\mu_s')$ [cm^2/s]
Diffusion equation (DE)
Distribution of light source power $S(\mathbf{r}, \hat{\Omega}, t)$ [W cm^{-3} $steradian^{-1}$]
Divergence operator, ∇ [cm^{-1}]
Estimate of optical properties, $\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}_e$ [cm^{-1}]
General nonlinear operator, F
Jacobian, J
Laplace operator, Δ [cm^{-2}]
Magnetic resonance imaging (MRI)
Measured bulk optical properties (absorption and reduced scattering coefficients) $\{\mu_a^m \mu_s'^m\}$ [cm^{-1}]
Modulation frequency, ν [s^{-1}]
Non-alternating part of PDW, direct current (dc)
Optical properties of the medium (absorption and reduced scattering coefficients) as functions of spatial coordinate, $\{\mu_a(\mathbf{r}), \mu_s'(\mathbf{r})\}$ [cm^{-1}]
Phase as a function of source–detector distance $\phi(r)$
Phase function, $f(\hat{\Omega}, \hat{\Omega}')$

Three-Dimensional Field Transformations

R Piestun, University of Colorado, Boulder, CO, USA

Introduction

Conventional optical imaging is understood as an isomorphic mapping from an object space onto an image space. The object space is composed of scattering or emitting objects. The scattering objects can be opaque, transparent, or partially absorbing, while emitting objects can be as diverse as stars in astronomical imaging or fluorescent molecules in microscopic imaging. The image space is an optical field representation of the object.

In most classical applications of optical imaging the goal is to optimize the mapping between one plane in the object space and one plane in the image space. Modern optical systems, though, are aimed at acquiring three-dimensional information regarding the object. The image is thus a three-dimensional field representation of the object.

While many imaging systems are aimed at obtaining visually appealing images, many modern imaging systems register the field information in some type of sensitive device such as film or CCD cameras for later processing. This processing is typically performed electronically by a computer and the final image is ultimately a mathematical digital representation of the object. This type of imaging is called computational imaging. An example of computational imaging is optical tomography, which involves the registration of a set of images that do not necessarily resemble the object, and off-line digital processing to obtain a three-dimensional representation of the object.

In this article we will focus on imaging in the conventional sense but will also focus on the three-dimensional aspects of the image.

Geometrical Optics Transformations

In many optical problems it is appropriate to consider the wavelength of the electromagnetic wave as infinitely small. This approximation is the origin of the field of geometrical optics in which the propagation of light is formulated in terms of geometrical laws. Accordingly, the energy is transported along light rays and their trajectories are determined by certain differential or integral equations that can be directly derived from Maxwell's equations. One of these formulations uses Fermat's principle that states the principle of the shortest optical path. The optical path between two points P_1 and P_2 is defined as:

$$OP = \int_{P_1}^{P_2} n(P)\mathrm{d}s \qquad [1]$$

where n is the refractive index of the medium. Fermat's principle states that the optical path of a real ray is always a local minimum.

In ideal optical imaging systems, every point P_o of the so-called object space will generate a sharp image point P_i, that is a point where infinite rays emerging from P_o pass through P_i. Perfect imaging occurs when every curve defined by object points is geometrically similar to its image. Perfect imaging can occur between three-dimensional spaces or between surfaces.

An interesting result of geometrical optics is Maxwell's theorem. This theorem states that if an optical instrument produces a sharp image of a three-dimensional domain, the optical length of any curve in the object is equal to the optical length of its image. More explicitly, if the object space has index n_o and the image space index n_i, the theorem states that:

$$\int_{C_o} n_o \, \mathrm{d}s_o = \int_{C_i} n_i \, \mathrm{d}s_i \qquad [2]$$

where C_i is the image of the object curve C_o.

An important consequence of Maxwell's theorem is a theorem by Carathéodory which states that any imaging transformation has to be a projective transformation, an inversion, or a combination of them. Another consequence of this theorem is that if the two media are homogeneous, perfect imaging can only occur if the magnification is equal to the ratio of the refractive indices in the object and image space. If the media have the same index, the imaging is trivial with unit magnification. The simplest example of a perfect imaging instrument is a planar mirror. Therefore, if we want to achieve nontrivial imaging between homogeneous spaces with equal index, we must give up either the perfect imaging (similarity) or the sharpness of the image.

The geometrical optics approximation is very useful in the design of optical imaging systems. However, it fails to provide a complete description

of wave optical effects, notably diffraction. Therefore, the following sections provide a description of field transformations based on wave optics.

Systems Approach to 3D Imaging

In this article we deal with linear imaging systems. Hence the relation between three-dimensional (3D) input (object) signals and 3D output (image) signals can be completely specified by the 3D impulse response or point spread function (PSF) of the system $h(x, y, z; x'y', z')$. This function specifies the response of the system at image space coordinates (x, y, z) to a δ-function input (point source) at object coordinates (x', y', z'). The optical system object and image signals are related by the superposition integral:

$$\mathrm{i}(x, y, z) = \int\int\int_{\Omega} \mathrm{o}(x', y', z') h(x, y, z; x'y', z') \mathrm{d}x'\, \mathrm{d}y'\, \mathrm{d}z' \qquad [3]$$

where Ω is the object domain. It is clear that for a generic linear imaging system the image signal is completely specified by the response to input impulses located at all possible points of the image domain.

If the system is shift invariant, the PSF due to a point source located anywhere in the object domain will be a linearly shifted version of the response due to a reference point source. This approximation is in general not valid and the system's PSF is a function of the position of the point source in the object domain. Shift invariance is traditionally divided into radial and axial shift invariance. Radial shift variance is the change in the image of a point source as a function of its radial distance from the optical axis. Radial shift variance is caused by lens aberrations. Axial shift variance is the change in the image of a point source as a function of its axial position, z', in the object space. Axial shift variance is inherent to any rotationally symmetric lens system because they can only have one pair of conjugate surfaces, i.e., object–image corresponding surfaces.

In most practical cases the image is detected at a single plane, $z = z_1$ transverse to the optical axis Oz. In those situations, we need to specify the impulse response on this plane:

$$h(x, y, z_1; x'y', z') = h_{z'}(x, y; x'y') \qquad [4]$$

The condition for lateral shift invariance is then expressed as $h_{z'}(x, y; x'y') = \tilde{h}_{z'}(x - x', y - y')$. In this case, the superposition integral is a two-dimensional (2D) convolution and it is possible to define the transfer function of the system that is the 2D Fourier transform of the impulse response $\tilde{h}_{z'}(x - x', y - y')$.

Point Spread Function for Coherent, Incoherent, and Partially Coherent Illumination

The input–output relations of an optical imaging system relate different magnitudes according to the type of illumination. If the illumination is coherent, the system is linear in the complex amplitude, while if the illumination is fully incoherent the system is linear in intensity. The 3D impulse response of the incoherent (h_{Inc}) and coherent (h_{Coh}) systems are related as follows:

$$h_{\mathrm{Inc}}(x, y, z; x'y', z') = \left|h_{\mathrm{Coh}}(x, y, z; x'y', z')\right|^2 \qquad [5]$$

Notwithstanding, many optical systems cannot be considered fully coherent or fully incoherent. In these situations the system is said partially coherent. If the optical path differences within the optical system are much shorter than the coherence length of the illumination, the light effectively has complete temporal coherence and the magnitude of interest is the mutual intensity. The mutual intensity is defined as the statistical correlation of the complex wavefunction $U(\mathbf{r}, t)$ between different points in space:

$$J(\mathbf{r}_1, \mathbf{r}_2) = \langle U^*(\mathbf{r}_1, t) U(\mathbf{r}_2, t) \rangle \qquad [6]$$

where $\mathbf{r}_i = (x_i, y_i, z_i), i = 1, 2$. The illumination is then called quasi-monochromatic. For the case of partially coherent quasi-monochromatic illumination, the system is linear in the mutual intensity. The partially coherent impulse response (h_{PC}) is also related to the coherent impulse response as follows:

$$h_{\mathrm{PC}}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}'_1, \mathbf{r}'_2) = h^*_{\mathrm{Coh}}(\mathbf{r}_1; \mathbf{r}'_1) h_{\mathrm{Coh}}(\mathbf{r}_2; \mathbf{r}'_2) \qquad [7]$$

The 3D superposition integral that relate object and image mutual intensities is now:

$$J_{\mathrm{image}}(\mathbf{r}_1, \mathbf{r}_2) = \int\int\int_{\Omega} h_{\mathrm{PC}}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}'_1, \mathbf{r}'_2) \times J_{\mathrm{object}}(\mathbf{r}'_1, \mathbf{r}'_2) \mathrm{d}\mathbf{r}'_1\, \mathrm{d}\mathbf{r}'_2 \qquad [8]$$

Therefore, we conclude that knowledge of the coherent PSF is enough to characterize the optical system for illumination of various degrees of coherence.

Spatial Frequency Content of the 3D Point Spread Function

As previously stated, the coherent impulse response of the optical system completely defines its imaging characteristics. Therefore, it is justified to wonder

what the limitations are in the specification of this response. In this section we analyze the frequency domain of coherent and incoherent impulse responses.

The impulse response of the optical system will satisfy the corresponding wave equations regardless of the particulars of the optical system. In particular, assuming a homogeneous isotropic medium in the imaging domain, the coherent response $h(\mathbf{r})$ to an impulse at $\mathbf{r}'$ will satisfy the homogeneous Helmholtz equation in the image domain:

$$\nabla^2 h(\mathbf{r}) + k^2 h(\mathbf{r}) = 0 \qquad [9]$$

where $h(\mathbf{r})$ is the complex amplitude and $k = 2\pi/\lambda$, with λ the wavelength in the medium. If the field at a given origin of coordinates $z = 0$, $f(x, y)$, is known, $h(\mathbf{r})$ can be calculated using the angular spectrum representation as follows:

$$h(x, y, z) = \int\int_{-\infty}^{\infty} F(f_x, f_y) \times \exp[i2\pi(f_x x + f_y y + f_z z)]\mathrm{d}f_x\, \mathrm{d}f_y \qquad [10]$$

where $f_z = \sqrt{\lambda^{-2} - (f_x^2 + f_y^2)}$ and $F(f_x, f_y) = \mathrm{FT}\{f(x, y)\}$; FT represents a 2D Fourier transformation and f_x, f_y are the spatial frequencies along the x and y axes respectively.

Equation [10] can be written as a 3D integral as follows:

$$h(x, y, z) = \int\int_{-\infty}^{\infty} F(f_x, f_y)\cdot\delta\left[f_z - \sqrt{\lambda^{-2} - f_x^2 - f_y^2}\right] \times \exp[i2\pi(f_x x + f_y y + f_z z)]\mathrm{d}f_x\, \mathrm{d}f_y\, \mathrm{d}f_z \qquad [11]$$

where δ represents the dirac impulse. Next we represent the 3D impulse response $h(x, y, z)$ as a 3D Fourier decomposition:

$$h(x, y, z) = \int\int_{-\infty}^{\infty} H(f_x, f_y, f_z) \times \exp[i2\pi(f_x x + f_y y + f_z z)]\mathrm{d}f_x\, \mathrm{d}f_y\, \mathrm{d}f_z \qquad [12]$$

where $H(f_x, f_y, f_z) = \mathrm{FT}^{3\mathrm{D}}\{h(x, y, z)\}$. Comparing eqns [11] and [12] we can infer that:

$$H(f_x, f_y, f_z) = F(f_x, f_y)\cdot\delta\left[f_z - \sqrt{\lambda^{-2} - f_x^2 - f_y^2}\right] \qquad [13]$$

This relation implies that the domain of the Fourier transform of the impulse response is confined to a spherical shell of radius $1/\lambda$. Alternatively, $H(f_x, f_y, f_z)$ is zero everywhere, except from the surface of the sphere.

The previous derivation did not consider any limitation in the range of spatial frequencies allowed through the system. We now assume a finite aperture that will introduce an effective radial cutoff frequency $f_c < 1/\lambda$ and will further limit the spatial spectral domain of $h(x, y, z)$. This is depicted in Figure 1. Note that the transverse and longitudinal spatial frequencies are related, hence the longitudinal spatial frequencies are located within a bandpass of width $\Delta f_z = 1 - \sqrt{\lambda^{-2} - f_c^2}$.

Let us now consider the frequency content of possible incoherent PSFs. From eqn [5] we derive the 3D Fourier transform of the incoherent impulse response:

$$\begin{aligned} H_{\mathrm{Inc}}(f_x, f_y, f_z) &= \mathrm{FT}\left\{h_{\mathrm{Inc}}(x, y, z; x'y', z')\right\} \\ &= \mathrm{FT}\left\{|h_{\mathrm{Coh}}(x, y, z; x'y', z')|^2\right\} \\ &= H \otimes H(f_x, f_y, f_z) \end{aligned} \qquad [14]$$

where $\otimes$ represents a 3D correlation. The domain of H_{Inc} now becomes a volume of revolution as shown in Figure 2. Moreover, because h_{Inc} is real, H_{Inc} is conjugate symmetric, i.e., $H_{\mathrm{Inc}} = H_{\mathrm{Inc}}^*$. Now, the transverse cutoff frequency is $f_{\mathrm{c}}^{\mathrm{Inc}} = 2f_{\mathrm{c}}$ while the longitudinal cutoff frequency is $f_{\mathrm{cl}}^{\mathrm{Inc}} = 2\Delta f_z$.

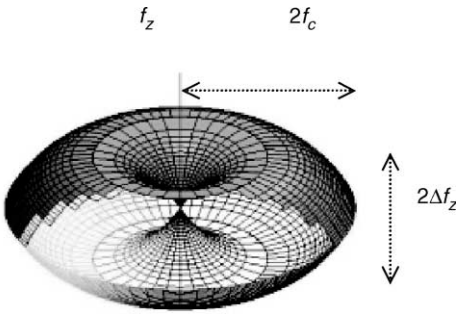

Figure 2 Three-dimensional spatial-frequency domain of the incoherent point spread function.

Diffraction Calculation of the 3D Point Spread Function

The 3D-image field created by a point source in the object space can be predicted by proper modeling of the optical system. In the absence of aberrations, the distortion of the PSF is originated in the diffraction created by the limiting aperture of the optical system. Diffraction is thus the ultimate limitation to the resolution of the optical system. Under the design conditions of the system, i.e., assuming all aberrations are corrected, the image of a point source is the diffraction pattern produced when a spherical wave converging to the (geometrical) image point is diffracted by the limiting aperture of the system. This is called a diffraction limited image.

There are many formulations to describe the 3D diffraction pattern obtained with a converging wave through an aperture. Here we review the Kirchhoff formulation. Let us consider the aperture **A** and the field at a point P_d originated from a converging spherical wave focused at point P_F (see Figure 3). We define the vectors **r** joining a generic point on the aperture P_0 and P_F, and **s** joining P_0 and P_d. The Kirchhoff formulation states that the complex amplitude $U(P_d/P_F)$ is the integral over the aperture of the complex amplitude at each point propagated to P_d by a spherical wave $\exp(iks)/s$ modified by the directional factor $\cos(\hat{\mathbf{n}}, \mathbf{r}) - \cos(\hat{\mathbf{n}}, \mathbf{s})$. $\hat{\mathbf{n}}$ is the unit vector normal to the aperture:

$$U(P_d/P_F) = \frac{-iC}{2\lambda} \int\int_A \frac{\exp[-ik(r-s)]}{rs} \times [\cos(\hat{\mathbf{n}}, \mathbf{r}) - \cos(\hat{\mathbf{n}}, \mathbf{s})] dS \qquad [15]$$

where $r = \|\mathbf{r}\|, s = \|\mathbf{s}\|$, and C is the amplitude of the spherical wave.

The directional factor varies slowly and in many situations can be approximated by a constant equal to 2 for small image-field angles. The amplitude over the aperture is also slowly varying and can be approximated by a constant, i.e., $C/r \approx C_0$. Different formulations of the Kirchhoff integral differ in the estimates of the factor $1/s$ and the phase $k(r-s)$. For example, one such formulation leads to the following expression for the 3D diffraction pattern for a focal point on the axis of an optical system with circular aperture:

$$U(P_d/P_F) = \frac{-ika^2 C_0}{z_d} \exp\left[ik\left(z_d - z_F + \frac{r_d^2}{2z_d}\right)\right] \times \int_0^1 J_0\left(\frac{ka\rho r_d}{z_d}\right) \exp\left[\frac{-ika^2\rho^2(z_d - z_F)}{2z_d z_F}\right] \rho d\rho \qquad [16]$$

where a is the radius of the aperture, r_d is the radial coordinate of P_d, and ρ is the radial coordinate of P_0.

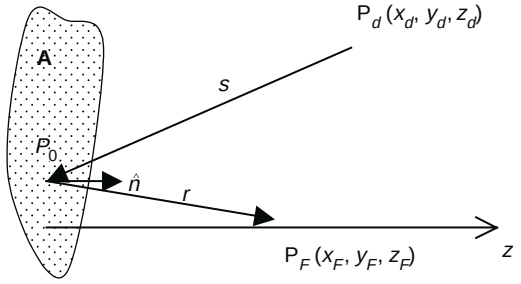

Figure 3 Diffraction of a spherical wave by a planar aperture.

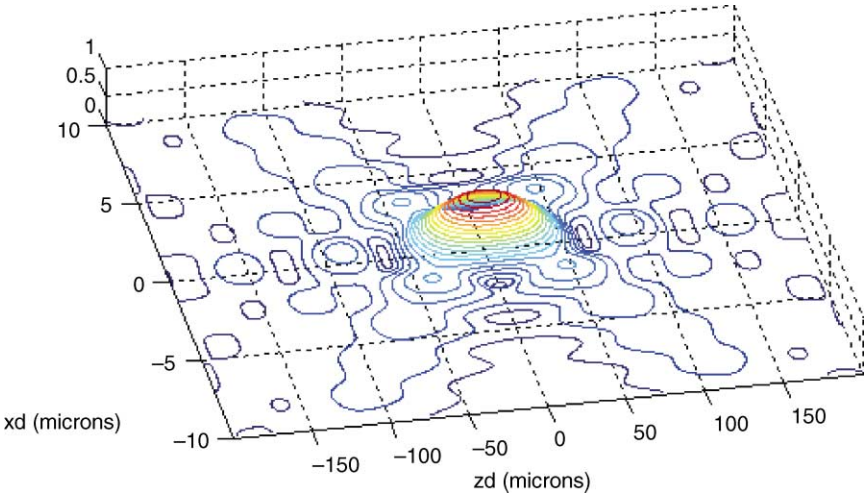

Figure 4 Lines of equal intensity in a meridional plane near the focus of a converging spherical wave diffracted at a circular aperture ($\lambda = 0.5$ μ, $a = 0.5$ cm, $z_F = 4$ cm).

To illustrate the use of eqn [16], we calculated the intensity around the focus of a spherical wave diffracted through a circular aperture of radius $a = 0.5$ cm, focusing at distance $z_F = 4$ cm from the screen. We assumed the wavelength to be $\lambda = 0.5$ μ. Figure 4 depicts the magnitude of the complex amplitude in a meridional plane near the focus of the converging spherical wave.

Models that take into account off-axis focal points have also been developed. For the most accurate calculations, it is necessary to consider the full electromagnetic nature of the optical field.

Conclusions

Classical imaging theory can be applied to the 3D imaging transformation from object to image. The systems approach to the imaging problem implies that knowledge of the 3D coherent PSF suffices to predict the 3D response of the system under illumination of varying degrees of coherence. The PSF response can be predicted using well-known formulations of diffraction.

Volume Holographic Imaging

G Barbastathis, Massachusetts Institute of Technology, Cambridge, MA, USA

© 2005 Published by Elsevier Ltd.

Volume holographic imaging (VHI) refers to a class of imaging techniques which use a volume hologram in at least one location within the optical path. The volume hologram acts as a 'smart lens,' which processes the optical field to extract spatial information in three dimensions (lateral as well as longitudinal) and spectral information.

Figure 1 is a generic VHI system. The object is either illuminated by a light source (e.g., sunlight or a pump laser) as shown in the figure, or it may be self-luminous. Light scattered or emitted by the object is first transformed by an objective lens and then illuminates the volume hologram. The role of the objective is to form an intermediate image which serves as input to the volume hologram. The volume hologram itself is modeled as a three-dimensional (3D) modulation $\Delta\varepsilon(\mathbf{r})$ of the dielectric index within a finite region of space. The light entering the hologram is diffracted by $\Delta\varepsilon(\mathbf{r})$ with efficiency η, defined as

$$\eta = \frac{\text{Power diffracted by the volume hologram}}{\text{Power incident to the volume hologram}} \quad [1]$$

We assume that diffraction occurs in the Bragg regime. The diffracted field is Fourier-transformed by the collector lens, and the result is sampled and measured by an intensity detector array (such as a CCD or CMOS camera).

Intuitively, we expect that a fraction of the illumination incident upon the volume hologram is Bragg-matched and is diffracted towards the Fourier-transforming lens. The remainder of the incident illumination is Bragg-mismatched, and as result is transmitted through the volume hologram un-diffracted. Therefore, the volume hologram acts as a filter which admits the Bragg-matched portion of the object and rejects the rest. When appropriately designed, this 'Bragg imaging filter' can exhibit very rich behavior, spanning the three spatial dimensions and the spectral dimension of the object.

To keep the discussion simple, we consider the specific case of a transmission geometry volume

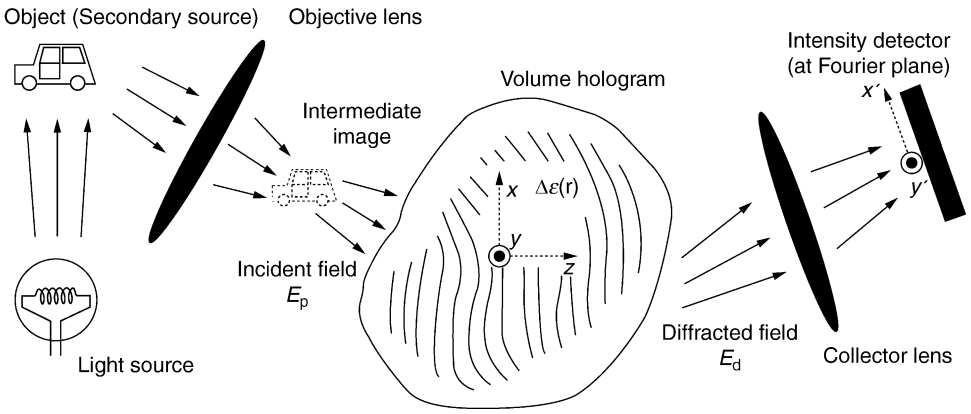

Figure 1 Volume holographic imaging (VHI) system.

hologram, described in Figure 2. The volume hologram is created by interfering a spherical wave and a planewave, as shown in Figure 2a. The spherical wave originates at the coordinate origin. The planewave is off-axis and its wavevector lies on the xz plane. As in most common holographic systems, the two beams are assumed to be at the same wavelength λ, and mutually coherent. The volume hologram results from exposure of a photosensitive material to the interference of these two beams.

First, assume that the object is a simple point source. The intermediate image is also approximately a point source, that we refer to as 'probe,' located somewhere in the vicinity of the reference point source. Assuming the wavelength of the probe source is the same as that of the reference and signal beams, volume diffraction theory shows that:

(i) If the probe point source is displaced in the y direction relative to the reference point source, the image formed by the volume hologram is also displaced by a proportional amount. Most common imaging systems would be expected to operate this way.

(ii) If the probe point source is displaced in the x direction relative to the reference point source, the image disappears (i.e., the detector plane remains dark).

(iii) If the probe point source is displaced in the z direction relative to the reference point source, a defocused and faint image is formed on the detector plane. 'Faint' here means that the fraction of energy of the defocused probe transmitted to the detector plane is much smaller than the fraction that would have been transmitted if the probe had been at the origin.

Now consider an extended, monochromatic, spatially incoherent object and intermediate image, as in Figure 2f. According to the above description, the volume hologram acts as a 'Bragg slit' in this case: because of Bragg selectivity, the volume hologram transmits light originating from the vicinity of the y axis, and rejects light originating anywhere else. For the same reason, the volume hologram affords depth selectivity (like the pinhole of a confocal microscope). The width of the slit is determined by the recording geometry, and the thickness of the volume hologram. For example, in the transmission recording geometry of Figure 2a, where the reference beam originates a distance z_0 away from the hologram, the planewave propagates at angle θ with respect to the optical axis z (assuming $\theta \ll 1$ radian), and the hologram thickness is L (assuming $L \ll z_0$), the width of the slit is found to be

$$\Delta x \approx \frac{\lambda z_0}{L\theta} \qquad [2]$$

The imaging function becomes richer if the object is polychromatic. In addition to its Bragg slit function, the volume hologram exhibits then dispersive behavior, like all diffractive elements. In this particular case, dispersion causes the hologram to image simultaneously multiple Bragg slits, each at a different color and parallel to the original slit at wavelength λ, but displaced along the z axis. Light from all these slits finds itself in focus at the detector plane, thus forming a 'rainbow image' of an entire slice through the object, as shown in Figure 2g.

To further exploit the capabilities of volume holograms, we recall that in general it is possible to 'multiplex' (superimpose) several volume gratings

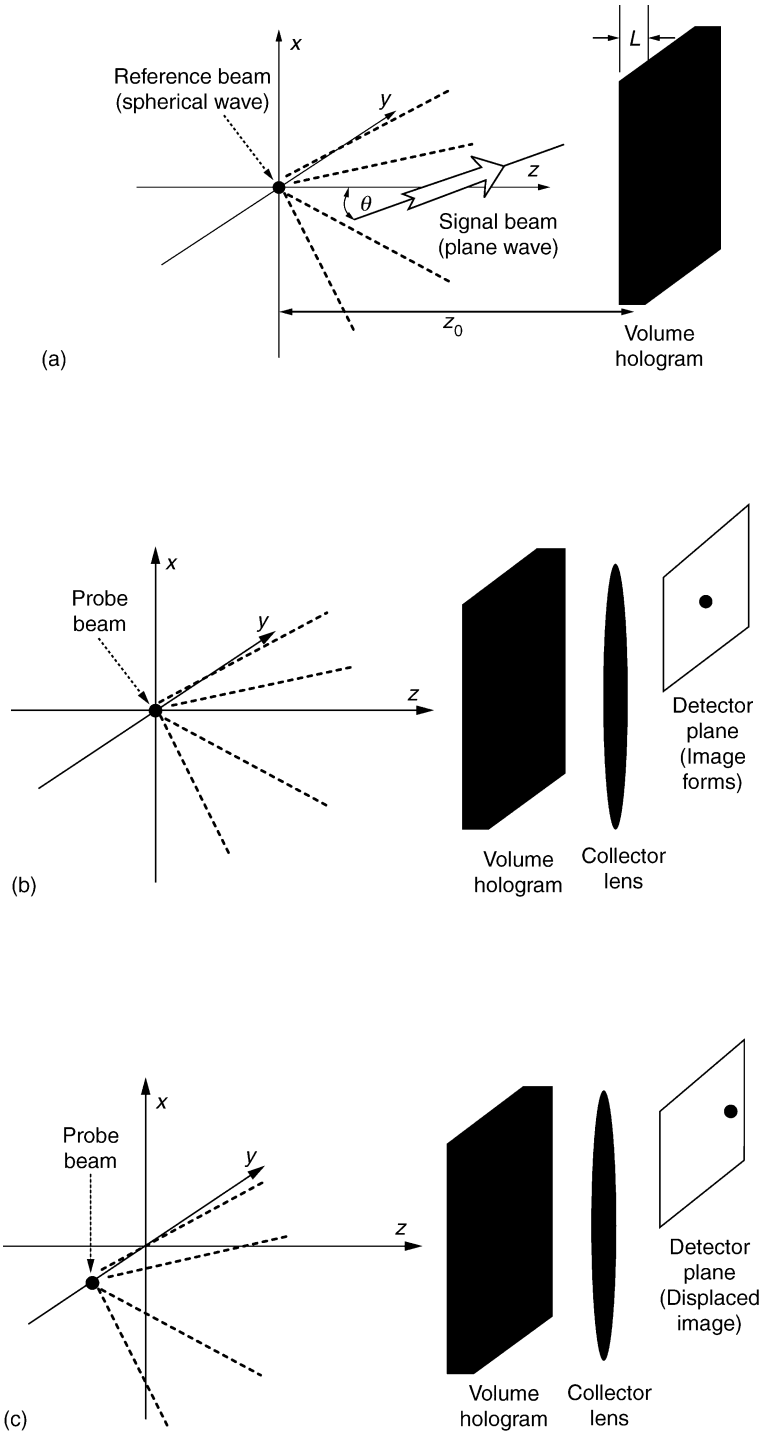

Figure 2 (a) Recoding of a transmission-geometry volume hologram with a spherical wave and an off-axis plane wave with its wave-vector on the *xz* plane. (b) Imaging of a probe point source that replicates the location and wavelength of the reference point source using the volume hologram recorded in part (a). (c) Imaging of a probe point source at the same wavelength but displaced in the *y* direction relative to the reference point source. (d) Imaging of a probe point source at the same wavelength but displaced in the *x* direction relative to the reference point source. (e) Imaging of a probe point source at the same wavelength but displaced in the *z* direction relative to the reference point source. (f) 'Bragg slitting:' Imaging of an extended monochromatic, spatially incoherent object using a volume hologram recorded as in (a). (g) Joining Bragg slits from different colors to form rainbow slices: Imaging of an extended polychromatic object using a volume hologram recorded as in (a). (h) Multiplex imaging of several slices using a volume hologram formed by multiple exposures.

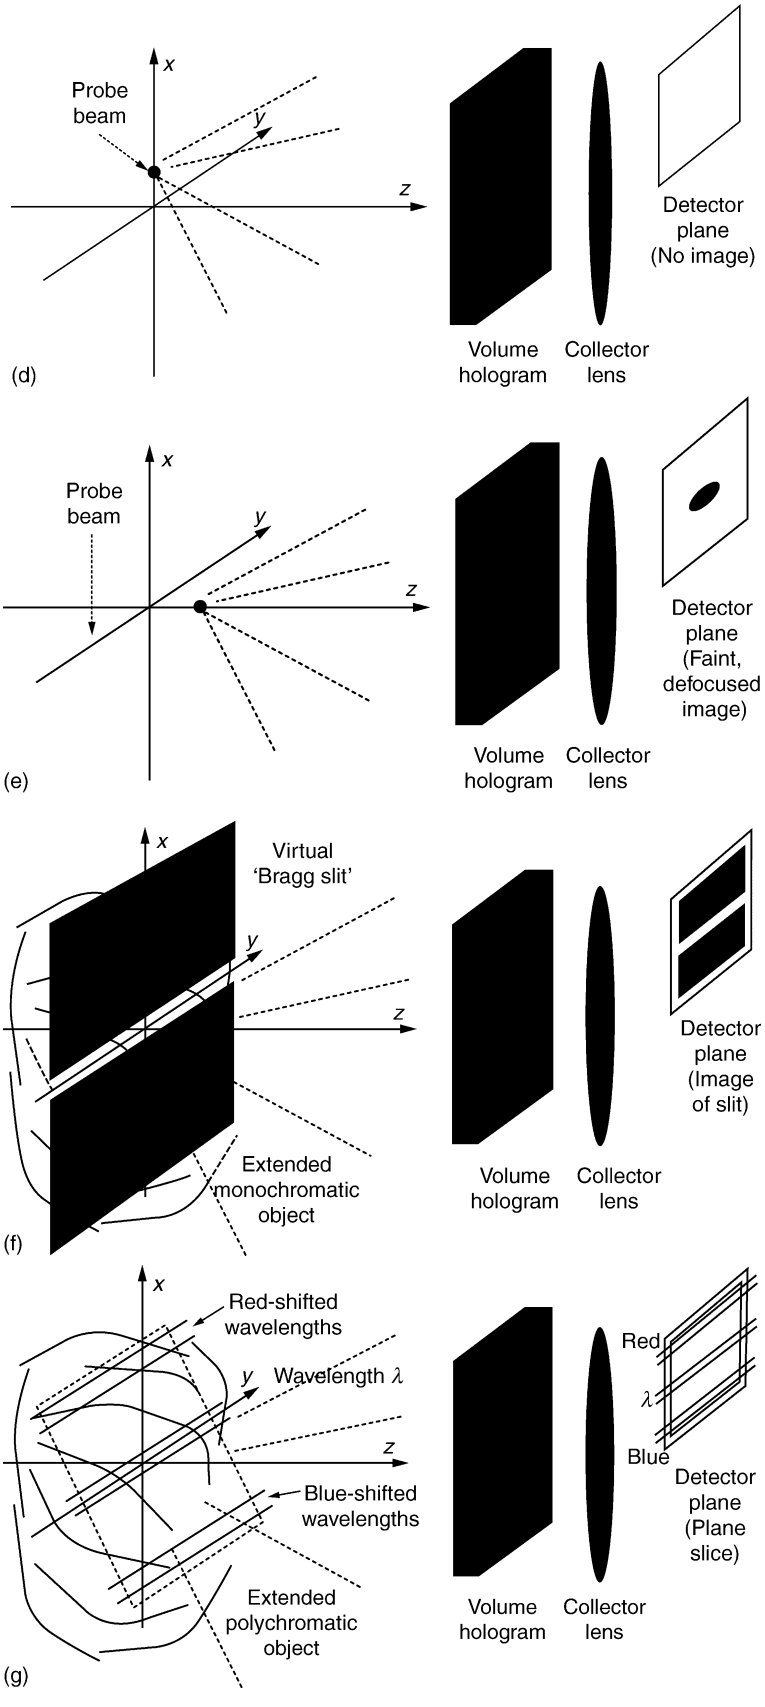

Figure 2 *Continued.*

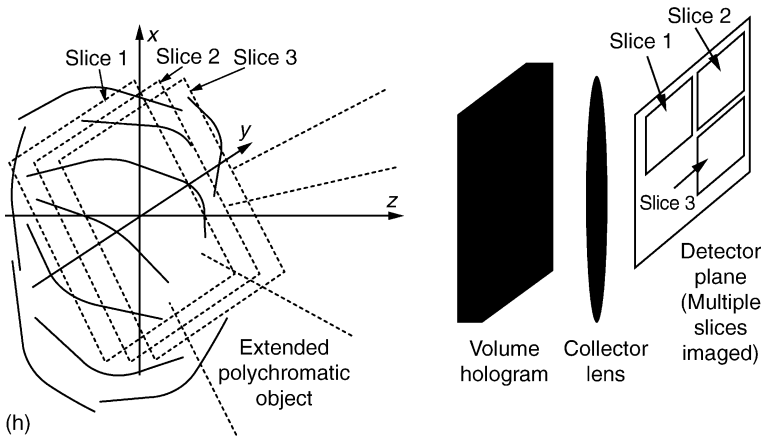

Figure 2 *Continued.*

within the same volume by successive exposures. In the imaging context, suppose that we multiplex several gratings similar to the grating described in Figure 2a but with spherical reference waves originating at different locations and plane signal waves at different orientations. When the multiplexed volume hologram is illuminated by an extended polychromatic source, each grating forms a separate image of a rainbow slice, as described earlier. By spacing appropriately the angles of propagation of the plane signal waves, we can ensure that the rainbow images are formed on nonoverlapping areas on the detector plane, as shown in Figure 2h. This device is now performing true four-dimensional (4D) imaging: it is separating the spatial and spectral components of the object illumination so that they can be measured independently by the detector array. Assuming the photon count is sufficiently high and the number of detector pixels is sufficient, this 'spatio-spectral slicing' operation can be performed in real time, without need for mechanical scanning.

The complete theory of VHI in the spectral and spatial domains is given in the Further Reading section below. Experimental demonstrations of VHI have been performed in the context of a confocal microscope where the volume hologram performs the function of a 'Bragg pinhole' as well as a real-time 4D imager. The limited diffraction efficiency η of volume holograms poses a major concern for VHI systems. Holograms, however, are known to act as matched filters. It has been shown that the matched filtering nature of volume holograms as imaging elements is superior to other filtering elements (e.g., pinholes or slits) in an information-theoretic sense. Efforts are currently underway to strengthen this property by design of volume holographic imaging elements which are more elaborate than described here.

Wavefront Sensors and Control (Imaging Through Turbulence)

C L Matson, Air Force Research Laboratory, Kirtland, NM, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

In many situations, distant objects are imaged using optical or near-infrared imaging systems. Examples include terrestrial surveillance from space, tactical surveillance from airborne imaging systems, and ground-based astronomical imaging. Ideally, the resolution in these images is limited only by the wavelength of light λ used to create the images divided by the imaging system's effective diameter D. The ratio λ/D is called the diffraction limit of the imaging system. Unfortunately, when the imaging system is located in the Earth's atmosphere, it is often atmospheric turbulence fluctuations that limit the level of detail in the long-exposure images, not the diffraction limit of the telescope. For example, the Keck telescopes, located on top of Mauna Kea in Hawaii, are 10 m diameter telescopes that have a diffraction-limited angular resolution of 0.2 μrad for an imaging wavelength of 2 μm. However, atmospheric turbulence limits the achievable resolution in long-exposure images to the order of 1–5 μrad at this wavelength.

The important discovery by Anton Labeyrie in 1970 that short-exposure images of objects retain meaningful diffraction-limited information about the object, where 'short' means that the exposure time is less than the atmospheric turbulence coherence time, has revolutionized imaging through turbulence. Atmospheric coherence times depend upon a number of factors, including wind speeds, wind altitudes, and observation wavelength. At astronomical observatories for visible observation wavelengths, a rule of thumb is that atmospheric turbulence stays essentially constant for exposure times of one to ten milliseconds under average clear-sky weather conditions. A variety of techniques that exploit this discovery have been developed. These techniques can be grouped into three different categories: techniques that remove blurring from the detected intensity images (post-detection compensation), techniques that modify the optical field prior to detecting the light (pre-detection compensation), and hybrid techniques that use both post-detection and pre-detection compensation. In this article, a variety of these techniques are presented that are representative of the myriad of methods that have been developed during the past decades. To simplify the discussion, it is assumed that the blurring due to atmospheric turbulence is the same at every point in the image (isoplanaticity), that the images are formed using incoherent light as emitted by the sun and stars, and that a single filled aperture is used to create the images. Interferometric techniques that use multiple apertures to estimate the mutual coherence function of the optical field and calculate an image from it, are discussed in a separate article (*see* **Imaging:** Interferometric Imaging).

The emphasis in this article is on identifying and removing atmospheric blurring in images. As part of this process, regularization techniques must be included in the image reconstruction algorithms in order to obtain the best possible resolution for an acceptable level of noise. Although regularization techniques are not discussed in this article, information can be found in the Further Reading section at the end of this article (*see* **Imaging:** Inverse Problems and Computational Imaging).

Imaging and Atmospheric Turbulence

In Figure 1, a conceptual diagram illustrates the impact that atmospheric turbulence has upon resolution in classical imaging systems. A distant star is being imaged by a telescope/detector system. In the absence of atmospheric turbulence, the field emitted by the star has a planar wavefront over the extent of the lens since the star is a long distance from the imaging system and thus unresolved by the telescope. When imaged by the telescope, the diffraction pattern of the telescope is obtained, resulting in a diffraction-limited image (Figure 2). However, in the presence of atmospheric turbulence near the telescope, the planar wavefront is randomly distorted by the turbulence, resulting in a corrugated wavefront with a spatial correlation scale given by the Fried parameter r_o. For visible wavelengths, at good astronomical observing sites, r_o ranges from 5 cm to 20 cm. When this corrugated wavefront is converted to an image by the telescope, a distorted image is obtained (Figure 3). Because atmospheric turbulence is time-varying, the distortions in the image also change over time. If the imaging shutter on the telescope remains open for many occurrences of atmospheric turbulence, the resulting image will be an average of all the individually distorted images, resulting in what is known as the seeing disk (Figure 4). It is the seeing disk that typically limits spatial resolution in long-exposure images, not the diffraction pattern of the

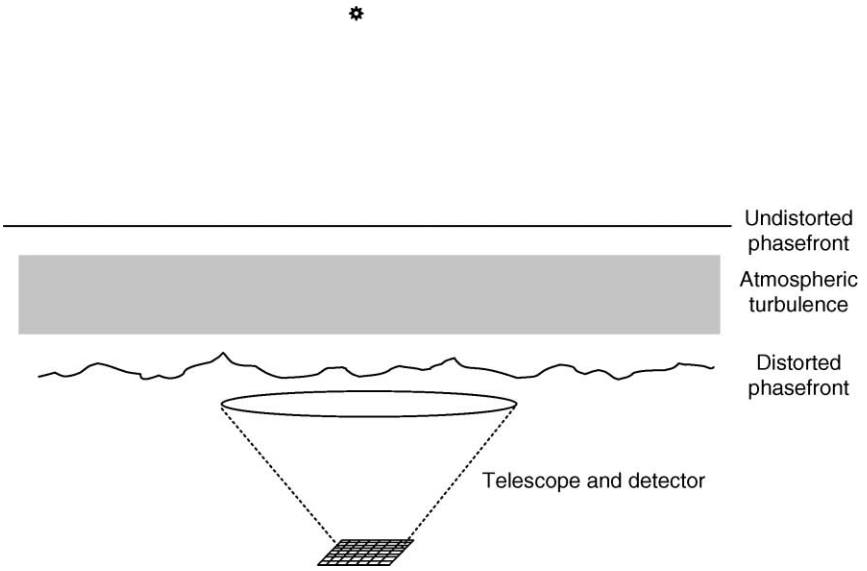

Figure 1 Conceptual diagram of imaging through atmospheric turbulence.

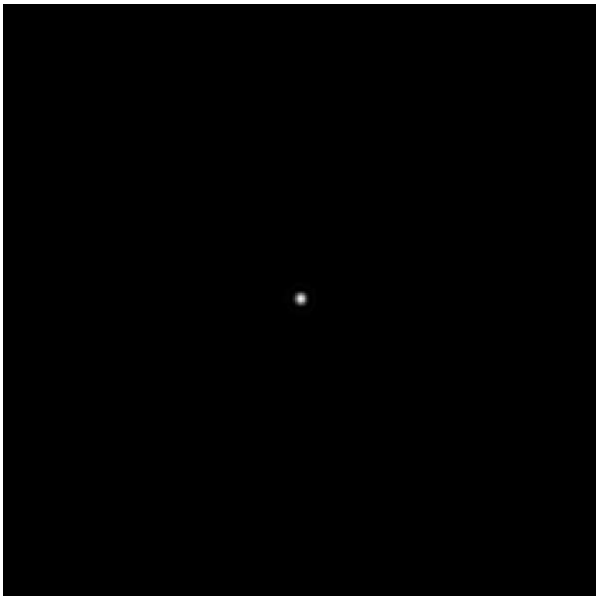

Figure 2 Computer-simulated diffraction-limited image of a point source.

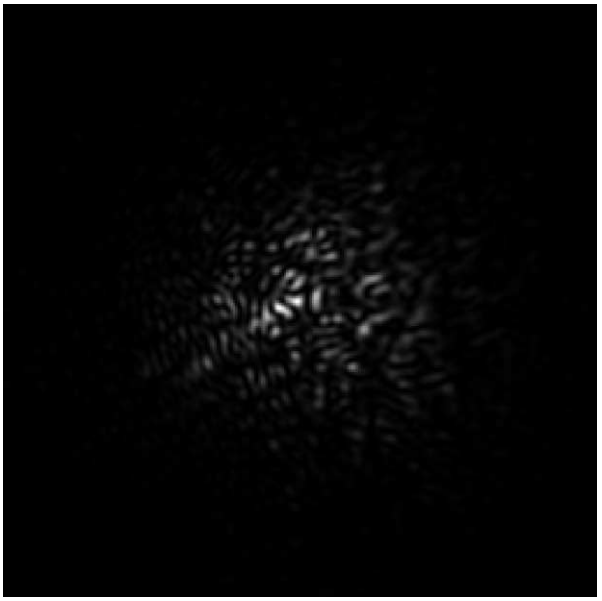

Figure 3 Computer-simulated short-exposure image of a point source through atmospheric turbulence.

telescope. As a result, the effective spatial resolution in long-exposure images in the presence of atmospheric turbulence is given by λ/r_o, not λ/D.

Atmospheric turbulence distorts a field's wavefront by delaying it in a way that is spatially and temporally random. The origin of these delays is the random variation in the index of refraction of the atmosphere as a result of turbulent air motion brought about by temperature variations. A Fourier optics imaging model is useful in characterizing the effects of atmospheric turbulence on spatial resolution in images. Let $i(\vec{x})$ be an image of an object $o(\vec{x})$, where $\vec{x}$ is a two-dimensional spatial vector, and let $I(\vec{f})$ and $O(\vec{f})$ be their spatial Fourier transforms, where $\vec{f}$ is a two-dimensional spatial frequency vector. In the absence of atmospheric turbulence, the diffraction-limited Fourier transform $I(\vec{f})$ is given by

$$I_d(\vec{f}) = O(\vec{f})H_d(\vec{f}) \qquad [1]$$

where the subscript 'd' denotes the diffraction-limited case and where $H_d(\vec{f})$ is the diffraction-limited

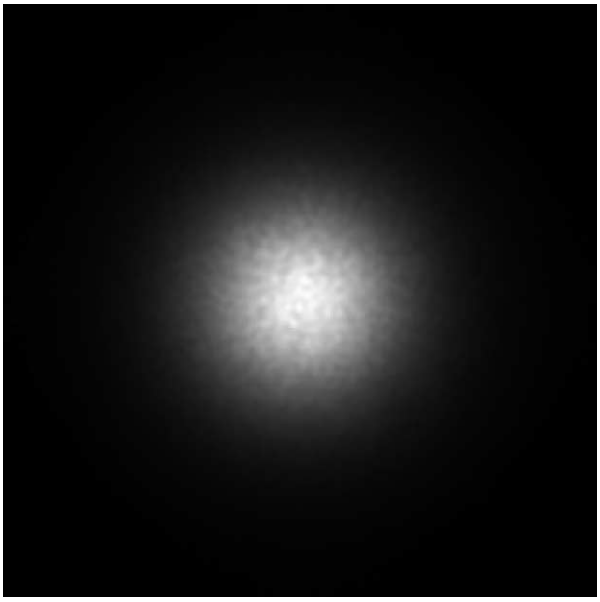

Figure 4 Computer-simulated long-exposure image of a point source through atmospheric turbulence.

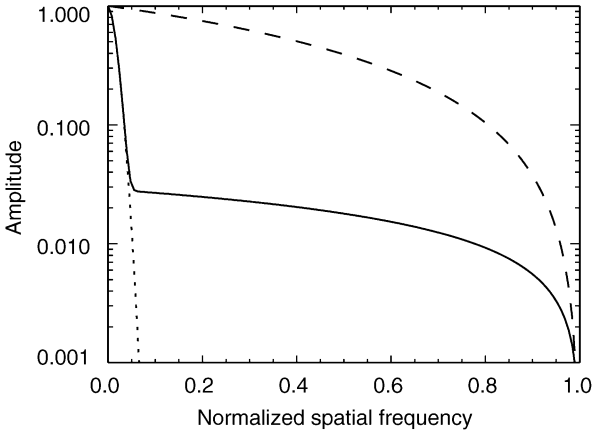

Figure 5 Plots of the Fourier amplitudes of the diffraction-limited transfer function (dashed line), Fourier amplitudes of the long-exposure transfer function (dotted line), and the square root of the average short exposure energy spectrum. The spatial frequency axis is normalized to one at the diffraction limit of the telescope.

telescope transfer function. In the presence of atmospheric turbulence, the Fourier transform of a long exposure image $i_{\mathrm{le}}(\vec{x})$ is given by

$$I_{\mathrm{le}}(\vec{f}) = O(\vec{f})H_{\mathrm{d}}(\vec{f})H_{\mathrm{le}}(\vec{f}) = I_{\mathrm{d}}(\vec{f})H_{\mathrm{le}}(\vec{f}) \qquad [2]$$

where the subscript 'le' denotes long exposure. If the turbulence satisfies Kolmogorov statistics, as is typically assumed, then:

$$H_{\mathrm{le}}(\vec{f}) = \exp\left[-3.44\left(\frac{\lambda d|\vec{f}|}{r_{\mathrm{o}}}\right)^{5/3}\right] \qquad [3]$$

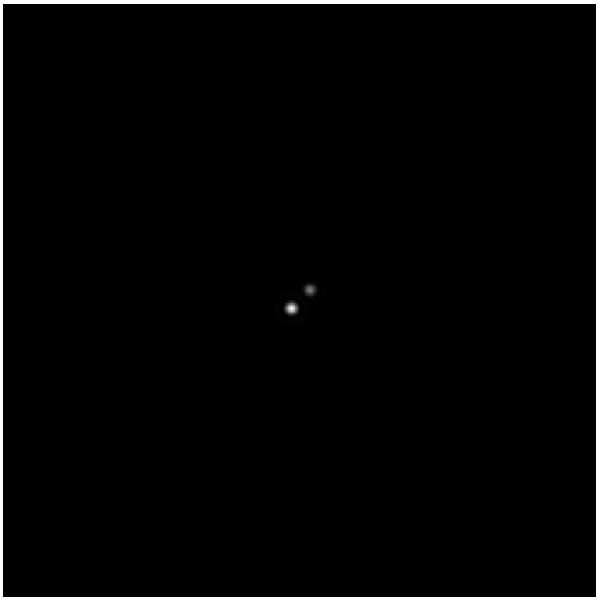

Figure 6 Computer-simulated diffraction-limited image of a binary star.

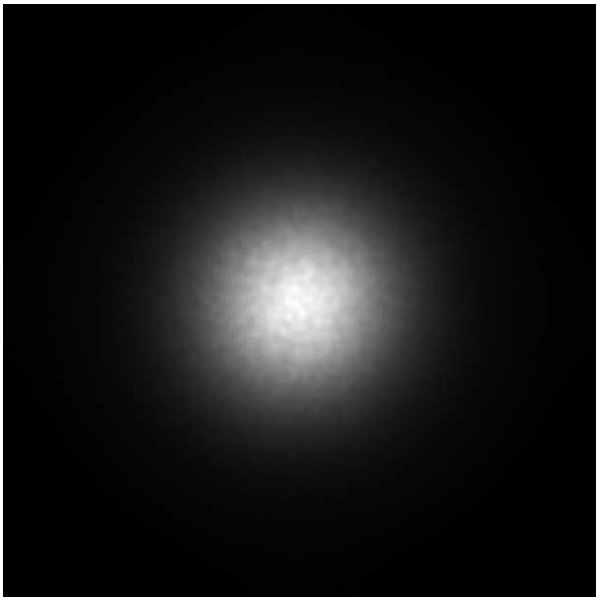

Figure 7 Computer-simulated long-exposure image of a binary star.

where d is the distance between the imaging system's exit pupil and detector plane. As can be seen from eqn [2], the effect of atmospheric turbulence on a long-exposure image is a multiplication of the diffraction-limited image's Fourier transform by a transfer function due to atmospheric turbulence. In Figure 5, an amplitude plot of a diffraction-limited transfer function is displayed along with an amplitude plot of a long-exposure transfer function for a 2.3 m

diameter telescope, an imaging wavelength of 0.5 μm, and an r_o value of 10 cm. Notice that the long exposure transfer function significantly reduces the amount of high spatial frequency information in an image. Diffraction-limited and long-exposure turbulence-limited images of a binary star are shown in Figures 6 and 7, illustrating the significant loss of spatial resolution brought on by atmospheric turbulence.

Post-Detection Compensation

Speckle Imaging

Labeyrie's 1970 discovery was motivated by his analysis of short-exposure star images. In these images (see Figure 3), a number of speckles are present, where the individual speckle sizes are roughly the size of the diffraction-limited spot of the telescope. From this, he realized that high spatial frequency information is retained in short-exposure images, albeit distorted. He then showed that the energy spectra $E_I(\vec{f})$ of the individual short-exposure images can be averaged to obtain an estimate of the average energy spectrum that retains high signal-to-noise ratio (SNR) information at high spatial frequencies. The square root of the average energy spectrum (the amplitude spectrum) of a star, calculated using Labeyrie's method (also known as speckle interferometry), is shown in Figure 5, along with the diffraction-limited and long-exposure amplitude spectra. Notice that meaningful high spatial frequency information is retained in the average amplitude spectrum out to the diffraction limit of the telescope. Because the atmospherically corrupted amplitude spectrum estimate is significantly lower than the diffraction-limited amplitude, a number of short exposure images must be used to build up the SNRs at the higher spatial frequencies.

To reconstruct an image, both the Fourier amplitudes and Fourier phases of the image must be known. In fact, it is well known that the Fourier phase of an image carries most of the information in the image. Because only the Fourier amplitudes are available using Labeyrie's method, other techniques were subsequently developed to calculate the Fourier phase spectrum from a sequence of short-exposure images. Techniques that combine amplitude spectrum estimation using Labeyrie's method along with phase spectrum estimation are called speckle imaging techniques. The two most widely used phase spectrum estimation methods are the Knox–Thompson (or cross spectrum) and bispectrum algorithms. Both of these algorithms calculate Fourier-domain quantities that retain high spatial frequency information about the Fourier phase spectrum when averaged over multiple short-exposure images. The cross spectrum and bispectrum techniques calculate the average cross spectrum $C(\vec{f}, \Delta\vec{f})$ and bispectrum $B(\vec{f}_1, \vec{f}_2)$, respectively, that are given by

$$C(\vec{f}, \Delta\vec{f}) = I(\vec{f})I^*(\vec{f} + \Delta\vec{f}) \quad [4]$$

$$B(\vec{f}_1, \vec{f}_2) = I(\vec{f}_1)I(\vec{f}_2)I^*(\vec{f}_1 + \vec{f}_2) \quad [5]$$

where the superscript $*$ denotes complex conjugate. Although the cross spectrum is defined for all values of $\vec{f}$ and $\Delta\vec{f}$, only for values of $\Delta\vec{f}$ or $\vec{f}$ less than r_o/λ are the cross spectrum elements obtained with sufficiently high SNRs to be useful in the reconstruction process. The equivalent constraint on the bispectrum elements is that either $\vec{f}_1, \vec{f}_2$, or $\vec{f}_1 + \vec{f}_2$ must be less than r_o/λ. Once the average cross spectrum or bispectrum is calculated from a series of short-exposure images, the phase spectrum $\phi_I(\vec{f})$ of the underlying image can be calculated from their phases using one of a number of algorithms based upon the following equations:

$$\phi_I(\vec{f} + \Delta\vec{f}) = \phi_I(\vec{f}) - \phi_C(\vec{f} + \Delta\vec{f}) \quad [6]$$

for the cross spectrum and:

$$\phi_I(\vec{f}_1 + \vec{f}_2) = \phi_I(\vec{f}_1) + \phi_I(\vec{f}_2) - \phi_B(\vec{f}_1 + \vec{f}_2) \quad [7]$$

for the bispectrum. Because the phases are only known for units of 2π, phasor versions of eqns [6] and [7] must be used. For the cross spectrum technique, each short-exposure image must be centroided prior to calculating its cross spectrum and adding it to the total cross spectrum. The bispectrum technique is insensitive to tilt, so no centroiding is necessary; however, the bispectrum technique requires setting two image phase spectrum values to arbitrary values to initialize the phase reconstruction process. Typically, the image phase spectrum values at $\vec{f} = (0, 1)$ and $\vec{f} = (1, 0)$ are set equal to zero, which centroids the reconstructed image but does not affect its morphology.

To obtain an estimated Fourier transform $I_e(\vec{f})$ of the image from the energy and phase spectrum estimates, the square root of the average energy spectrum is combined with the average phase spectrum calculated from either the bispectrum or cross spectrum. The result is given by

$$I_e(\vec{f}) = [E_I(\vec{f})]^{1/2} \exp[j\phi_I(\vec{f})] \quad [8]$$

where $j = \sqrt{-1}$. The result in eqn [8] includes atmospheric attenuation of the Fourier amplitudes, so it must be divided by the amplitude spectrum of the atmosphere to obtain the desired object spectrum estimate. The atmospheric amplitude spectrum estimate is obtained by using Labeyrie's technique on a sequence of short-exposure images of a nearby unresolved star. No phase spectrum correction is necessary because it has been shown theoretically and verified experimentally that atmospheric turbulence has a negligible effect upon $\phi_I(\vec{f})$.

Blind Deconvolution

Speckle imaging techniques are effective as well as easy and fast to implement. However, it is necessary to obtain a separate estimate of the atmospheric energy spectrum using an unresolved star in order to reconstruct a high-resolution image. Usually, the star is not co-located with the object and the star images are not collected simultaneously with the images of the object. As a result, the atmospheric energy spectrum estimate may be inaccurate. At the very least, collecting the additional star data expends valuable observation time. In addition, there is often meaningful prior knowledge about the object and the data, such as the fact that measured intensities are positive (positivity), that many astronomical objects are imaged against a black background (support), and that the measured data are band-limited, among others. Speckle imaging algorithms do not exploit this additional information. As a result, a number of techniques have been developed to jointly estimate the atmospheric blurring effects as well as an estimate of the object being imaged using only the short-exposure images of the object and available prior knowledge. These techniques are called blind deconvolution techniques. Two of the most common techniques are known as multi-frame blind deconvolution (MFBD) and projection-based blind deconvolution (PBBD).

The MFBD algorithm is based upon maximizing a figure of merit to determine the best object and atmospheric short-exposure point spread function (PSF) estimates given the data and available prior knowledge. This figure of merit is created using a maximum likelihood problem formulation. Conceptually, this technique produces estimates of the object and the atmospheric turbulence short-exposure PSFs that most likely generated the measured short-exposure images. Mathematically, the MFBD algorithm obtains these estimates by maximizing the conditional probability density function (pdf) $\mathrm{p}[i_m(\vec{x})|o(\vec{x}); h_m(\vec{x}),\ m = 1, \ldots, M]$, where $i_m(\vec{x})$ is the mth of M short exposure images and is given by

$$i_m(\vec{x}) = h_m(\vec{x}) * o(\vec{x}) + n_m(\vec{x}) \qquad [9]$$

where $h_m(\vec{x})$ and $n_m(\vec{x})$ are the atmospheric/system blur and detector noise functions for the mth image, respectively, and the asterisk denotes convolution. The noise is assumed to be zero mean with variance $\sigma^2(\vec{x})$. The conditional pdf $\mathrm{p}[i_m(\vec{x})|o(\vec{x}); h_m(\vec{x}),\ m = 1, \ldots, M]$ is the pdf of the noise with a mean equal to $h_m(\vec{x}) * o(\vec{x})$ and, as a function of $o(\vec{x})$ and $h_m(\vec{x})$, it is known as a likelihood function. For spatially independent Gaussian noise, as is the case for camera read noise, the likelihood function is given by

$$\mathrm{L_G}[o(\vec{x}); h_m(\vec{x}),\ m = 1, \ldots, M] = \prod_m \prod_{\vec{x}} \frac{1}{\sqrt{2\pi\sigma^2(\vec{x})}} \times \exp\left\{ -\left[i(\vec{x}) - (o * h_m)(\vec{x})\right]^2 / 2\sigma^2(\vec{x}) \right\} \qquad [10]$$

For Poisson noise, the likelihood function is given by

$$\mathrm{L_P}[o(\vec{x}); h_m(\vec{x}), m = 1, \ldots, M] = \prod_m \prod_{\vec{x}} \frac{\left[(o * h_m)(\vec{x})\right]^{i(\vec{x})} \exp\left\{ -\left[(o * h_m)(\vec{x})\right] \right\}}{i(\vec{x})!} \qquad [11]$$

In practice, logarithms of eqns [10] and [11] are taken prior to searching for the estimates of $o(\vec{x})$ and $h_m(\vec{x})$ that maximize the likelihood function.

In general, there are an infinite number of estimates of $o(\vec{x})$ and $h_m(\vec{x})$ that reproduce the original dataset when convolved together. However, when additional prior knowledge is included to constrain the solution space, such as positivity, support, and the knowledge that $h_m(\vec{x})$ is band-limited, along with regularization, the MFBD algorithm almost always converges to the correct estimates of $o(\vec{x})$ and $h_m(\vec{x})$.

The PBBD technique also uses prior knowledge constraints to jointly estimate $o(\vec{x})$ and $h_m(\vec{x})$. However, instead of creating and maximizing a likelihood function, the PBBD technique uses the method of convex projections to find estimates of $o(\vec{x})$ and $h_m(\vec{x})$ that are consistent with the measured short-exposure images and all the prior knowledge constraints. The data consistency constraint and the prior knowledge constraints are mathematically formulated as convex sets and the PBBD technique repeatedly takes the current estimates of $o(\vec{x})$ and $h_m(\vec{x})$ and projects them onto the convex constraint sets. As long as all the sets are truly convex, the

algorithm is guaranteed to converge to a solution that is in the intersection of all the sets as long as the algorithm doesn't stagnate at erroneous solutions called traps. These traps are the projection equivalent of local minima in cost function minimization algorithms.

A key component of this algorithm is the ability to formulate the measured short-exposure images and prior knowledge constraints into convex sets. As an example, consider the convex set $C_{\text{pos}}[u(\vec{x})]$ that corresponds to the positivity constraint. This set is given by

$$C_{\text{pos}}[u(\vec{x})] \triangleq \{u(\vec{x}) \text{ such that } u(\vec{x}) \geq 0\} \qquad [12]$$

It is straightforward to show that $C_{\text{pos}}[u(\vec{x})]$ is a convex set. Other constraints can be converted into convex sets in a similar manner. Although all constraints can be formulated into sets, most but not all of these sets are convex.

The projection process is straightforward to implement. For example, the projections of the current estimates of $o(\vec{x})$ and $h_{\text{m}}(\vec{x})$ onto $C_{\text{pos}}[u(\vec{x})]$ are carried out by zeroing out the negative values in these estimates. Similarly, the projections of $o(\vec{x})$ and $h_{\text{m}}(\vec{x})$ onto the convex sets that correspond to their support constraints are carried out by zeroing out all their values outside of their supports. In practice, some versions of PBBD algorithms have been formulated to use minimization routines as part of the projection process in order to minimize the possibility of stagnation.

Deconvolution from Wavefront Sensing

A key distinguishing feature of post-detection compensation algorithms is the type of additional data required to estimate and remove atmospheric blurring in the measured short-exposure images. Blind deconvolution techniques need no additional data. Speckle imaging techniques estimate average atmospheric blurring quantities and need an estimate of the average atmospheric energy spectrum. Because average quantities are calculated when using speckle imaging techniques, only an estimate of the average atmospheric energy spectrum is needed, not the specific energy spectra that corrupted the measured short-exposure images. As a result, the additional data need not be collected simultaneously with the short-exposure images. The technique described in this section, deconvolution from wavefront sensing (DWFS), seeks to deconvolve the atmospheric blurring in each short-exposure image by estimating the specific atmospheric field phase perturbations that blur each short-exposure image. Thus, the additional data must be collected simultaneously with the short-exposure images. The atmospheric field phase perturbations are calculated from data obtained with a wavefront sensor using a different region of the optical spectrum than used for imaging so that no light is taken from the imaging sensor. Most commonly, the wavefront sensor data consists of the first derivatives of the phasefront (phase differences) as obtained with Shack–Hartmann or shearing interferometer wavefront sensors, but curvature sensing wavefront sensors are also used that produce data that are proportional to the second derivatives of the phasefront.

The original algorithm to implement the DWFS technique produced an estimate $\hat{O}(\vec{f})$ of the Fourier transform $O(\vec{f})$ of the object being imaged using the following estimator:

$$\hat{O}(\vec{f}) = \frac{\sum_m I_{\text{m}}(\vec{f})\tilde{H}^*_{\text{m}}(\vec{f})}{\sum_m |\tilde{H}_{\text{m}}(\vec{f})|^2} \qquad [13]$$

where $\tilde{H}_{\text{m}}(\vec{f})$ is the overall system transfer function (including the telescope and atmospheric effects) for the mth short-exposure image estimated from the wavefront sensor data. To create $\tilde{H}_{\text{m}}(\vec{f})$, the atmospheric field phase perturbations corrupting the mth image must be calculated from the wavefront sensor measurements. This topic is discussed in more detail in **Imaging**: Adaptive Optics. Then $\tilde{H}_{\text{m}}(\vec{f})$ is obtained using standard Fourier optics techniques. Although eqn [13] is easily implemented given an existing system that includes a wavefront sensor, it suffers from the fact that it is a biased estimator. An unbiased version of eqn [13] is given by

$$\hat{O}(\vec{f}) = \frac{\sum_m I_{\text{m}}(\vec{f})\tilde{H}^*_{\text{m}}(\vec{f})}{\sum_n H_{\text{n,ref}}(\vec{f})\tilde{H}^*_{\text{n,ref}}(\vec{f})} \qquad [14]$$

where $\tilde{H}_{\text{n,ref}}(\vec{f})$ and $H_{\text{n,ref}}(\vec{f})$ are estimates of the overall system transfer function obtained from data collected on a reference star using wavefront sensor data and image-plane data, respectively. Thus, to obtain an unbiased estimator, two more datasets must be collected. The number of frames in the reference star dataset need not be the same as for the imaging dataset. As for speckle imaging, the atmospheric statistics must be the same for the reference star and imaging datasets.

Another technique that uses at least one additional data channel along with the measured image is called

phase diversity. In the additional data channels, images are also recorded, but with known field phase aberrations intentionally introduced to add known diversity to the unknown field phase corrupting the measurements. The most commonly introduced field phases aberration in an additional channel is defocus due to its ease of implementation. In the case of defocus, the additional data channel along with the imaging channel can be viewed as samples of the focal volume of the imaging system. Both the noise-free object and the unknown field phase aberrations can be recovered from the measured data using optimization techniques to enforce data consistency along with other prior knowledge constraints. These types of systems can use higher-order aberrations as well. The phase diversity concept has been generalized to an approach known as computational imaging, where an imaging system is designed by taking into account its intended use, the expected image degradation mechanisms, and the fact that the image will be the product of both an optical system and a postprocessing algorithm.

Pre-Detection Compensation

The primary pre-detection-only compensation technique in use today employs dynamical electro-optical systems to sense and remove the phases in the impinging wavefront due to atmospheric turbulence. This technique, known as adaptive optics, provides much higher-quality data than post-detection compensation techniques, when there is enough light from the object being imaged or a guidestar (artificial or natural) to drive the adaptive optics system at a bandwidth high enough to keep up with the temporal changes in atmospheric turbulence. It consists of a wavefront sensor that measures the portion of the phasefront in the pupil of the telescope that is due to atmospheric turbulence, a wavefront reconstructor that generates the deformable mirror drive signals from the wavefront sensor data, and a deformable mirror that applies the conjugate of the atmospheric phase distortions to a reimaged pupil. Some of the light reflected off the deformable mirror is then sent to the imaging sensor. Adaptive optics systems are discussed in much greater detail in **Imaging**: Adaptive Optics. Here, it suffices to say that no adaptive optics system produces imagery that is diffraction limited in quality, although, under the right conditions, the images can be near diffraction limited. However, atmospheric seeing conditions fluctuate significantly over a night as well as seasonally. Therefore, virtually all adaptive optics images benefit from applying post-compensation techniques, as is discussed next.

Hybrid Techniques

Adaptive Optics and Post-Processing

Often, an adaptive optics system does not fully correct for atmospheric turbulence. This can occur when atmospheric conditions become worse than the system is designed to handle. Also, an adaptive optics system may be intentionally designed to only partially correct for atmospheric turbulence in order to lower the cost of the system. As a result, there still may be significant atmospheric blurring in systems that use adaptive optics. For this reason, additional post-processing of adaptive optics imagery can result in significant improvement in image quality. All of the techniques discussed in the section on post-detection compensation can be applied to adaptive optics imagery. Applying these techniques should never degrade image quality, and will improve the quality if the adaptive optics system doesn't fully correct for atmospheric turbulence. Generally speaking, the amount of improvement decreases as the performance of the adaptive optics system increases. Because the adaptive optics system's performance parameters can vary as atmospheric conditions vary, the blind deconvolution algorithms are especially applicable to processing adaptive optics imagery since they estimate the overall system transfer function from the imaging data. Because speckle imaging techniques require a separate estimate of the overall system transfer function, it can be difficult and time-consuming to obtain all of the additional data necessary to apply these techniques to adaptive optics data. Since these post-detection compensation techniques require short-exposure images, the adaptive optics system needs to have a camera capable of collecting short-exposure images. Finally, even if an adaptive optics system fully corrects for the atmosphere, deconvolution techniques that remove the diffraction-limited transfer function amplitude attenuation can improve image quality.

Partially Redundant Pupil Masking

Although adaptive optics systems can function very well, currently they are expensive and require significant maintenance. The primary benefit of adaptive optics systems is that they remove atmospheric turbulence phase distortions in the pupil of the telescope, thus permitting light from all areas of the pupil to interfere in phase when creating an image. An interferometric view of imaging reveals that multiple regions of the light in the pupil contribute to a single spatial frequency in the image. When the phasefront in the pupil is distorted

by the atmosphere, these multiple regions tend to not interfere in phase, reducing the amplitude of the image's Fourier component at that spatial frequency. This amplitude reduction effect occurs for all spatial frequencies greater than the limit imposed by the atmosphere, r_o/λ. Therefore, techniques have been developed to modify the wavefront by masking part of the pupil prior to measuring the field with an imaging sensor. This class of techniques has various names including optical aperture synthesis, pupil masking, and aperture masking. Here this class of techniques will be referred to as partially redundant pupil masking (PRPM).

PRPM techniques function by masking the pupil in such a way as to minimize the amount of out-of-phase interference of light on the imaging detector. Early efforts used pupil masks that were opaque plates with r_o-sized holes in them. Because the atmospheric coherence length is r_o, all the light from an r_o-sized hole is essentially in phase. By choosing the holes in the mask so that only two holes contribute to a single spatial frequency in the image, out-of-phase interference problems are removed. This type of mask is called a nonredundant pupil mask. Of course, a significant amount of light is lost due to this masking, so only bright objects benefit from this particular implementation. Often, the pupil mask needs to be rotated in order to obtain enough spatial frequencies in the image to be able to reconstruct a high-quality estimate of the object. To increase the light levels in the image, masks have been made to allow some out-of-phase interference for a given spatial frequency, thus trading off the amplitude of the spatial frequencies allowed in the image with the amount of light in the image. Masks with this property are called partially redundant pupil masks.

One version of PRPM is called the variable geometry pupil (VGP) technique. It is envisioned to work in conjunction with an adaptive optics system that does not fully correct the wavefront for atmospheric phase distortions. It employs a spatial light modulator or a micro-electromechanical mirror between the deformable mirror and the imaging sensor. Either of these two devices is driven by signals from the wavefront sensor in the adaptive optics system in such a way that the portions of the pupil where the phasefront has a sufficiently large second derivative is blocked, while the remainder of the phasefront is transmitted.

All PRPM techniques benefit from post-compensation processing. For the case of nonredundant pupil masks, post-processing techniques are required to convert the discrete-spatial-frequency information into an image with reasonable quality. These techniques are essentially the same techniques as used in interferometric imaging, not those described in this article. When partially redundant pupil masks are used (including VGP masks), the image may include enough spatial frequency content that the methods described in the post-detection compensation section can be applied.

Introduction

Electric lamps are by far the most common source of light used on Earth, other than our sun. These sources are composed of a very large number of individual radiating elements, all acting independently. This independence causes the light generated by electric lamps to have a very low degree of spatial and temporal coherence. When compared to lasers, lamps are usually considered to be incoherent sources.

Electric lamps are widely used for general lighting, such as residential, commercial and industrial space, and task lighting. A much less frequent use of incoherent sources, but perhaps of more interest to the reader, is as wavelength, intensity, and total light output standard used to calibrate various coherent light sources. We will discuss the general characteristics of incandescent, gas discharge, and solid state lamps, with sources in the Further Reading section at the end of this article, which are used as calibration standards for coherent sources.

Definitions

Before discussing individual lamp technologies, we need to define some of the key terms that are used for describing the performance of electric lamps. Most of these definitions are based on or abstracted from the IESNA Lighting Handbook:

- *Efficacy*: The total light output of a lamp, measured in lumens, divided by the power input in watts. Efficacy has the units of lumens per watt, or $\mathrm{l\,m\,W^{-1}}$, and can be greater than 100. The efficacy of common light sources varies from $10\,\mathrm{l\,m\,W^{-1}}$ to over $200\,\mathrm{l\,m\,W^{-1}}$.
- *Correlated Color Temperature* (*of a light source*) (*CCT*): the absolute temperature of a blackbody whose chromaticity most nearly resembles that of the light source. CCT is measured in Kelvin (K). The CCT of typical light sources varies from 2000 K to 6000 K, with the most popular sources being in the range from 2700 K to perhaps 4500 K.
- *Color Rendition Index* (*of a light source*) (*CRI*): a measure of the degree of color shift objects undergo when illuminated by the light source as compared with those same objects when illuminated by a reference source of comparable color temperature. The highest possible CRI is 100. The lowest theoretical CRI is less than zero, but CRI less than 50 is generally considered to have no value in determining the color quality of a light source.
- *Photopic Luminous Efficiency Function* (V_λ): a measure of the sensitivity of the human eye in lumens per watt of radiation received, as a function of wavelength, for luminance levels higher than $\sim 3\,\mathrm{cd\,m^{-2}}$. V_λ is based on relatively few observations, and individuals may differ significantly from the standard V_λ function. V_λ provides the basis for measuring the efficacy of all light sources.
- *Visible Light*: generally accepted to mean radiation between 380 nm and 780 nm.

Incandescent Lamps

Incandescent lamps are quasi-blackbody thermal radiators. A true blackbody radiator would generate light according to Planck's Law, as shown in eqn [1] and Figure 1, for various temperatures. Most incandescent lamps use tungsten filaments, and the emissivity of tungsten, the ratio of its radiative output to that of a blackbody at the same temperature, is about 0.44 in the visible region of the spectrum and about 0.33 in the infrared. The radiative output of a tungsten incandescent lamp is, therefore, less than half that of a blackbody of the same temperature and the intensity versus wavelength curve does not exactly follow Plank's law, being slightly favorable to visible

radiation:

$$E(\lambda) = \frac{2\pi hc^2 10^{-9}}{\lambda^5(\exp^{hc/k\lambda T} - 1)} \qquad [1]$$

where:

E = power per square meter of surface area per nm of wavelength
λ = wavelength in meters
h = Plank's constant, 6.63×10^{-34} Joule seconds
c = speed of light, 3×10^{8} meters sec^{-1}
κ = Boltzman's constant, 1.38×10^{-23} Joule K^{-1}
T = temperature of the source in K

Tungsten lamps have excellent color quality, reflected in a perfect CRI of 100, are inexpensive, available in a great variety of sizes, shapes, and operating voltages, have a small source size that permits excellent light control with relatively small reflectors and lenses, run equally well on AC or DC power, can be easily dimmed, can have very long life, are insensitive to operating position, are relatively insensitive to ambient temperature, contain no hazardous materials, and light virtually instantly, though not as fast as LEDs. However, incandescent lamps have one major disadvantage; they are very inefficient. Most of the energy consumed by incandescent lamps is radiated in the infrared, while only 5% to 10% is radiated in the visible portion of the spectrum. The reason for this is shown in Figure 2, which shows the visible region of the spectrum superimposed on the blackbody radiation curves.

There are a number of techniques that have been used or are being investigated to increase the efficacy of incandescent lamps. First, as can be seen in Figure 2, increasing the filament temperature shifts the wavelength for peak emission toward lower wavelengths, and will result in a larger fraction of the radiated energy being in the visible region. Unfortunately, increasing filament temperature also increases the rate of tungsten evaporation and therefore shortens the life of tungsten lamps, since evaporation of tungsten is the dominant incandescent lamp failure mode. In a similar manner, the life of incandescent lamps can be increased to arbitrarily long times by decreasing filament temperature. This technique, which is the means used in far too many 'long life' incandescent lamps, unfortunately leads to a decrease in the already low efficacy of incandescent lamps. The approximate dependences of life, efficacy, and color temperature on operating voltage, for common incandescent lamps operating between 90% to 110% of rated voltage, are shown in eqns [2], [3], and [4]:

$$\frac{\text{LIFE}_1}{\text{LIFE}_2} = \left(\frac{\text{VOLTS}_2}{\text{VOLTS}_1}\right)^{13} \qquad [2]$$

$$\frac{\text{EFFICACY}_1}{\text{EFFICACY}_2} = \left(\frac{\text{VOLTS}_1}{\text{VOLTS}_2}\right)^{1.9} \qquad [3]$$

$$\frac{\text{COLOR\_TEMPERATURE}_1}{\text{COLOR\_TEMPERATURE}_2} = \left(\frac{\text{VOLTS}_1}{\text{VOLTS}_2}\right)^{0.42} \qquad [4]$$

Combining eqns [2] and [3] yields eqn [5]:

$$\frac{\text{LIFE}_1}{\text{LIFE}_2} = \left(\frac{\text{EFFICACY}_2}{\text{EFFACACY}_1}\right)^{6.84} \qquad [5]$$

Under the assumption that the color temperature of an incandescent lamp is approximately the same as the operating temperature of the filament, we can combine eqns [2] and [4] to obtain eqn [6], and combine eqns [3] and [4] to obtain eqn [7]:

$$\frac{\text{LIFE}_1}{\text{LIFE}_2} = \left(\frac{\text{TEMPERATURE}_2}{\text{TEMPERATURE}_1}\right)^{30.95} \quad [6]$$

$$\frac{\text{EFFACACY}_1}{\text{EFFICACY}_2} = \left(\frac{\text{TEMPERATURE}_1}{\text{TEMPERATURE}_2}\right)^{4.52} \quad [7]$$

One way to allow operation with higher filament temperatures, while not decreasing filament life, is to fill the lamp with a high molecular weight and/or high pressure gas, as either will retard tungsten evaporation. Lamps using krypton or xenon in place of the normal argon fill allow for a moderate increase in filament temperature. Better yet is a fill of halogen gas, such as HBr, CH_3Br, or CH_2Br^2 plus Kr or Xe at total pressures that range from 2 to 15 atmospheres. The high total pressure inhibits tungsten evaporation from the filament, and the halogen fill gas reacts with tungsten that deposits on the wall of the lamp to remove this tungsten and maintain light output over the life of the lamp. The tungsten removed from the wall of the lamp is redeposited on the tungsten filament, increasing lamp life under some circumstances. Due to the high gas pressures involved, tungsten halogen incandescent lamps are constructed in small 'filament tubes' to minimize both the amount of gas needed and the total explosive energy. The filament tubes are manufactured from quartz or special high temperature glass. For general purpose applications, the quartz or high temperature glass filament tube is enclosed in a larger glass envelope to protect the user should the filament tube explode and to protect the filament tube from environmental contaminants, such as salts from human fingers.

Since 90% to 95% of the energy consumed by an incandescent lamp is radiated as infrared energy, it is easy to see that the potential exists to dramatically increase the efficacy of incandescent lamps by reflecting some of this infrared energy back onto the filament, thus allowing the filament to be maintained at its normal operating temperature with far less electrical power. The reflector must have very low absorption in the visible region of the spectrum, high reflectivity in the IR and a reasonably sharp transition between the two, because the greatest IR emission is just below the visible band. The reflector and filament must also be precisely positioned so that the reflected IR radiation hits the filament, and the reflector must also be low enough in cost to be commercially viable. Successful IR reflectors have been made from multilayer dielectric films. These are similar to the coatings used to make high reflectivity mirrors for He–Ne lasers, but they have much broader bandwidth and lower reflectivity. The reflector-filament alignment problem is most easily solved using the geometry of a tungsten halogen filament tube as the carrier for the IR reflector. The typical efficacy gain is about 50%: a 60-watt IR-halogen lamp produces about as much light as a 90-watt halogen lamp.

Other methods being investigated to increase the efficacy of incandescent lamps involve modification of the filament to decrease its emissivity in the IR and/or increase its emissivity in the visible, and hence turn it into more of a 'selective radiator' than natural tungsten. Three general methods are under investigation: one involves creating a dense pattern of submicron size cavities on the surface of the tungsten to inhibit IR radiation; a second involves coating the tungsten with a material that is itself a selective radiator that favors the visible portion of the spectrum, while a third involves replacing the tungsten filament with a material that is a natural selective radiator. No products exist that employ these techniques, but active R&D projects are underway that may yield a more efficient incandescent lamp in the future.

Incandescent lamps can be used as standards for total flux and color temperature if carefully constructed and operated. The National Institutes for Standards and Technology (NIST) in the US sells 1000-watt tungsten halogen lamps calibrated to an accuracy of 0.6% in luminous intensity and 8 K in color temperature at a color temperature of 2856 K. Similar service are provided by standards organizations in other countries.

Discharge Lamps

The most efficient lamps produced today are based on electric discharges in gasses. These include 'low pressure' lamps such as fluorescent lamps and low pressure sodium lamps; and 'high pressure' or high intensity discharge (HID) lamps such as metal halide, high pressure sodium, high pressure mercury, and sulfur lamps. These lamps are all more efficient than incandescent lamps because they are 'selective radiators' instead of blackbody sources and have been designed to generate as much radiant energy as possible in the visible band while minimizing energy produced outside the visible band. The best white light discharge lamps have conversion efficiencies from electric power to visible light of 25% to 30%, making them almost five times as efficient as the typical incandescent lamp.

Fluorescent Lamps

Fluorescent lamps, as shown in Figure 3, are generally constructed in a cylindrical soda lime glass envelope with a length to diameter ratio significant greater than one. Most contain thermionic electrodes at each end to generate an electric field that establishes and sustains the discharge. The lamps are filled with about 2 Torr of Argon and/or another rare gas, and a few mg of liquid mercury, while the inside surface of the tube is coated with a phosphor that converts UV radiation generated by excited mercury atoms into visible light.

As with any other low pressure gas discharge, various discharge regions are aligned along the axis of the tube:

- Aston Dark Space
- Cathode Glow
- Cathode Dark Space
- Negative Glow
- Faraday Dark Space
- Positive Column
- Anode Glow
- Anode Dark Space

The axial lengths of all these regions, except for the positive column, are fixed by the properties of the cathode and anode, the fill gas type and pressure, and the discharge current. The length of the positive column is variable and fills the space between the Faraday Dark Space and the Anode Glow. The cathode and anode regions of the discharge have a total axial length of about twice the diameter of the discharge tube. Therefore, if the length-to-diameter ratio of the discharge tube is substantially greater than one, the majority of the tube is filled by the Positive Column, as shown in Figure 3. The positive column is the part of the discharge that creates the UV photons that excite the phosphor and cause it to generate visible light. The remainder of this discussion will therefore focus on the positive column.

The basic operation of a fluorescent lamp positive is shown in Figure 4. Free electrons are accelerated by the electric field established between the two electrodes. These electrons collide with both the mercury and rare gas atoms, but selectively excite and ionize mercury atoms, since the excitation and ionization energies of mercury are significantly lower than that

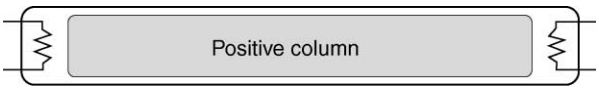

Figure 3 Linear fluorescent lamp. © 2005 Roberts Research and Consulting, Inc. Published by Elsevier Ltd. All rights reserved.

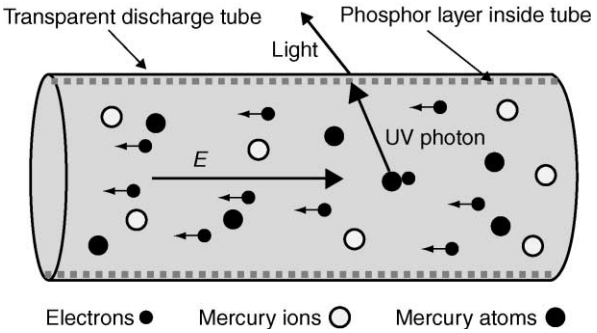

Figure 4 Operation of fluorescent lamp positive column. © 2005 Roberts Research and Consulting, Inc. Published by Elsevier Ltd. All rights reserved.

of any rare gas used in the lamps. Ionization of mercury creates more free electrons to sustain the discharge. The gas density in the lamp is low enough to require that most of the recombination of mercury ions and free electrons takes place on the wall of the tube, since this recombination requires a three-body collision. The excited mercury atoms generate both UV and visible photons, and the UV photons generate visible light once they reach the phosphor coated on the inner surface of the lamp.

The high efficiency of fluorescent lamps is directly related to the fact that 60% to 65% of the electric power consumed by the positive column of the fluorescent lamp discharge is converted into 245 nm UV photons as a result of the resonance transition from the 6^3P_1 state of mercury at 4.86 eV to the 6^1S_0 ground state. The resonance transition from the 6^1P_1 state of mercury generates 185 nm UV photons that carry about 10% of the energy. About 3% of the positive column energy ends up in mercury visible lines at 405 nm, 436 nm, 546 nm, 577 nm, and 579 nm.

The 245 nm and 185 nm photons generated by the excited mercury atoms travel only a fraction of a mm before they are absorbed by a ground-state mercury atom. However, due to the relative absence of other de-excitation mechanisms, a large fraction of these absorbed photons are re-emitted by the absorbing atoms, and most of the UV photons generated in the core of the discharge eventually reach the phosphor coated interior wall of the discharge tube where they are converted into visible light (and waste heat).

The phosphors used in modern fluorescent lamps are a blend of three rare-earth phosphors:

- Blue: $BaMg_2Al_{16}O_{27}:Eu^{2+}$
- Green: $CeMgAl_{11}O_{19}(Ce^{3+}):Tb^{3+}$
- Red: $Y_2O_3:Eu^{3+}$

Rare earth phosphors provide a combination of high efficiency, high color rendition index, and high resistance to degradation that far exceeds the performance of the halophosphate phosphors used in older generations of fluorescent lamps.

However, due to the Stokes Shift, there is a substantial energy loss converting the UV photons produced by excited mercury atoms into visible light, even using a 'perfect' phosphor that has quantum efficiency of 1.0. The average energy of a visible photon is 2.43 eV, using the 380 nm to 780 nm limits for visible radiation discussed at the start of this article. When one 245 nm photon that has 4.885 eV of energy is converted to one visible photon with an average energy of 2.43 eV, a bit over 50% of the photon's energy is lost. The situation is worse for the 185 nm photons, which each have 6.707 eV of energy. They lose 64% of their energy when they are converted to visible photons, so it is good that the fluorescent lamp discharge generates six to seven 245 nm photons for each 185 nm photon. The Stokes shift is responsible for the largest single energy loss mechanism in fluorescent lamps. Work is underway to develop phosphors with a quantum efficiency greater than 1.0, so less energy will be lost in the UV-to-visible light conversion process, but no practical phosphors have been developed to date.

The mercury pressure for optimum UV production is about 6×10^{-3} Torr, which is the vapor pressure of mercury over a liquid pool at 40 °C. At higher mercury pressure there is too much absorption by ground state mercury atoms, and at lower pressures there is an insufficient number of mercury atoms for excitation by the electrons. The diameter of most linear lamps is chosen so that the coolest spot on the interior of the lamp wall will be at 40 °C when the lamp is operated at its design power in an ambient temperature of 25 °C. Usually this 'cold spot' will be near the middle of the lamp, but in some higher power linear lamps the wall temperature is well over 40 °C. In these lamps a cold spot is often created at the end of the lamp by use of a longer electrode mount and a heat shield mounted between the electrode and the end of the lamp. Obviously, the performance of fluorescent lamps designed in this manner is highly sensitive to ambient temperature. In some smaller, high-power density lamps, most commonly compact fluorescent lamps (CFLs), it is not possible to create a region with a temperature as low as 40 °C. In these lamps the mercury pressure is controlled by amalgamating the mercury with Pb, Bi, or Sn, creating a compound that both reduces the mercury vapor pressure at any given temperature and also reduces the variability of mercury vapor pressure with temperature. These mercury amalgams have the secondary advantage of making the fluorescent lamp less sensitive to ambient temperature.

Mercury, which is the key ingredient in fluorescent lamps, is considered to be a hazardous material by regulatory agencies in many countries. At least as early as the mid-1980s researchers began to study ways to reduce or eliminate mercury from fluorescent lamps.

Development of a mercury-free fluorescent lamp is very difficult and the only mercury-free fluorescent lamp that exists, as of mid-2003 has an efficacy of about $10\,\mathrm{l\,mW^{-1}}$, one-tenth the efficacy of the best mercury-based fluorescent lamp (Osram Sylvania LINEX® Linear Excimer Lamp System, Model LINEX A3-10W40). There are three key problems that have to be solved to develop an efficient mercury-free fluorescent lamp system:

(i) Identify a nontoxic material that generates UV photons and has its optimum gas density at a convenient and safe temperature. The most promising candidate is xenon, used as either an atomic radiator or an excimer.

(ii) Develop a phosphor that produces high-quality white light with high efficiency when excited by UV photons from the chosen mercury-replacement material. This has proven a major challenge. The resonance line of atomic Xe has a wavelength of 147 nm, while the output from a xenon excimer discharge is at 172 nm. The Stokes shift loss converting each of these to visible light is 71% for atomic xenon and 66% for xenon excimers. To reduce the Stokes shift loss, a quantum-splitting phosphor, one that generates more than one visible photon for each UV photon, is needed. Most of the effort to develop mercury-free fluorescent lamps has been concentrated in this area. No viable phosphor has been developed, but work continues.

(iii) Develop a 'reservoir' for xenon or the other working gas. The mass of 'active' gas needed for a fluorescent lamp is small; a 4-foot, 1.5-inch diameter lamp needs 0.1 mg of mercury in the gas phase to operate properly. However, during life, some of this gas is consumed through physical attachment or chemical reaction and must be replaced. The drop of liquid mercury or small mass of mercury amalgam used in conventional fluorescent lamps provides a reservoir that maintains the mercury gas pressure in the presence of these consumption mechanisms.

In contrast to the failure to develop a mercury-free fluorescent lamp, there has been great success in

reducing the amount of mercury used in each lamp. A typical 4-foot, 1.5-inch diameter fluorescent lamp produced in the 1970s would have 50 mg to 100 mg of mercury. This high amount of mercury was mostly the result of the type of manufacturing equipment used, but mercury consumption required that each lamp had 15 mg to 20 mg of mercury in order to survive for its rated 20 000-hour life. The development of coatings and other materials that reduce mercury consumption, when combined with new manufacturing technology, has allowed the amount of mercury used in modern 4-foot fluorescent lamps to be reduced to 3 mg to 5 mg, and further reductions are possible with improved technology.

As stated above, the length-to-diameter ratio of most fluorescent lamps is significantly greater than one. The reason for this is that there is a 10 to 15 volt drop at the electrodes, and the power lost in these regions does not produce a significant amount of light. A large length-to-diameter ratio increases the voltage and power of the positive column, where the bulk of the UV photons are generated, relative to the power lost in the electrode regions. When the energy crunch hit in the mid-1970s, there was strong interest in developing a fluorescent lamp that could replace the inefficient incandescent lamp. However, the need for high length-to-diameter ratios meant that it would not be practical to make a fluorescent lamp shaped like an incandescent lamp. This need created the technology to manufacture CFLs which are constructed of long tubes bent or coiled into shapes that allow them to fit into spaces occupied by incandescent lamps.

Fluorescent lamps and other discharge lamps have a negative incremental voltage vs. current (V/I) characteristic, which means that their operating voltage decreases as the operating current increases. Due to this, such discharges need to be operated from a current limited power source, commonly known as a 'ballast' in the lighting industry. Ballasts were originally simple series inductors and lamps operated at the power line or mains frequency, though many line frequency ballasts are now considerable more complex than an inductor. In the 1940s, it was discovered that the efficacy of fluorescent lamps could be increased by operation at frequencies of a few kHz. It was not until the 1970s, however, until the cost of power electronics came down to the point where it was possible to make affordable high frequency electronic ballasts. Electronic ballasts operating in the 20 kHz to 100 kHz range are now used with almost all CFLs and in most commercial applications using linear fluorescent lamps.

The desire for fluorescent lamps shaped like incandescent lamps also sparked the development of electrodeless fluorescent lamps. Since the need for high length-to-diameter ratios is driven by the losses at the lamp electrodes, researchers realized they could make fluorescent lamps in short, wide shapes if they eliminated the electrodes. As shown in Figure 5, an electrodeless lamp is just like a transformer, except it has a single-turn discharge secondary instead of a multiturn copper or aluminum secondary. An open core version of an electrodeless fluorescent lamp with integral ballast is shown in Figure 6. The electric field is created by a time-varying magnetic field. Because of the relative high voltage-per-turn imposed by the discharge secondary, these lamps operate only at high frequency. There are three electrodeless fluorescent lamps on the market. The closed core design

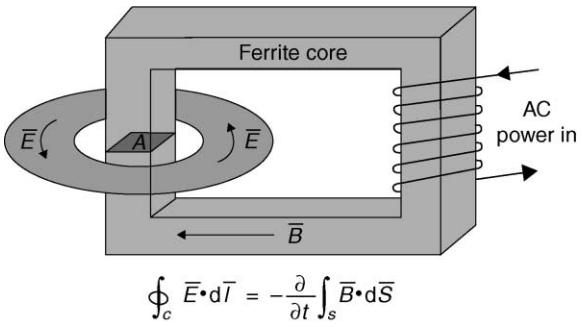

Figure 5 Basic electrodeless fluorescent lamp with closed ferrite core. © 2005 Roberts Research and Consulting, Inc. Published by Elsevier Ltd. All rights reserved.

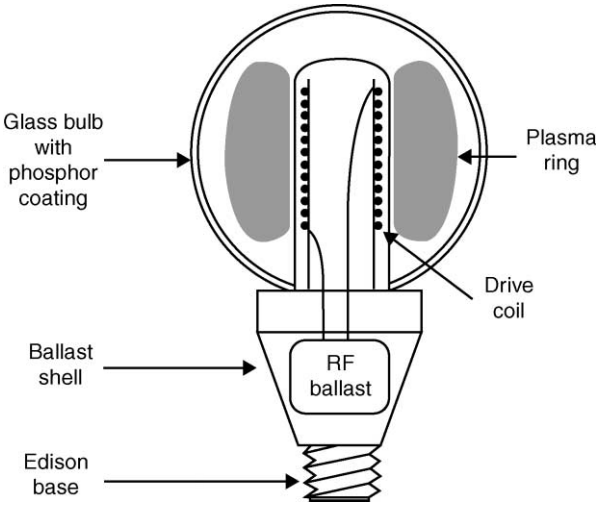

Figure 6 Open core electrodeless lamp with integral ballast. © 2005 Roberts Research and Consulting, Inc. Published by Elsevier Ltd. All rights reserved.

shown in Figure 7 operates near 250 kHz with an external ballast, while the open core design shown in Figure 8 operates near 2.5 MHz. Figure 9 shows an open core design with an integral ballast that also operates near 2.5 MHz. Some people have suggested that electrodeless fluorescent lamps are fundamentally different from normal fluorescent lamps and the high frequency field drives the phosphor to emit light. This is incorrect. Other than the manner in which the electric field is created, and the new shapes this allows, electrodeless fluorescent lamps operate in the same manner as normal fluorescent lamps.

Due to the strong dependence of fluorescent performance on mercury temperature, these lamps are not useful as flux standards. However, the five mercury visible lines listed above, plus the 365 nm line of mercury, make the ordinary fluorescent lamp an ideal source for wavelength calibration of spectrometers. Germicidal lamps, which do not use phosphor but are constructed in quartz envelopes and use the same type of mercury-rare gas discharge as fluorescent lamps, are a convenient source of 254 nm radiation that can be used to calibrate UV spectrometers. Care should be taken when using these lamps, as the 254 nm radiation can damage human eyes and skin.

High Intensity Discharge Lamps

If the mercury pressure in a discharge lamp is raised from 6×10^{-3} Torr to an atmosphere or

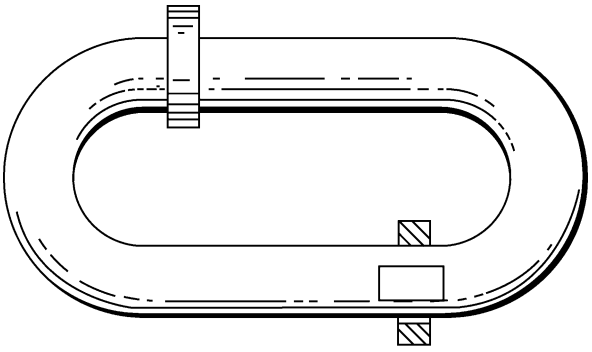

Figure 7 Closed core electrodeless fluorescent lamp, Osram Sylvania Icetron/Endura Lamp, from US Patent 5,834,905.

greater, the 245 nm and 185 nm resonance lines are trapped via absorption by ground-state mercury atoms and the radiation output from the discharge shifts to the five optically thin visible lines listed in the discussion of fluorescent lamps, plus the 365 nm near-UV line and a number of lines near 300 nm. The result is a high pressure mercury lamp that operates with an efficacy of about $55\,\mathrm{l\,m\,W^{-1}}$ and has a CRI of about 50. The high-mercury vapor pressure requires a wall temperature of at least 360 °C, which in turn requires that the arc tube be constructed from quartz and operated at high power density. A 400-watt high-pressure mercury arc tube has a diameter of 22 mm and length of about 100 mm. In contrast, a 32-watt fluorescent lamp has a diameter of 25.4 mm and a length of about 1200 mm. This accounts for the classification of these high pressure lamps as high intensity discharge (HID) lamps. Due to the high temperature of the arc tube, most HID lamps are constructed with the arc tube mounted inside a hard glass outer jacket that protects both the user and the arc tube. The high-pressure mercury lamp is a direct visible radiator, but the arc tube does generate a small amount of radiation in the 254 nm to 365 nm region, that radiation is trapped by the outer glass jacket. Some high-pressure mercury lamps have a phosphor coating on the inside of the outer jacket to convert this UV radiation into visible radiation, mostly in regions of the spectrum where the high-pressure mercury arc is deficient in radiation, thus improving the color of the lamp.

Most high-pressure mercury lamps operate at a mercury pressure of about four atmospheres. Because their spectrum is dominated by mercury line emission, the output of these lamps is deficient in the red portion of the spectrum and the lamps have poor color rendition. In 1992, Philips received a US patent for a new type of ultra-high pressure mercury lamp that they call UHP for 'Ultra High Performance'. This lamp operates at a mercury pressure of 200 atmospheres or more. The output spectrum is characterized by a significant amount of continuum radiation from quasi-molecular states of mercury and this continuum includes energy in the red portion of the spectrum that is missing from conventional high pressure mercury lamps. UHP lamps also include a small amount of halogen, such as bromine, which creates a tungsten-halogen cycle similar to that discussed earlier in relation to tungsten-halogen incandescent lamps. During lamp operation, tungsten is sputtered and evaporated from the electrodes. In the absence of the halogen fill, this tungsten rapidly deposits on the walls, leading to very short lamp life. The halogen combines with most of the tungsten before it has a chance to reach the wall of the arc tube. The halogen will also combine with any tungsten that has deposited on the wall of the arc tube. The tungsten-halogen compound formed is gaseous at the operating temperature of the lamp and will diffuse back toward the core of the discharge where the high temperature of the arc dissociates the tungsten-halogen compound. The tungsten is deposited back on the electrodes, thereby greatly extending the life of the lamp. Due to their very high pressures, UHP lamps are constructed in small discharge tubes and have a very short discharge length, typically 1 to 2 mm, making these lamps a virtual point source. Due to their excellent spectral characteristics and small source size, UHP lamps have found application in various projection applications, including LCD-based electronic projectors.

The performance of high-pressure mercury lamps can be substantially improved by adding metals such as sodium and scandium to the high-pressure mercury arc. The sodium emits near the peak of the eye sensitivity curve, providing high efficacy, while the scandium has many transitions in the visible, which fill out the spectrum and provide high CRI. If metallic elements are added directly to the high-pressure mercury arc they would deposit on or react with the wall of the arc tube. To prevent this they are added as iodides, such as NaI or ScI_3. This creates a regenerative cycle in which the NaI and ScI_3 are heated and dissociated in the 5000 K core of the arc, allowing the free metals to radiate. As the metals diffuse toward the cooler sections of the arc near the walls, they recombine with the iodine to reform the iodides. These metal halide lamps have produce light with an efficacy of about $90\,\mathrm{l\,m\,W^{-1}}$ to $100\,\mathrm{l\,m\,W^{-1}}$ and a CRI of about 65 to 75.

The high-pressure sodium (HPS) lamp is an HID lamp that uses hot sodium vapor to generate a golden white light. The lamp uses a mixture of sodium, mercury, and rare gas such as xenon. The core temperature of the sodium-mercury-xenon discharge is typically about 4000 K, while the temperature at the edge of the discharge and the walls of the ceramic arc tube is typically about 1500 K. At low pressure, emission from sodium is dominated by the resonance lines at 589.0 and 589.6 nm, so the light is virtually monochromatic. However, in the HPS lamp, the sodium pressure is typically 75 Torr, which is high enough to almost completely trap emission from the resonance lines, forcing radiant energy to escape in the wings of

these lines, thereby increasing the color quality of the light. Since sodium will attack quartz, this mixture is contained in a translucent alumina (aluminum oxide) ceramic arc tube. As with other HID lamps, the alumina arc tube is contained in a hard glass outer bulb. HPS lamps are the most efficient generators of 'white light' available. A typical 400 watt HPS lamp produces light with an efficacy of $125\,\mathrm{l\,m\,W^{-1}}$, this high efficacy being due to the fact that the emission matches the peak of the eye sensitivity curve. The light has a CRI of only 22; however, the HPS lamp is widely used for roadway and other outdoor lighting applications.

Solid State Sources

The newest incoherent sources to be used for general purpose lighting are solid state devices: light emitting diodes (LEDs), and organic light emitting diodes (OLEDs). LEDs are very similar to laser diodes but without the two mirrors used to form the laser cavity in laser diods. Photons are generated as a result of electron-hole recombination as electrons move across the energy gap of a biased p-n junction. By appropriate selection of materials, photons can be created at visible wavelengths. Low brightness infrared and red LEDs have been available for quite some time. It was not until the mid-1980s that high brightness red LEDs were developed. These were followed by increasingly more challenging yellow, green, and then blue high brightness LEDs, developed in 1994 by Shuji Nakamura, of Nichia Chemical Industries. Nakamura added phosphor to his high brightness blue LEDs in 1996 and developed the first 'white' LED, thus triggering the current level of excitement concerning the use of LEDs to replace incandescent and discharge lamps. Monochromatic high brightness LEDs have already replaced color-filtered incandescent lamps in many applications, such as traffic lights, vehicle signal lights, and signage. In these applications, LEDs are the clear winner in life and efficacy. However, when compared to unfiltered sources, the best white LEDs are about as efficient as tungsten halogen incandescent lamps and far less efficient than fluorescent and metal halide lamps. They also cost far more per lumen than even the most expensive discharge lamp. LEDs have high internal quantum efficiency, so the main technical challenges are to fabricate devices to minimize internal light trapping in order to improve device efficiency and reduce the cost per lumen produced.

Organic light emitting diodes (OLEDs) generate light by the passage of electric current through special organic molecules, using a process known as electrophosphorescence. The electrophosphorescent material is usually coated on a transparent and perhaps flexible substrate, and overcoated with a transparent conductor. OLEDs currently have lower efficacy and shorter life than LEDs, but they also have lower manufacturing costs. If LEDs are the 'new' point sources that replace incandescent lamps and perhaps CFLs, then OLEDs are the 'new' diffuse sources that some say will replace liner fluorescent lamps.

Since their discovery by Röntgen in 1895, X-rays have been used in a wide variety of applications ranging from medical and industrial radiography to crystallographic studies of the structure of biomolecules. The short wavelength ($\lambda \sim 0.1$ nm) and high penetrating power of hard X-rays makes them an ideal probe of the internal structure and composition of condensed matter. Indeed, Watson and Crick's elucidation of the double helix structure of DNA in the early 1950s, based on the X-ray diffraction patterns of Rosalind Franklin, has revolutionized biology and provided an atomistic view of the stuff of life.

The quest for ever higher spatial resolution, and the desire to obtain high-quality X-ray data on shorter time-scales, have both been prime motivations for the development of high intensity hard X-ray sources since the mid-1970s. This evolutionary trend has led to the design and construction of large synchrotron radiation facilities, serving many thousands of users and enabling forefront experimental studies across a broad range of disciplines. One such example of a national facility, dedicated to high-brightness X-ray synchrotron radiation, is the Advanced Photon Source (APS), located at Argonne National Laboratory in the United States (**Figure 1**). Facilities of a similar scope and purpose have also been constructed in Europe and Japan, and a number of new high brightness sources are currently under construction in several countries around the world (see **Table 1**).

Table 1 Third-generation synchrotron radiation sources

Location	*Facility*	*Electron energy (GeV)*
Grenoble, France	European Synchrotron Radiation Facility (ESRF)	6
Argonne, Illinois, USA	Advanced Photon Source (APS)	7
Nishi Harima, Japan	8-GeV Super Photon Ring (SPring-8)	8
Berkeley, CA, USA	Advanced Light Source (ALS)	1.5–1.9
Canberra, Australia	Boomerang[a]	3
Didcot, UK	DIAMOND[a]	3
Orsay, France	SOLEIL (LURE)	2.75
Karlsruhe, Germany	Angströmquelle-Karlsruhe (ANKA)	2.5
Hamburg, Germany	PETRA III[b]	6
Indore, India	INDUS II[a]	2.5
Villigen, Switzerland	Swiss Light Source (SLS)	2.4
Saskatoon, Canada	Canadian Light Source[a]	2.9
Stanford, CA, USA	SPEARS	3
Upton, New York, USA	NSLS II[b]	2.5–2.8
Trieste, Italy	Elettra	2.0–2.4

[a]Under construction as of March 2004.
[b]Planning stage.

In this article we will draw on examples from APS to illustrate the characteristics and performance of the current generation of synchrotron sources in the hard X-ray region.

From the earliest days of particle physics studies in the 1930s and 40s, it was realized that copious amounts of X-rays could be produced by accelerating charged particles in a curved trajectory, as in a cyclotron or a synchrotron. For particle physics such radiation is highly detrimental because it limits the ultimate energy of particle accelerators and forces their circumference to become inordinately large in order to reduce radiation losses.

Originally considered to be a major source of concern in particle accelerator design, synchrotron radiation soon began to emerge as a boon to X-ray science. This came about in the early 1970s after the capability was developed to produce and store significant circulating currents of high-energy charged particles (electrons or positrons) for colliding beam experiments. At that time X-ray scientists were tolerated as 'parasitic' experimenters at such storage rings, taking X-ray radiation from the bending magnets which maintained the stored current in an overall circular trajectory. The PETRA (Positron–Electron Tandem Ring Accelerator) facility at HASYLAB/DESY in Hamburg, Germany, and the Cornell Electron Storage Ring (CESR)/Cornell High-Energy Synchrotron Source (CHESS) at Cornell University, Ithaca, New York, are examples of accelerator facilities that were primarily intended for particle physics experiments and then became partly dedicated to X-ray production. Such shared synchrotron facilities are referred to as 'first-generation sources'.

The first generation sources demonstrated several attractive features of synchrotron radiation, including a high degree of collimation in the vertical direction with a divergence half-angle given approximately by the relativistic factor $\gamma^{-1} = m_0c^2/E$, where m_0c^2 is the rest-mass energy (0.51 MeV) of the electron (or positron) and E is the energy of the stored particle beam. For a bending magnet source with $E = 2-3$ GeV the beam would have a vertical collimation of ~ 0.3 mrad (17 mdeg). This would produce an X-ray beam with a vertical extent of ~ 3 mm at a distance of 10 m from the bending magnet source. The horizontal fan of bend magnet radiation is broad and is usually limited by a mask or a slit to a few mrad. The most useful characteristic of bend magnet radiation is its large bandwidth whereby the X-ray spectrum is continuous and increasing in intensity (see **Figure 2**) until some critical energy above which the intensity begins to fall off. Bending magnet radiation is therefore useful for X-ray measurements requiring a 'white' beam, for example, Laue X-ray diffraction, energy dispersive diffraction, and Extended X-ray Absorption Fine Structure (EXAFS) analysis.

Beginning in the 1980s, several second-generation storage rings were constructed in various locations around the world. The design of these facilities for the first time was optimized for the production of bright beams of X-ray and XUV (soft X-ray to ultraviolet) and their operation was dedicated exclusively to synchrotron radiation science. The increase in brightness provided by these new storage ring sources, compared to standard laboratory X-ray sources (e.g., rotating anode generators), was dramatic (5 or 6 orders of magnitude) and this opened up many new experiments that were not previously feasible. However, it was soon realized that the capabilities of such sources could be extended to

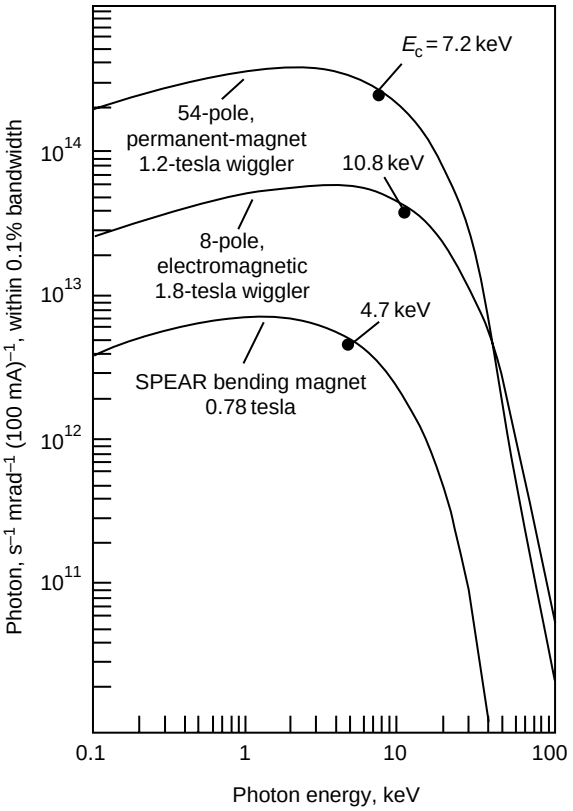

Figure 2 Comparison of bending magnet and wiggler sources. With permission from Stanford Synchrotron Radiation Laboratory, Stanford Linear Accelerator Center, Menlo Park, CA.

even higher levels of intensity and to significantly higher X-ray energies.

One of the limitations of bending magnet sources relates to the X-ray critical energy alluded to above:

$$E_c = 3hc\gamma^3/4\pi\rho \qquad [1]$$

where ρ is the radius of curvature imposed on the particle beam trajectory by the bending magnet. For a given particle acceleration energy, E, eqn [1] leads to a critical X-ray energy given by:

$$E_c\,(\text{keV}) = 2.2\,E^3\,(\text{GeV})/\rho\,(\text{m}) \qquad [2]$$

For a typical second-generation machine with $E = 2.5$ GeV and $\rho = 7$ m (limited by the magnetic field generated by the dipole electromagnet), the critical energy is only about 5 keV. There is useable flux well above this energy, but X-ray photons become scarce in the energy range above 10 keV for a bending magnet source with these characteristics. Since E is effectively fixed by the design parameters of the storage ring, the only possibility to achieve higher photon energies is to install additional magnetic devices which will introduce perturbations of the trajectory with effectively smaller radius of curvature in the denominator of eqn [2]. Such a device, known as a 'wiggler', shifts the effective critical X-ray energy to higher values in proportion to the strength of the magnetic field B (see Figure 2). Using wigglers based on superconducting magnets ($B \sim 5$ Tesla), E_c can be raised to >20 keV, a value which would require accelerator energies of more than 6 GeV using conventional bending magnets alone. In addition to shifting the output spectrum to higher energies, it is possible to enhance the intensity at a given energy by producing multiple wiggles with no net displacement of the particle trajectory. Multipole wigglers are able to produce significant increases in flux in the hard X-ray range. The 27-pole hybrid wiggler installed on beamline X25 at the National Synchrotron Light Source, a second generation facility at Brookhaven National Laboratory, Upton, New York, is one of the most successful designs of its kind, providing $\sim 6 \times 10^{14}$ photons/sec per 1% bandwidth at 8 keV. When focused with a toroidal X-ray mirror, this beam is about an order of magnitude brighter than the standard bending magnet sources at NSLS. For reasons that will become clear later in this article, the radiation from multiple wiggles in such a device adds incoherently.

Insertion Devices

The idea of using wigglers to enhance the characteristics of synchrotron radiation sources has led to the design and construction of storage rings with many straight sections to accommodate wigglers and other types of 'insertion devices'. Such facilities are referred to as third-generation sources. Coming on-line in the mid-1990s, several such sources are now in mature operation and are supporting a large international community of X-ray scientists.

One of the most important types of insertion device to emerge from the development of third-generation facilities is the undulator. Conceptually, the idea behind an undulator is similar to that of the wiggler, i.e., it provides additional tightly curved transverse displacements in the particle beam. There are two important differences: in an undulator the displacements are smaller and they are more numerous, being produced by a linear periodic array of many short alternating dipoles (Figure 3). Under these conditions the synchrotron radiation emitted from each 'undulation' of the particle beam trajectory adds coherently and therefore the peak intensity from such a device can be enhanced by a factor of N^2 where N is the number of dipole magnet pairs, or periods.

A simple theoretical description of the basic operation of an undulator can be discussed in terms of radiation from a charged particle moving at

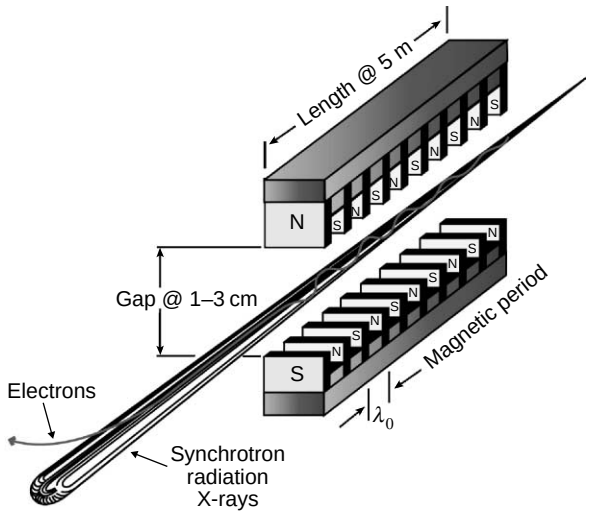

Figure 3 Schematic of undulator. Courtesy of Advanced Photon Source.

relativistic speeds through an alternating magnetic field. The magnetic field in the vertical direction (y) is taken to be periodic:

$$B_y = B_0 \sin[(2\pi/\lambda_u)z] \qquad [3]$$

where z is in the direction of average particle motion.

The transverse particle trajectory is described by:

$$x = (\lambda_u \phi_{max}/2\pi) \sin[(2\pi/\lambda_u)z] \qquad [4]$$

where λ_u is the magnet period, and ϕ_{max} is the maximum particle deflection angle:

$$\phi_{max} = (eB_0\lambda_u c)/2\pi m_0 c^2 \gamma = K/\gamma \qquad [5]$$

where

$$K = 93.4B_0 \text{ (Tesla)}\lambda_u \text{ (meters)} \qquad [6]$$

The field strength parameter K serves as a useful quantity for discussing the characteristics of various insertion device designs. For $K \leq 1$, which defines the undulator regime, the transverse angular deflections are less than or on the order of the angular spread of the emitted radiation and in this case the radiation from each of the deflections adds coherently. This is distinguished from the case of a multipole wiggler where $K \gg 1$ leading to incoherent superposition.

Most of the interesting features of undulator radiation are revealed by considering the trajectory of the particle in a Lorentz frame moving at speed v^* with respect to the laboratory frame. In this frame the particle will execute oscillatory motion with the period of oscillations T' given by the Lorentz transformation:

$$T' = \gamma^*(T - \beta^*\lambda_u/c) = \lambda_u/(v^*\gamma^*) \qquad [7]$$

with a corresponding oscillation frequency $\omega' = 2\pi/T' = (2\pi c/\lambda_u)\gamma^*$.

For $K \ll 1$, the motion in the co-moving frame is purely transverse and nonrelativistic. However, for $K \sim 1$, the oscillatory motion in this frame can have a longitudinal component and in this case the transverse motion becomes nonharmonic with frequency components at odd multiples of the fundamental frequency ω'. This nonharmonic motion is a consequence of the fact that in the laboratory frame the particle is moving with constant speed $\approx c$ but its path length is slightly longer than λ_u, owing to the transverse motion. This constrains the motion in the co-moving frame to be nonharmonic.

Undulator Spectrum

It now remains to transform ω' into the laboratory frame so that we can obtain the spectral distribution of the output of the undulator. Invoking the Doppler transformation:

$$\omega = \gamma^*\omega'(1 + \beta^* \cos\theta') \qquad [8a]$$

$$\tan\theta = (\sin\theta')/[\gamma^*(\cos\theta' + \beta^*)] \qquad [8b]$$

where θ is the angle at which the radiation is observed:

$$\omega_n(\theta) = (4\pi cn\gamma^2)/(\lambda_u[1 + \tfrac{1}{2}K^2 + (\gamma\theta)^2]) \qquad [9a]$$

or in terms of wavelength:

$$\lambda_n(\theta) = (\lambda_u/2n\gamma^2)[1 + \tfrac{1}{2}K^2 + (\gamma\theta)^2] \qquad [9b]$$

Equation [9] is the central expression describing the spectral output of an undulator. Notice how the macroscopic period of the undulator λ_u is transformed into a microscopic wavelength $\lambda_n(\theta)$ by the relativistic factor γ^2. For third-generation hard X-ray sources with particle energies in the 6–8 GeV range, $\gamma \sim 14\,000$, taking cm scales down to the angstrom level.

Equation [9] describes a spectrum of monochromatic peaks, for on-axis radiation ($\theta = 0$), with wavelengths that increase with increasing K. Since $K \sim B_0\lambda_u$ (eqn [6]) any particular harmonic can be tuned either by changing B_0 or λ_u. In most undulator designs, λ_u is fixed by the construction of the permanent magnet array, so the tuning is conveniently accomplished by varying B_0. In practice this is done by changing the vertical distance between the poles

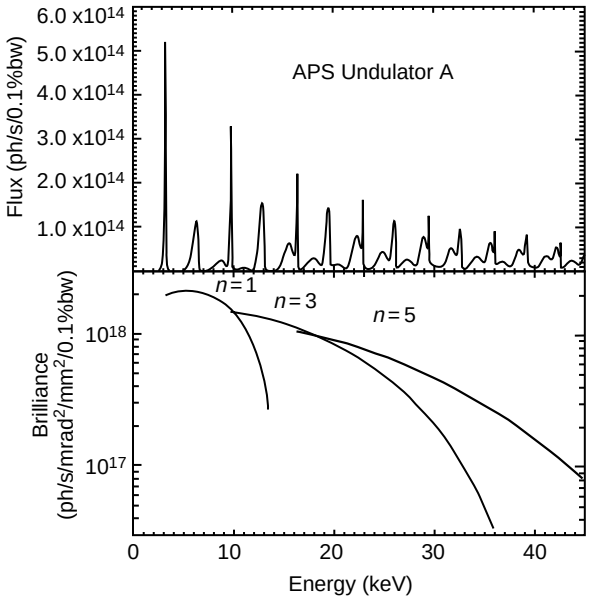

Figure 4 Undulator spectrum (upper panel) and tuning range for first, third and fifth harmonics (lower panel) of Advanced Photon Source Undulator A.

of the magnets (the 'undulator gap') similar to opening the jaws of a vise. Typical tuning ranges for the $n = 1$, 3, and 5 harmonics are illustrated in Figure 4.

Since the number of undulator oscillations of the particle beam is finite, the nth harmonic is not strictly monochromatic and has a spectral broadening of order $1/nN$, where N is the number of oscillator periods. In practice with N typically ~ 100, a bandwidth of $\sim 1\%$ is expected for the first harmonic. Additional broadening of a similar magnitude might also be expected from the θ-dependence in eqn [9], depending on the acceptance angle of the optics that is used in a particular experiment. This quasi-monochromatic radiation is sometimes referred to as 'pink beam'.

The storage ring energy of the APS was carefully chosen so that the tuning ranges of the different harmonics would overlap in energy, thus providing a continuous tuning of the X-ray energy over a wide range (Figure 4). Note also that the discrete spectral characteristics of the undulator can be deliberately smeared out to mimic the broadband (white beam) characteristics of a bend magnet (with consequent reduction in brightness). This is done simply by tilting the jaws of the undulator with respect to each other so that B_0 is made to vary along the length of the undulator. The ability to taper the undulator in this way is a standard feature of most designs.

The radiation from an undulator is sharply peaked in the forward direction in both the vertical and horizontal directions. The half-angle of the emission cone is given by:

$$\theta_{1/2} = (1/\gamma)[(1 + \tfrac{1}{2}K^2)/2Nn]^{1/2} = [\lambda_n/L]^{1/2} \qquad [10]$$

where L is length of the undulator. For a typical third-generation source undulator, such as the Type A undulator at the Advanced Photon Source, $L = 2.4$ m, giving $\theta_{1/2} \approx 6$ μrad for the first harmonic tuned to 12 keV. This corresponds to an X-ray beam size of ~ 180 μm at a distance 30 m from the source.

The very tight collimation of undulator radiation (eqn [10]) highlights the importance of distinguishing between the brightness and the 'brilliance' of the beam. The latter term takes into account the natural collimation of the beam, as reflected in its units of photons/sec/mm^2/mrad^2/0.1% bandwidth. Undulator radiation is well matched to the acceptance angle of ideal crystal monochromators and is $\sim 10\,000$ times more brilliant than the radiation from a bend magnet source. The high brilliance of undulator X-ray beams is extremely advantageous in X-ray imaging applications, X-ray microprobe measurements, and in experiments where the sample size is very small (e.g., high-pressure diamond anvil cell measurements).

In practice the emission cone of the source might be broadened a little when the undulator characteristics are convolved with those of the storage ring. The largest effect is in the horizontal direction where the photon beam divergence is dominated by the electron beam divergence. This is a consequence of the particular conditions under which the storage ring is operated in order to stabilize the particle beam orbit.

Equation [10] demonstrates that preserving the exquisite performance capabilities of an undulator insertion device places severe demands on the stability and precision of the storage ring orbit. An important measure of this precision is characterized by the 'emittance' of the particle beam defined in terms of the area of phase space (position and angular divergence) occupied by the stored beam. In general, storage rings are designed to achieve very low emittances and in current third-generation sources they are close to being diffraction limited. Table 2 summarizes the characteristics of the APS storage ring operated in 'high-emittance' and 'low-emittance' modes.

The large power densities resulting from the extreme brightness of undulator sources (up to 160 kW/mrad^2 for APS Undulator A) necessitates careful design of the X-ray optical components that are used to condition the beam. For example, if a double-bounce Silicon crystal pair is used as the first optical component to monochromatize the undulator

Table 2 Advanced photon source storage ring parameters

Parameter	*Low emittance*	*High emittance*
Storage ring energy, E	7.0 GeV	7.0 GeV
Storage ring current, I	100 mA	100 mA
Beam energy spread, $\delta E/E$	0.096%	0.096%
Horizontal emittance, ε_x	3.5×10^{-9} m-rad	7.7×10^{-9} m-rad
Vertical emittance, ε_y	3.5×10^{-11} m-rad	7.7×10^{-11} m-rad
Coupling constant	1%	1%
Horizontal beta function, β_x	14.4 m	16.1 m
Vertical beta function, β_y	4.0 m	4.3 m
Dispersion function, η_x	0.124 m	0.0 m
Horizontal beam size, σ_x	254 μm	351 μm
Vertical beam size, σ_y	12 μm	18 μm
Horizontal beam divergence, $\sigma_{x'}$	15.6 μrad	21.8 μrad
Vertical beam divergence, $\sigma_{y'}$	3.0 μrad	4.2 μrad

beam, the first crystal is normally cooled with liquid nitrogen to dissipate the heat. Alternately, high thermal conductivity diamond crystals are sometimes used as monochromators.

Helical Undulators

The use of undulators to produce extremely bright, tunable X-ray beams has enabled many new applications of X-ray science, as well as offering significant improvements to existing techniques in terms of quality of data and the time required to accumulate a high degree of statistical accuracy. One of the areas that has benefited significantly from novel undulator design is research on magnetic materials and other spin-dependent phenomena. It is often advantageous to probe such systems with circularly polarized X-rays, for example to study magnetic X-ray circular dichroism (MXCD). Early MXCD measurements utilized the left and right elliptical polarization of bending magnet radiation above and below the plane of the ring. Such measurements are difficult because the intensity falls off dramatically out of the plane. The problem to produce high-brightness beams of circularly polarized X-rays is effectively solved by designing an undulator which produces a transverse periodic helical magnetic field of constant magnitude. Several helical undulators are now in operation at third-generation sources. The soft X-ray region (500–1500 eV) is particularly interesting because it covers the L-edges of the 3d transition elements.

Coherence

While this article describes what would be nominally considered as 'incoherent' sources in the parlance of conventional optics, it should be pointed out that undulators are in fact excellent sources of coherent X-rays. This is by virtue of the high degree of collimation inherent in the emission of radiation from the undulations of a highly relativistic charged particle (eqn [10]). The spatial (transverse) coherence angle is given by:

$$\lambda_n/2d \qquad [11]$$

where d is the source size. This is the angle within which the beam is spatially coherent.

For APS undulator A, the source size is ~15 μm (vertical) × 240 μm (horizontal), giving a coherence angle in the vertical direction of 6.5 μrad and 0.4 μrad in the horizontal direction. The X-ray beam divergence is approximately 4 μrad (vertical) by 15 μrad (horizontal). This means that the beam has complete spatial coherence in the vertical direction and is coherent over about 3% of the horizontal fan. At a distance of 30 m from the source, an on-axis pinhole of ~12 micron diameter will be completely illuminated by coherent X-rays. Transversely coherent X-ray beams are finding novel applications in X-ray photon correlation spectroscopy, coherent X-ray scattering, and phase reconstruction (lensless) imaging.

Timing Structure

X-ray storage rings produce pulsed X-rays. In the Advanced Photon Source, one or more long trains of electron bunches (15 ns long) are accelerated by the linac to 325 MeV. The electron bunches are injected into a booster that ramps the single bunch from 325 MeV to 7 GeV in about 225 ms. At the end of the booster cycle, the bunch is extracted and injected into the storage ring. The bunch can be injected into any of 1296 'buckets' that are spaced by 2.842 ns, forming any arbitrary pattern after several injection cycles.

The APS storage ring rf frequency of 351.927 MHz determines the bucket spacing of 2.842 ns. The circumference of 1104 m gives a revolution frequency of 271.5 kHz which allows for 1296 buckets in 3683 ns. The storage ring is filled with a selected bunch pattern depending on the requirements for a particular operations cycle. The standard 'singlets' bunch pattern at APS is 102 mA of average current in a train of 23 bunches (4.43 mA per bunch) each spaced by 153 ns (54 buckets). There is a gap of 306 ns (108 buckets) in this pattern, useful as

a timing guide. The singlets pattern has a lower lifetime than patterns with less charge per bunch, due to natural internal scattering processes. A 'top-up' mode has been devised to overcome the problem of overall intensity fall-off due to the exponential decay of the stored current. In top-up mode, new bunches are injected into the storage ring every few minutes to maintain the stored current at 102 mA.

A second fill pattern, known as the 'hybrid' pattern, is again 102 mA but distributed in one bunch of 5 mA, plus 8 groups of 7 consecutive bunches (1.73 mA/bunch), spaced by 68 ns (24 buckets). The 8 groups are diametrically opposite the 5 mA bunch, allowing for a 1.5 μs gap on both sides of the 5 mA bunch. This hybrid mode permits a single bunch to be isolated using a mechanical chopper or a fast framing camera. Since the RMS width of the single bunch is ~36 ps, relatively fast time-resolved experiments can be performed stroboscopically using this pulsed X-ray beam. In another implementation of time-resolved experiments, the singlet pattern is used, isolating each bunch with a fast avalanche photodiode detector, or an X-ray streak camera. With the streak camera it is possible to achieve time resolutions of a few picoseconds. This approach has been used to study impulsive phonon excitations and ultrafast strain wave propagation in solids.

The Future

This article highlights current (third-generation) storage ring sources based on undulator-type insertion devices. These sources will provide high-brightness tunable X-rays in support of a wide range of experiments for many years to come. The brightness of these sources will increase steadily into the future as continual improvements are made, such as further reducing the emittance of the particle beam, improved undulator design, increasing the average storage ring current, and making changes to the storage ring lattice. These incremental improvements will be important to maintain the vitality and usefulness of national user facilities based on third-generation sources. New storage ring sources with designs and specifications optimized for low emittance and new types of undulators (e.g., in-vacuum undulators) will come online and will undoubtedly lead to new technical advances, supporting new and exciting science. It seems likely that linear accelerator (linac) based undulator sources will provide a promising route towards higher brilliance in the future. The superconducting Energy Recovery Linac (ERL) proposed by CHESS is an interesting concept which uses regeneration of the electron beam to overcome the high energy cost of single pass particle acceleration.

A new generation of X-ray sources (the 'fourth generation') is envisioned to take on the task of providing vastly brighter beams (>10 orders more peak brilliance than at present, see Figure 5) with much shorter pulses (~100 fs). These facilities will also be based on linear accelerators. Two such *Free Electron Laser* sources are currently being designed and should be operational towards 2010: the Linac Coherent Light Source (LCLS), to be built at the Stanford Linear Accelerator Center (SLAC), and the X-ray Free Electron Laser (XFEL) Source, to be constructed by the TESLA collaboration at HASYLAB, Hamburg.

Introduction

The ever-increasing aggregate demand of electrically based time division multiplexing systems should have coped with the steady growth rate of voice traffic. However, since 1990, the explosive growth of the Internet and other bandwidth-demanding multimedia applications, has meant that long-haul telecommunication traffic has been increasingly dominated by data, not voice traffic. Such systems suffer from a bandwidth bottleneck due to speed limitations of the electronics. This limits the maximum data rate to considerably less than the THz bandwidth offered by an optical fiber. Optical technology is proposed as the only viable option and is expected to play an ever increasing role in future ultrahigh-speed links/networks. There are a number of multiplexing techniques, such as space division multiplexing (SDM), wavelength division multiplexing (WDM), and optical time division multiplexing (OTDM), that are currently being applied to effectively utilize the bandwidth of optical fiber as a means to overcome the bandwidth bottleneck imposed by electrical time division multiplexing (TDM). In SDM a separate optical fiber is allocated to each channel, but this is the least preferred option for increasing channel numbers. In WDM, a number of different data channels are allocated to discrete optical wavelengths for transmission over a single fiber. Dense WDM technology has been improving at a steady rate in recent years, with the latest systems capable of operating at a data rate of >1 T bps, using a large number of wavelengths over a single fiber link. However, there are a number of problems associated with the WDM systems such as:

- Performance of WDM is highly dependent on the nonlinearities associated with fiber, i.e.:
  - *Stimulated Raman scattering*: degrades the signal-to-noise (SNR) as the number of channels increases;
  - *Four-wave mixing*: limits the channel spacing;
  - *Cross-phase modulation*: limits the number of channels.
- Relatively static optical paths, thus offering no fast switching with high performance within the network;

- Switching is normally carried out by separating each wavelength of each fiber onto different physical outputs. Space switches are then used to spatially switch the separated wavelengths, an extremely inefficient way of utilizing network resources;
- The need for amplifiers with high gain and flat spectra.

In order to overcome these problems, OTDM was introduced that offers the following:

- Flexible high bandwidth on demand (>1 Tbit/s compared to the bit rates of 2.5–40 Gbit/s per wavelength channel in WDM systems);
- The total bandwidth offered by a single channel network is equal to DWDM;
- In a network environment, OTDM provides potential improvements in:
  - Network user access time, delay and throughput, depending on the user rates and statistics.
  - Less complex end node equipment (single-channel versus multichannels).
- Self-routing and self-clocking characteristics;
- Can operate at second- and third-transmission windows:
  - 1500 nm (like WDM) due to Erbium doped fiber amplifier (EDFA);
  - 1300 nm wavelengths.
- Offers both broadcast and switched based networks.

Principle of OTDM

Figure 1 show the generic block diagram of a point-to-point OTDM transmission link, where N optical data channels, each of capacity M Gbps, are multiplexed to give an aggregate rate of $N \times M$ Gbps. The fundamental components are a pulsed light source, an optical modulator, a multiplexer, channel, add/drop unit, and a demultiplexer. The light source needs to have good stabilities and be capable of generating ultrashort pulses (<1 ps). Direct modulation of the laser source is possible but the preferred method is based on external modulation where the optical signal is gated by the electronic data. The combination of these techniques allows the time division multiplexed data to be encoded inside a subnanosecond time slot, which is subsequently interleaved into a frame format. Add/drop units provide added versatility (see Figure 2) allowing the 'adding' and 'dropping' of selected OTDM channels to interchange data at chosen points on the link. At the receiving end, the OTDM pulse stream is demultiplexed down to the individual channels at the initial M Gbps data rate. Data retrieval is then within the realm of electronic devices and the distinction between electronic and optical methods is no longer relevant. Demultiplexing requires high-speed all optical switching and can be achieved using a number of methods, which will be discussed in more detail below.

The optical multiplexing (or interleaving) can be carried out at the bit level (known as bit interleaving) or at the packet level (known as packet interleaving), where blocks of bits are interleaved sequentially. This is in accord with the popular conception of packet switched networks. The high data rates required and consequently narrow time slots necessitate the need for strict tolerances at processing nodes, e.g., switches. As such, it is important that the duration

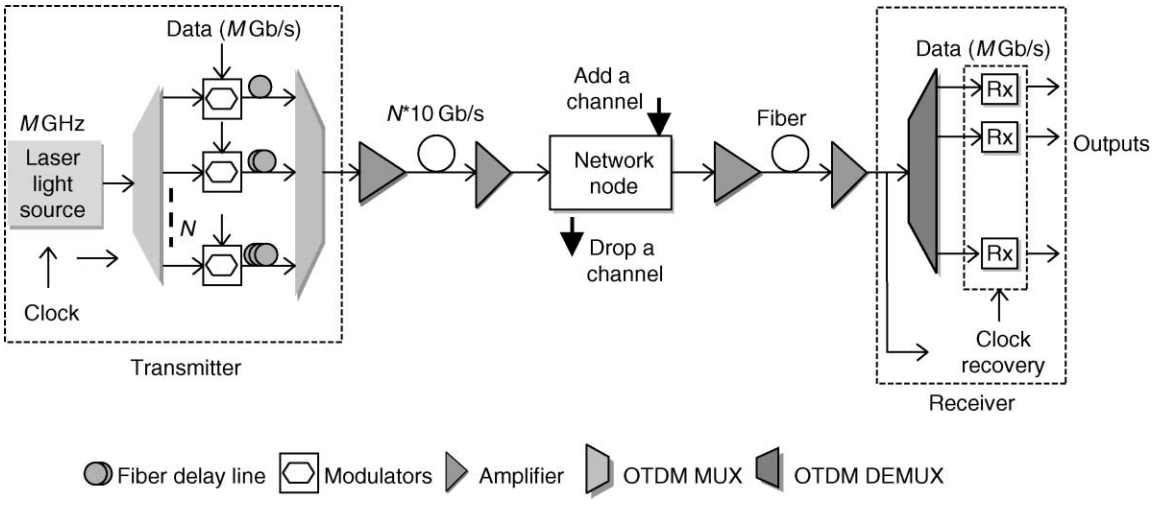

Figure 1 Block diagram of a typical OTDM transmission system.

of the optical pulses is chosen to be significantly shorter than the bit period of the highest multiplexed line rate, in order to reduce the crosstalk between channels.

Bit Interleaved OTDM

A simple conceptual description of a bit interleaved multiplexer is shown in Figure 3. It uses a number of different length optical fiber delay lines (FDL) to interleave the channels. The propagation delay of each FDL is chosen to position the optical channel in its corresponding time slot in relation to the aggregate OTDM signal. Prior to this, each optical pulse train is modulated by the data stream. The output of the modulators and an undelayed pulse train, labeled the framing signal, are combined, using a star coupler or combiner, to produce the high bit rate OTDM signal (see Figure 3b). As shown in Figure 3b, the framing pulse has a higher intensity for clock recovery purpose. At the demultiplexer, the incoming OTDM pulse train is split into two paths (see Figure 4a). The lower path is used to recover the framing pulse by means of thresholding, this is then delayed by an amount corresponding to the position of the *i*th (wanted) channel (see Figure 4b). The delayed framing pulse and the OTDM pulse stream are then passed through an AND gate to recover the *i*th channel. The AND operation can be carried out all optically using, for example, a nonlinear loop mirror, a terahertz optical asymmetric demultiplexer, or a soliton-trapping gate.

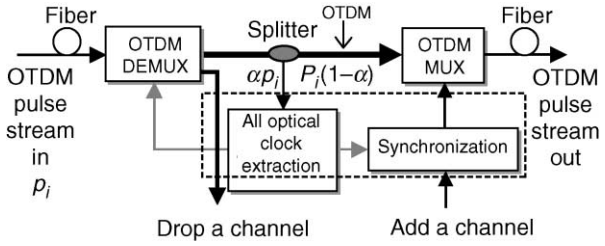

Figure 2 Add/drop unit in an OTDM network node.

Packet Interleaved OTDM

Figure 5a shows the block diagram of a system used to demonstrate packet interleaving. Note that the time interval between successive pulses now needs to be much less than the bit interval T. This is achieved by passing the low bit rate output packet of the modulator into a compressor, which is based on a feed forward delay line structure. The feed forward delay lines are based on a cascade of passive M–Z interferometers with unequal arm lengths. This configuration generates the delay times required, i.e., $T-\tau, 2(T-\tau)\ldots(2^{n-1})(T-\tau)$, etc., where $n = \log_2 k$ is the number of stages, T and τ are the

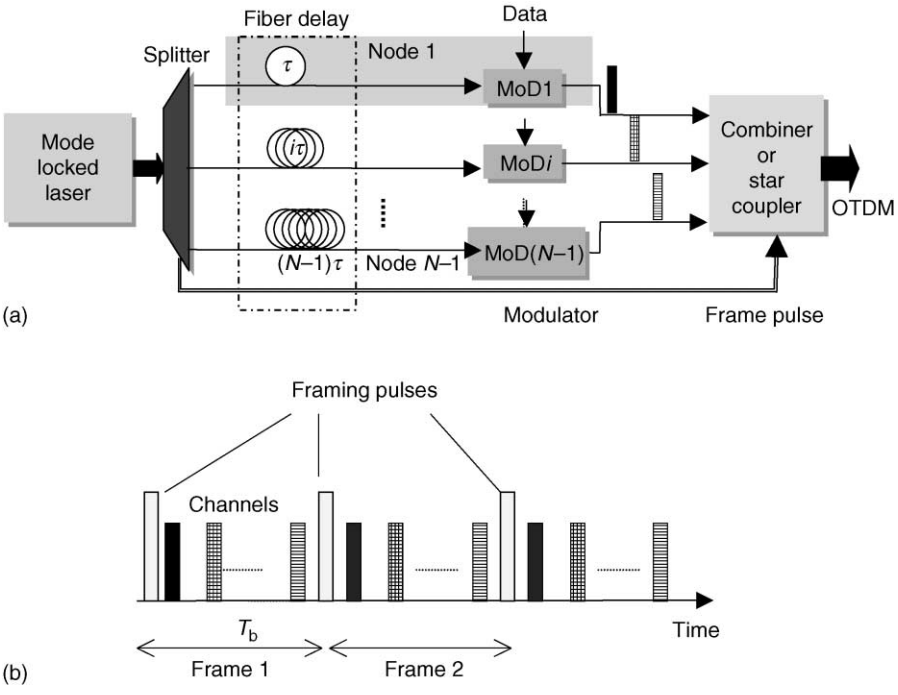

Figure 3 Bit interleaved OTDM; (a) block diagram and (b) timing waveforms.

incoming bit duration and the outgoing bit duration, respectively, and k is the packet length in bits. Pulse i's location at the output is given by $(2^n - 1)(T - t) + (i - 1)\tau$. The signal at the input of the compressor is:

$$I_{\text{in}}(t) = \sum_{i=0}^{k-1} \delta(t - iT)A_i \qquad [1]$$

Where $\delta(\cdot)$ is the optical carrier pulse shape, and A_i is the ith data bit in the packet.

As shown in Figure 5b, each bit is split, delayed, and combined to produce the four bit packets O_i:

$$O_i(t) = \frac{1}{2^{n+1}} \sum_{i=0}^{k-1} I_i[t - i(T - \tau)] \qquad [2]$$

Note the factor of $1/(2^{n-1})$ is due to the signal splitting at the 2×2 3-dB coupler at the input of each stage.

The combined signal is shown in Figure 5b, and is defined as:

$$I_{\text{out}} = \sum_{i=0}^{k-1} O_i = \frac{1}{2^{n+1}} \sum_{i=0}^{k-1} \sum_{j=0}^{k-1} I_i[t - (i+j)T + j\tau]A_i \qquad [3]$$

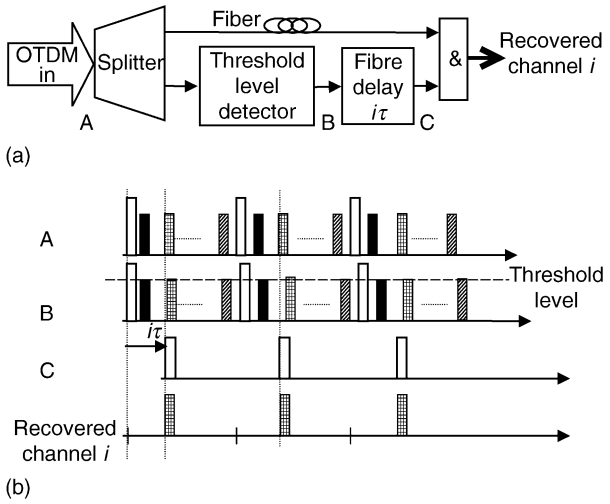

Figure 4 Bit interleaving demultiplexer: (a) block diagram and (b) typical waveforms.

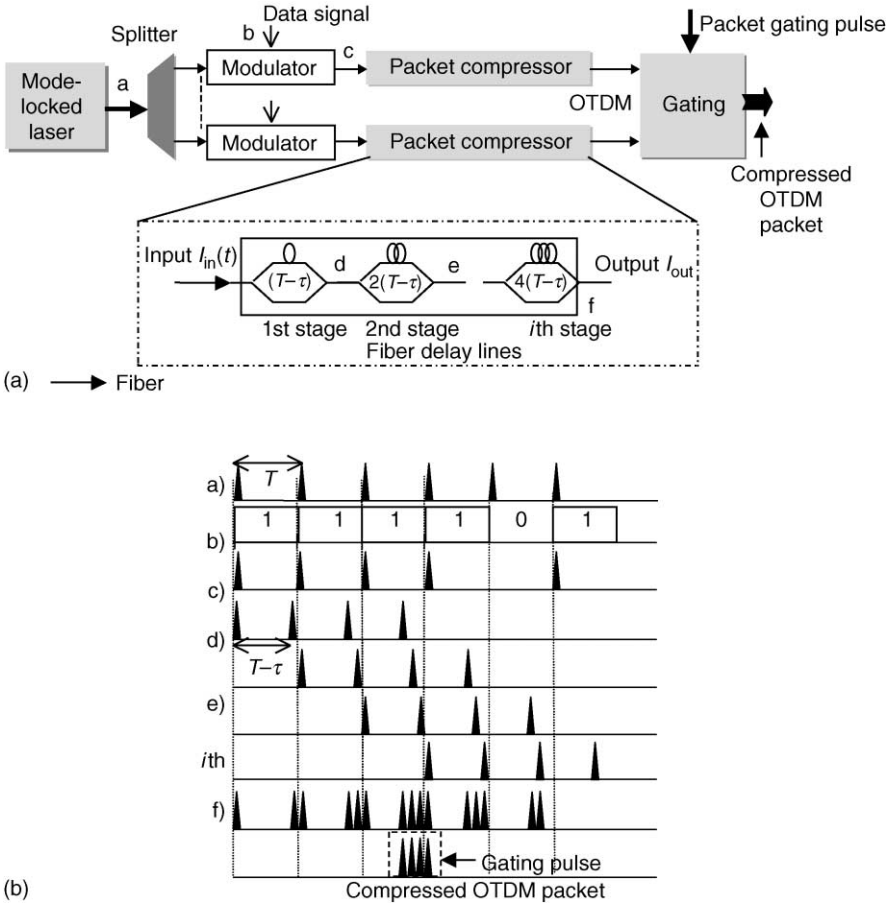

Figure 5 Packet interleaving multiplexer: (a) block diagram and (b) typical waveforms.

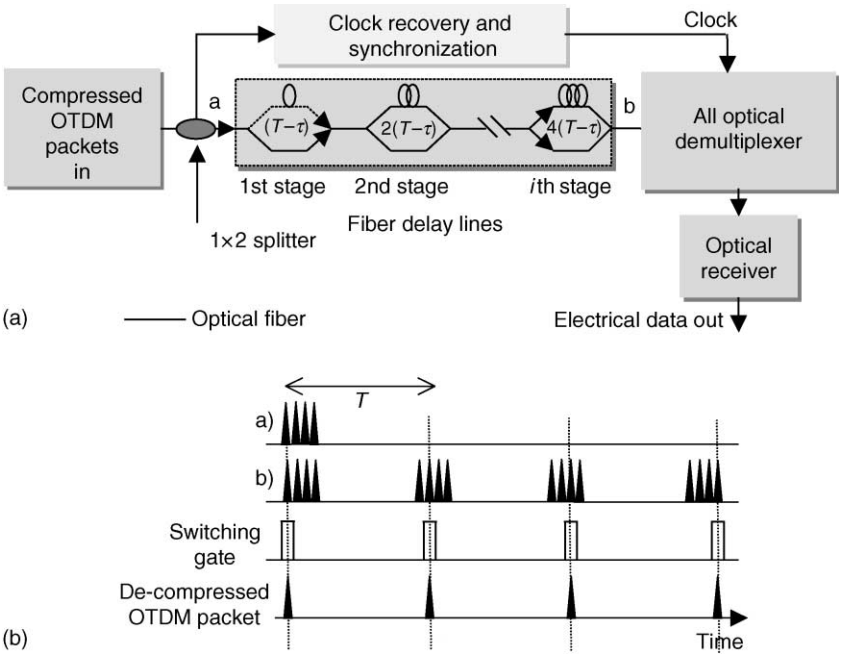

Figure 6 Packet interleaving demultiplexer: (a) block diagram and (b) typical waveforms.

For a packet delay of $(i + j)T$ packets are being built up. For the case $(i+j) = 3$, four bits are compressed into a packet (see Figure 5b). An optical gating device is used to select the only complete usable compressed copy of the incoming packets from the unwanted copies.

At the receiving end, demultiplexing is carried out by decompressing the OTDM packet stream using the same delay line structure (see Figure 6). Multiple copies of the compressed packet are generated, and each is delayed by $(T - \tau)$. An optical demultiplexer placed at the output of the delay lines generates a sequence of switching window at the rate of $1/T$. By positioning the switching pulses at the appropriate position, a series of adjacent packet (channel) bits from each of the copied compressed packets is extracted (see Figure 6b). The output of the demultiplexer is the decompressed packet signal, which can now be processed at a much slower rate using electronic circuitry.

Components of an OTDM System

Optical Sources

In an ultrahigh speed OTDM system, it is essential that the optical sources are capable of generating transform-limited subnanosecond pulses having low duty cycles, tuneability, and a controllable repetition rate for synchronization. A number of suitable light sources are: gain-switch distribute feedback laser (DFB), active mode locked lasers (MLL) (capable of generating repetitive optical pulses), and harmonic mode-locking Erbium-doped fiber (EDF) lasers. Alternative techniques include super-continuum pulse generation in a dispersion shifted fiber with EDF pumping, adiabatic soliton compression using dispersion-flattened dispersion decreasing fiber, and pedestal reduction of compressed pulses using a dispersion-imbalanced nonlinear optical loop mirror. As shown in Figure 1, the laser light source is power split to form the pulse source for each channel. These are subsequently modulated with an electrical data signal (external modulation). External modulation is preferred in an OTDM system as it can achieve narrow carrier linewidth, thus reducing the timing jitter of the transmitted pulse. For ultrahigh bit rate OTDM systems, the optical pulses emerging from the external modulators may also need compressing. One option is to frequency-chirp the pulses and pass them through an anomalous dispersive medium. Using this approach, it is essential that the frequency chirp be linear throughout the duration of the pulse, in addition the midpoint of the linear-frequency chirp should coincide with the center of the pulse. When a frequency-chirped pulse passes through a dispersive medium, different parts of the pulse travel at different speeds, due to a temporal variation of frequency. If the trailing edge travels faster than the leading edge, the result would be pulse compression. An optical fiber cable or a semiconductor laser amplifier (SLA) can be used to create the frequency chirp.

Multiplexers

Multiplexing of the pulses generated by the optical sources can be implemented either passively or actively. The former method is commonly implemented using a mono-mode optical fiber. This method has the advantage of being simple and cost-effective. The latter method uses devices more complex in nature, for example, electro-optic sampling switches, semiconductor optical amplifiers, and integrated optics.

An integrated active multiplexer can be made by integrating semiconductor laser amplifiers (SOA) into a hybrid planar light-wave circuit (PLC). If the optical path length is kept short then temperature control is made easier. An alternative to this approach is to use lithium niobate (LiNb) technology. Periodically poled LiNb (PPLN) based OTDM multiplexers offer compact size and low noise (due to the absence of amplifier spontaneous emission noise and pattern effect, which is a feature of SOA based devices). Figure 7 is a schematic of a PLC-based OTDM multiplexer composed of two PLCs (R and L), composed of 1×8 and 8×1 couplers, eight 2×1 couplers, and eight different path length PPLN waveguides. The input clock pulse is split into eight by the 1×8 coupler in PLC-L, and are combined with the modulated optical pulse trains using the 2×1 couplers. The outputs of the 2×1 couplers are then passed through a PPLN waveguide to generate a return-to-zero (RZ) optically modulated signal. These are then combined, using the 8×1 coupler in PLC-R. When the path-length difference between the waveguides is set to one time slot (equal to 1/8 of the base data rate), then the output of the 8×1 coupler is the required high-bit rate OTDM pulse.

Demultiplexers

In contrast to multiplexing, demultiplexing must be performed as an active function. It can be implemented electro-optically or optically. The former method needs to complete demultiplexing of all channels in order to extract a single channel (see Figure 8). The demultiplexer in Figure 8 uses two LiNb Mach–Zehender (M–Z) modulators in tandem. The first and second modulators are driven with a sinusoidal signal of amplitudes $2V_\pi$ and V_π, respectively, to down-covert the N-bit rate to $N/2$ and $N/4$, respectively. Channels can be selected by changing either the DC-bias V + to the M–Zs, or the electrical phase delay. At ultrahigh speed implementation of an electro-optics demultiplexer becomes increasingly difficult due to the higher drive voltage requirement by the M–Z. An alternative is to use all optical demultiplexing based on the nonlinear effect in a fiber and optical active devices offering switching resolution in the order of picoseconds. There are a number of methods available to implement all optical demultiplexing. The most popular methods that use fast phase modulation of an optical signal are based on M–Z and Sagnac interferometers. Four-wave mixing is another popular method.

Mach–Zehnder (M–Z) Interferometers

The key to interferometric switching is the selection of an appropriate material for the phase modulation. Semiconductor materials, often in the form of an SLA, are suitable devices for this purpose.

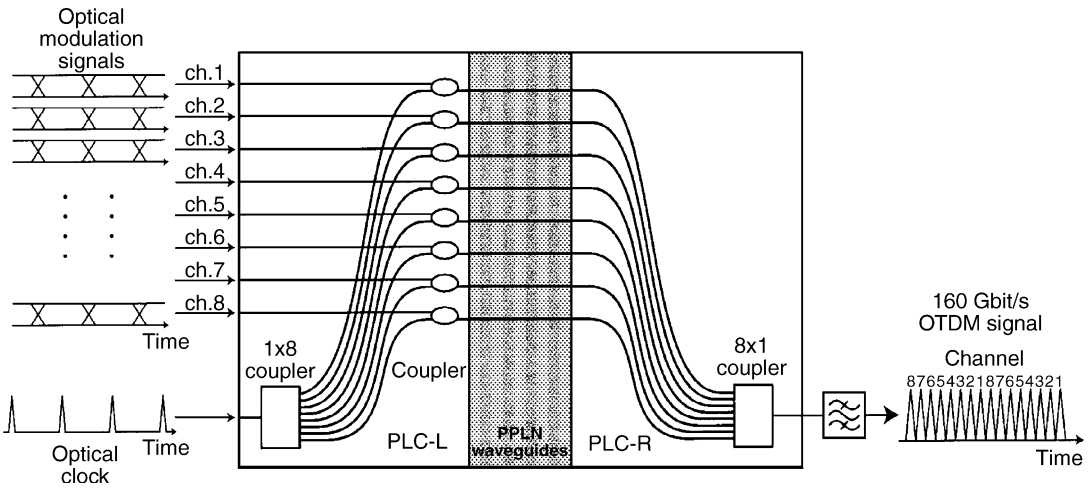

Figure 7 Configuration of a PLC-OTDM-MUX. Reproduced with permission from Ohara T, Takara H and Shake I, *et al.* (2003). 160-Gb/s optica-time-division multiplexing with PPLN hybrid integrated planar lightwave circuit. *IEEE Photonics Letters* 15(2): 302–304. © 2003 IEEE.

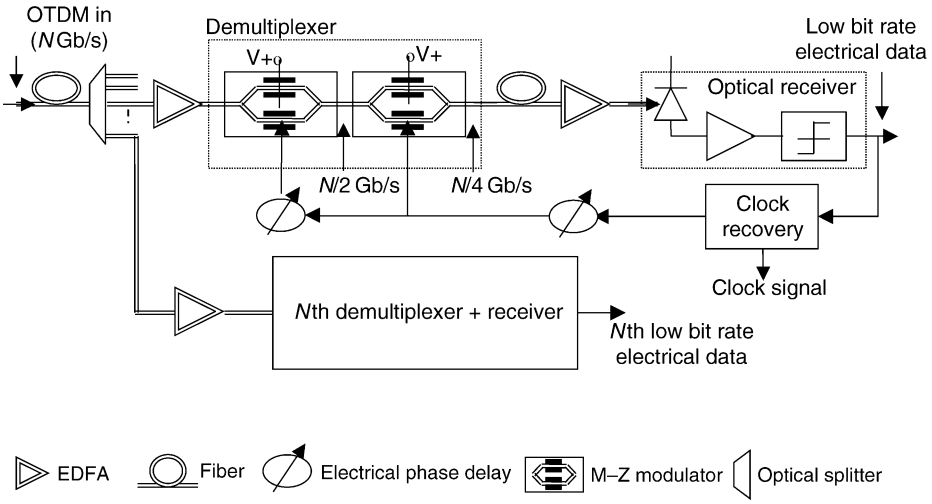

Figure 8 Electro-optics demultiplexer and receiver system block diagram.

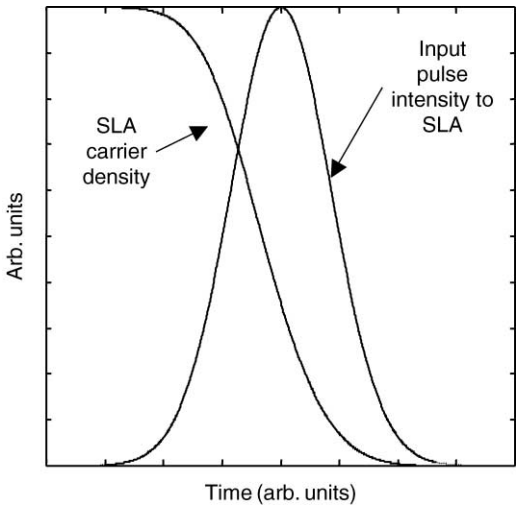

Figure 9 SLA carrier density response to input pulse.

The refractive index of an SLA is a function of the semiconductor carrier density, which can be modulated optically resulting in fast modulation. If a high-intensity pulse is input to an SLA the carrier density changes nonlinearly, as shown in Figure 9. Phase modulation is affected via the material chirp index (dN/dn), which represents the gradient of the refractive index carrier density curve for the material. The phase modulation is quite strong and, in contrast to the intensity-based nonlinearity in an optical fiber, (see Kerr effect below), is a consequence of a resonant interaction between the optical signal and the material. The nonlinearity is relatively long-lived and would be expected to limit the switching speed when using semiconductors. Semiconductors, when in excitation from an optical field, tend to experience the effect quite quickly (ps) with a slow release (hundreds of picoseconds) time. Advantage can be taken of this property by allowing the slow recovery to occur during the time between channels of an OTDM signal, as this time may be of the order of hundreds of pico-seconds or more. A Mach–Zehnder configuration using two SLAs, one in each arm of the interferometer placed asymmetrically, is shown in Figure 10. An optical control pulse entering the device via port 3 initiates the nonlinearity. The transmission equation relating the input signal (port 1) to the output port is given by

$$\frac{I_{\text{out}}(t)}{I_{\text{in}}(t)} = 0.25(G_{\text{SLA1}}(t) + G_{\text{SLA2}}(t) \pm 2\sqrt{G_{\text{SLA1}}(t)G_{\text{SLA2}}(t)}\cos\Delta\phi(t)) \quad [4]$$

where $G_{\text{SLA1}}(t)$ and $G_{\text{SLA2}}(t)$ refer to the gain profiles of the respective SLAs, and $\Delta\phi(t)$ is the time-dependent phase difference between them. Assuming that the gain and phase profiles of an excited amplifier are given by $G(t)$ and $\phi(t)$, respectively, then the signals passing through the upper and lower arms experience optical properties of the material given by:

$$G(t),\ G(t - T_{\text{d}}),\ \phi(t) \text{ and } \phi(t - T_{\text{d}}) \quad [5]$$

where T_{d} is given by $2L_{\text{d}}N_{\text{SLA}}/c$, L_{d} is the distance between SLA1 and SLA2, N_{SLA} is the SLA index, and c is the speed of light in a vacuum. As the width of the $\Delta\phi(t)$ profile is dependent on the distance between the SLAs, placing them in close proximity allows high-resolution switching. Less emphasis has been placed on the SLA gain as this is considered to be less effective when phase differences of π are reached. It only remains for the gain and phase

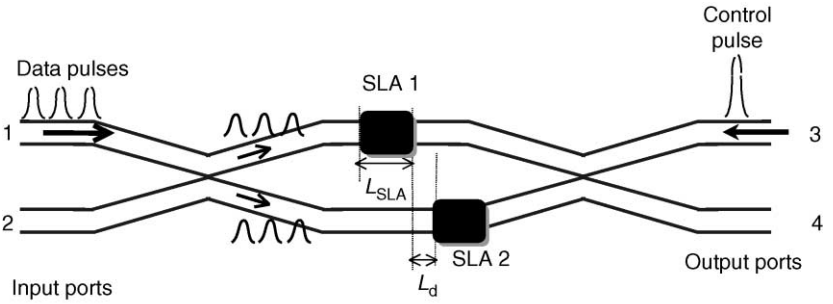

Figure 10 Asymmetric TWSLA Mach–Zehnder devices.

modulation to recover, and as indicated previously, this is allowable over a time-scale commensurate with tributary rates.

Sagnac Interferometers

There are two main types; the nonlinear optical loop mirror (NOLM), and the terahertz optical asymmetric demultiplexer (TOAD).

NOLM

In this method of switching the inherent nonlinearity of an optical fiber known as the Kerr effect is used. The phase velocity of any light beam passing through the fiber will be affected by its own intensity and the intensity of any other beams present. When the intrinsic third-order nonlinearity of silica fibers is considered via the intensity-dependent nonlinear refraction component, then the signal phase shift is

$$\Delta\phi_{\text{signal}} = \frac{2\pi}{\lambda_{\text{ds}}} n_2 L I_{\text{ds}} + 2\frac{2\pi}{\lambda_{\text{ds}}} n_2 L I_{\text{c}} \qquad [6]$$

where n_2 is the Kerr coefficient, I_{ds} is the intensity of the data signal to be switched, I_{c} is the intensity of the control signal used to switch the data signal, λ_{ds} is the data signal wavelength, and L is the fiber length. The optical loop mirror consists of a long length of mono-mode fiber formed into a fiber coupler at its free ends (see Figure 11). The input to the loop comprises the high-frequency data stream plus a control pulse at the frame rate. The data split at the coupler and propagate around the loop in contra directions (clockwise E_{CW} and counter-clockwise E_{CCW}) recombining back at the coupler. In the absence of a control pulse, the pulse exits via port 1. If a particular pulse in the loop (in this example E_{CW}) is straddled by the control pulse (see Figure 12), then that pulse experiences cross-phase modulation, according to the second term on the right-hand side of eqn [6], and undergoes a phase

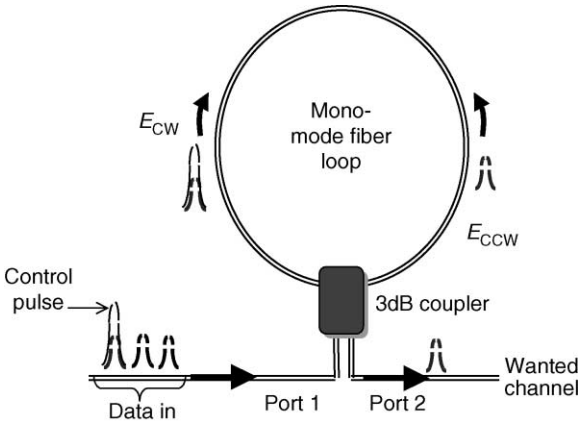

Figure 11 Nonlinear optical loop mirror.

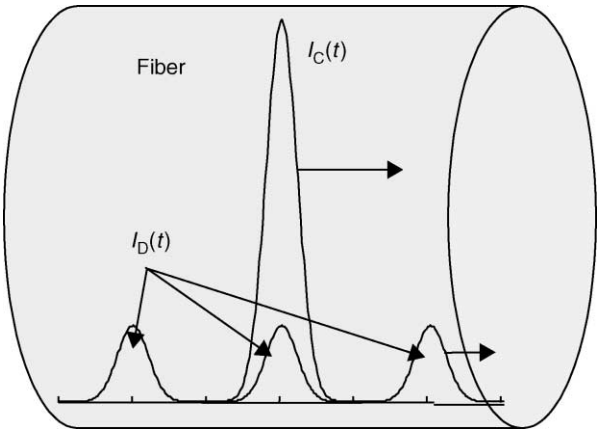

Figure 12 Control and data pulses propagation in the fiber.

change relative to E_{CW}. The difference in the phase between E_{CW} and E_{CCW} causes the pulse to exit via port 2. The phase shift profile experienced by the co-propagating pulse is

$$\Delta\phi(t) = \frac{4\pi}{\lambda_{\text{ds}}} n_2 \int_0^L I_{\text{c}}(t)\, \mathrm{d}x \qquad [7]$$

Assuming unity gain around the loop, the transmittance of the NOLM is

$$T_x = 1 - \cos^2\left(\frac{\Delta\phi}{2}\right) = \Delta\phi(t)$$

$$= 1 - \cos^2\left(\frac{2\pi}{\lambda_{ds}} n_2 \int_0^L I_C(t)\, dx\right) \qquad [8]$$

As it stands, the switching resolution is determined by the width of the control pulse; however, it is possible to allow the signal and control to 'walk off' each other, allowing the window width to be increased by an amount determined by the 'walk off'. The phase shift is now

$$\Delta\phi(t) = 2\frac{2\pi}{\lambda_{ds}} n_2 \int_0^L I_C(t - T_w x)dx \qquad [9]$$

where the parameter T_w, is the walk off time per unit length between control and signal pulses. The increased window width is accompanied by a lower peak transmission (see **Figure 13**).

TOAD

The TOAD uses a loop mirror architecture that incorporates an SLA and only needs a short length of fiber loop (see **Figure 14a**). The SLA carrier density is modulated by a high-intensity control pulse, as in the M–Z-based demultiplexer. The operation of the TOAD is similar to the NOLM, where the loop transmittance is determined by the phase difference between CW and CCW traveling pulses. Strictly speaking, the gain of the SLA must also be taken into account; however, without any loss of generality the effect is adequately described by considering only the phase property. **Figure 14a** shows the timing diagram associated with a TOAD demultiplexer. The control pulse, shown in **Figure 14b(1)**, is incident at the SLA at a time t_1; the phase profiles for the CCW and CCW data pulses are shown in **Figures 14b(2)** and **(3)**, respectively. The resulting transmission window is shown in **Figure 14b(4)**. The window width is given by $t_{asy} = 2\Delta x/c_f$, where Δx is the SLA offset from the loop center and c_f is the speed of light in the fiber. As in NOLM, if the phase difference is of sufficient magnitude, then data can be switched to port 2. The switch definition is, in principle, determined by how close the SLA is placed to the loop center when the asymmetry is relatively large. However, for small asymmetries the switching window is asymmetric, which is due to the CW and CCW gain profiles being different (see **Figure 15**). Assuming the phase modulation dominates the transmission then the normalized transmission for a small asymmetry loop is as depicted in **Figure 16**. The gain response (not shown) would have a similar shape and temporal position as the phase response.

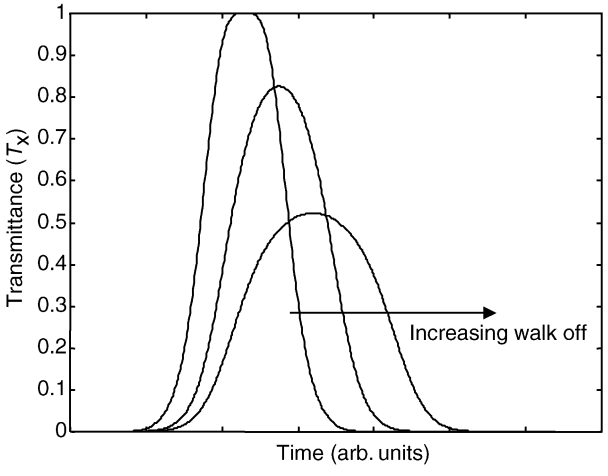

Figure 13 Transmittance profiles with the walk-off time as a parameter.

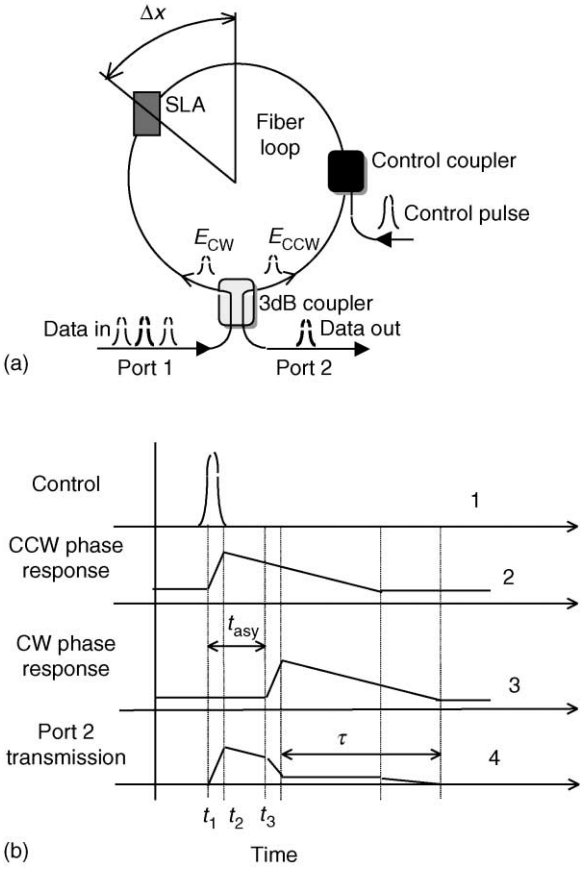

Figure 14 TOAD: (a) architecture and (b) timing diagrams.

Four-Wave Mixing (FWM)

FWM demultiplexing uses a concept whereby two optical signals of different wavelengths are mixed together in a nonlinear medium to produce harmonic components. The nonlinearity in this case arises from the third-order nonlinear susceptibility $\chi^{(3)}$ of an optical fiber, such that the polarization P induced on a pair of electric fields propagating through the fiber is

$$P = \varepsilon_0 \chi^{(3)} (E_{ds} + E_c)^3 \qquad [10]$$

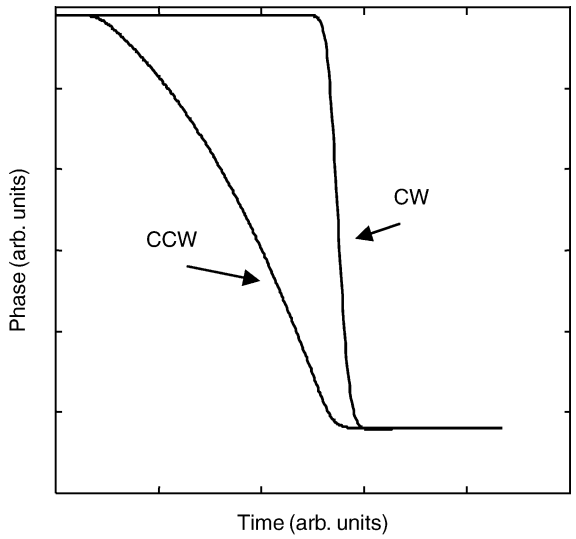

Figure 15 Phase responses for CW and CCW components of TOAD.

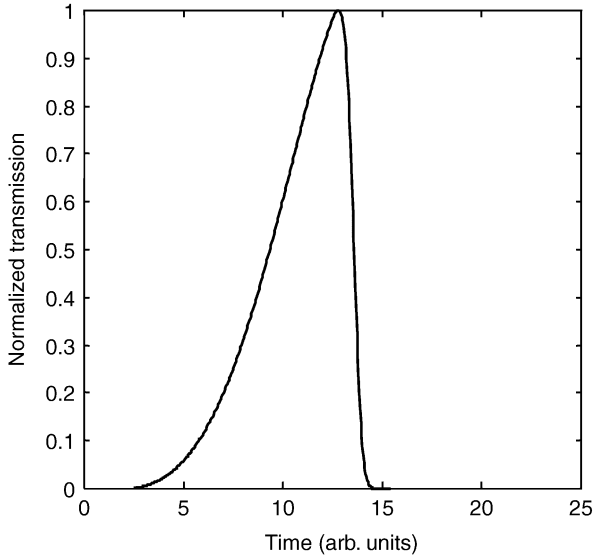

Figure 16 TOAD transmission window profile for small asymmetry loop.

where ε_0 is the vacuum permittivity of the medium, E_{ds} and E_c are the electric fields of data and control signals, respectively. The mixing of the two signals takes place in a long length of fiber in which the control signal propagates alongside the channel to be demultiplexed (see Figure 17). The control signal is of sufficient intensity to cause the fiber to operate in the nonlinear regime. The nonlinear relationship causes a number of frequencies to be generated, with the ones of interest having a frequency given by

$$f_{FWM} = 2f_c - f_{ds} \qquad [11]$$

An optical filter is then used to demultiplex the required channel from the composite signal. The nonlinearity is detuned from the resonant frequency of the fiber glass and as such tends to be weak, requiring long lengths of fiber to give a measurable effect. The power in the demultiplexed signal, for given data and control signal wavelengths and fiber material, depends on the input power and the fiber length according to

$$P_{FWM} = kP_{ds}P_cL_E^2 \qquad [12]$$

where k is a constant, P_{ds} is the signal launch power, P_c is the control signal launch power, and L_E is the fiber effective length. FWM is essentially an inefficient method as power is wasted in the unused frequency components of the four-wave signal. More in line with integrated structures, the nonlinear properties of a semiconductor laser amplifier can be used. Here a relatively high-power optical signal is input to the SLA (see Figure 18). This enables saturation and operation in the nonlinear regime

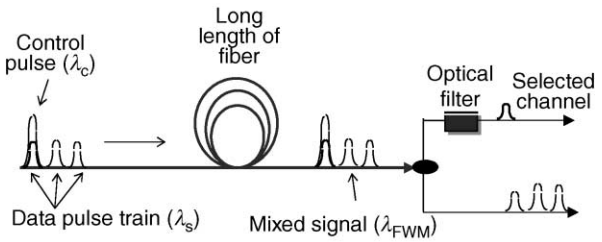

Figure 17 Block diagram of FWM demultiplexer.

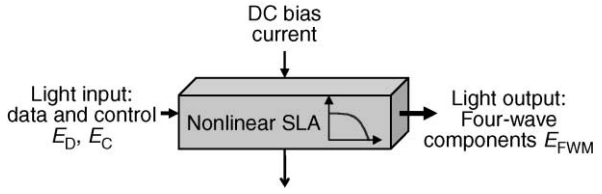

Figure 18 Four-wave mixing in SOA.

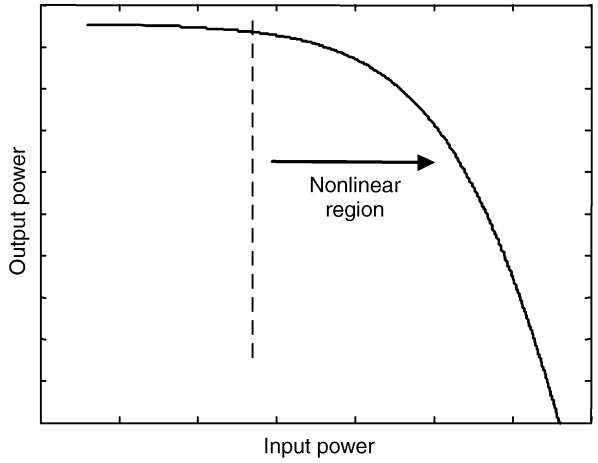

Figure 19 SLA output–input power curve.

(see Figure 19). Operating the SLA in saturation allows the nonlinear effects to produce the FWM components as in the fiber method.

Clock and Data Synchronization in OTDM

In common with electronically based TDM systems, clock recovery is fundamental to the recovery of data in ultrahigh-speed OTDM systems. Two main methods are proposed: (i) clock signal transmitted with the OTDM signal (i.e., multiplexed); and (ii) extraction of clock signal from the incoming OTDM pulse stream. In a packet-based system, synchronization between the clock and the data packet is normally achieved by sending a synch pulse with each packet. However, techniques based on optical-phased locked loops are proving popular and remove the need for a separate clocking signal.

Clock Multiplexing

(i) *Space division multiplexing*: This is conceptually the simplest to implement, where the clock signal is carried on a separate fiber from the data. However, it is susceptible to any differential delay between the different paths taken by clock and data due to temperature variation. It is difficult to justify in systems where the installed fiber base is at a premium.

(ii) *Wavelength division multiplexing*: Here different wavelengths are allocated to the clock, and payload. It is only really practical for predetermined path lengths between nodes in single-hop networks such as point–point links or broadcast-and-select star networks. It also suffers from random delays between the clock and the payload, which is problematic in an asynchronous packet switched based network, where the optical path length a packet may take is nondeterministic.

(iii) *Orthogonal polarization*: This is suitable for small links, where separate polarizations are used for the clock and data. However, in large networks it is quite difficult to maintain the polarization throughout the transmission link due to polarization mode dispersion and other nonlinear effects.

(iv) *Intensity division multiplexing*: This uses higher-intensity optical clock pulses to differentiate it from the data pulses as discussed above. However, in long-distance transmission links, it is difficult to maintain both the clock intensity and its position, due to the fiber nonlinearity.

(v) *Time division multiplexing*: In this scheme a single clock pulse, which has the same wavelength, polarization, and amplitude as the payload pulses, is separated in time, usually ahead of the data pulses.

Synchronization – Optical Phased Locked Loops (PLL)

The PLL is a common technique used for clock recovery in electronic TDM systems. However, the speed of conventional electronic PLLs tends to be limited by the response of the phase comparators used. There are a number of approaches based on opto-electronic PLL. Opto-electronic PLLs based on four-wave mixing in a traveling wave laser amplifier are complex and can suffer from frequency modulation in the recovered clock. However, others based on balanced photo-detectors, result in low timing jitter and good phase stability. In contrast, a number of all optical methods clock recovery scheme exist, one technique based on the TOAD (see above) is depicted in Figure 20. The high-speed data stream enters the TOAD at a rate $n \times R$ where n is the number of channels per OTDM frame, and R is the frame rate. A pulse generator, such as a mode locked fiber laser (MLFL) clocked by a local oscillator (LO), is used as the TOAD control input (MLFL-C). The OTDM data is switched by the TOAD at a frequency of say, $R + \Delta f$ Hz. Thus, the switching window samples data pulses at a rate higher or lower than $n \times R$ Hz and uses this signal for cross correlation in the PLL unit. The output of the phase comparator is used to regulate a voltage controlled oscillator (VCO)

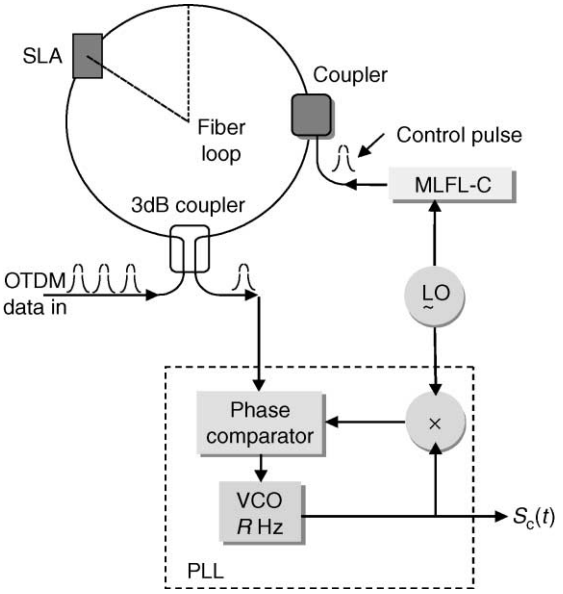

Figure 20 Ultrafast clock recovery using TOAD.

running at R Hz, which in turn feeds the control signal. The PLL circuit locks into the clock frequency, generating the clock signal $S_c(t)$.

OTDM Bit-Error Rate (BER) Performance

Figure 21 shows a typical block diagram of a high-speed optical receiver for an OTDM system, composed of a NOLM or a TOAD demultiplexer, an optical pre-amplifier, an optical bandpass filter, and a conventional optical receiver using a PIN photodiode. Due to the crosstalk introduced in the demultiplexing process, the demultiplexed optical signal contains not only the target channel but may also contain nontarget channels with reduced amplitude (see the inset in Figure 21). The intensity of the demultiplexed optical signal is boosted by the optical pre-amplifier (EDFA). Amplified spontaneous emission (ASE) from the optical preamplifier adds a wide spectrum of optical fields onto the demultiplexed optical signal. Although an optical bandpass filter (BPF) can reduce the ASE, it still remains one of the major noise sources. The function of the optical filter is to reduce the excess ASE to within the range of the signal spectrum. The PIN photodiode converts the received optical power into an equivalent electrical current, which is then converted to a voltage signal by an electrical amplifier. Finally, the output voltage is sampled periodically by a decision circuit for estimating the correct state (mark/space) of each bit.

The BER performance of an OTDM system deteriorates because of the noise and crosstalk

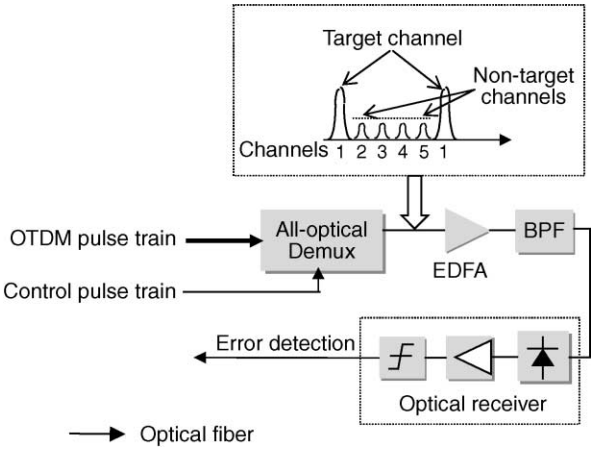

Figure 21 Block diagram of OTDM receiver.

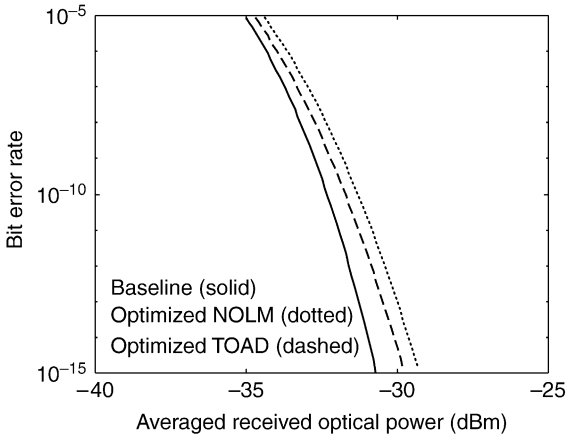

Figure 22 BER versus the average received optical power for 100 Gb/s (10 channels) OTDM system.

introduced by the demultiplexer and is:

$$\mathrm{BER} = \frac{1}{\sqrt{2\pi}} \frac{\exp\left(-Q^2/2\right)}{Q} \qquad [13]$$

where Q is defined as:

$$Q = \frac{\bar{I}_m - \bar{I}_s}{\sqrt{\sigma^2_{\mathrm{RIN,m}} + \sigma^2_{\mathrm{RIN,s}} + \sigma^2_{\mathrm{amp,m}} + \sigma^2_{\mathrm{amp,s}} + \sigma^2_{\mathrm{rec,m}} + \sigma^2_{\mathrm{rec,s}}}} \qquad [14]$$

and $\bar{I}_m$ and $\bar{I}_s$ are the average photocurrents for a mark and a space, respectively. $\sigma_{x,i}$ are the variances of the relative intensity noise (RIN), further optical pre-amplifier and receiver for a mark and a space.

For 100 Gb/s (10 channels) OTDM system, the BER against average received optical power for optimized NOLM and TOAD demultiplexers, is shown in Figure 22.

List of Units and Nomenclature

A_i	ith data bit in a packet
c	Speed of light in a vacuum
c_f	Speed of light within the fiber
E_c	Electric fields of control signals
E_{ds}	Electric fields of data signals
f_{FWM}	Frequency due to four-wave mixing
$G_{SLA}(t)$	Gain profiles of SLA
I_c	Intensity of the control signal
I_D	Intensity of the data signal
$\overline{I}_m$	Average photo current for a mark
$\overline{I}_s$	Average photo current for a space
k	Packet length in bits
L	Fiber length
L_d	Distance between two SLAs
L_E	Fiber effective length
n	Number of stages
n_2	Kerr coefficient
N_{SLA}	SLA index
P	Polarization
P_c	Control signal launch power
P_{ds}	Data signal launch power
t_{asy}	The window width is given by $t_{asy} = 2\Delta x/c_f$
T	Incoming bit interval
T_w	Walk off time per unit length between control and data pulses
T_x	Transmittance of the NOLM
$\delta(\cdot)$	Optical carrier pulse shape
$\Delta\phi(t)$	Time-dependent phase difference
Δx	SLA offset from the fiber loop center
ε_0	Vacuum permittivity of the medium
λ_s	Data signal wavelength
$\sigma_{amp,m}$	Variances for optical pre-amplifier for a mark
$\sigma_{amp,s}$	Variances for optical pre-amplifier for a space
$\sigma_{rec,m}$	Variances for receiver for a mark
$\sigma_{rec,s}$	Variances for receiver for a space
$\sigma_{RIN,m}$	Variances of RIN for a mark
$\sigma_{RIN,s}$	Variances of RIN for a space
τ	Outgoing bit interval
$\phi(t)$	Phase profile of SLA
$\chi^{(3)}$	Third-order non-linear susceptibility of an optical fiber

Introduction

Linear filtering is a useful tool commonly used in image processing. The correlation operation can be defined as:

$$f(x,y)*h(x,y)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}f(x,y)h(x-x',y-y')\mathrm{d}x'\mathrm{d}y' \quad [1]$$

where $*$ denotes the correlation. The operation of correlation and the Fourier transform

$$G(\mu,\nu)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}g(x,y)\mathrm{e}^{-j2\pi(\mu x+\nu y)}\mathrm{d}x\mathrm{d}y \quad [2]$$

are intimately related through the correlation theorem of Fourier theory, which states that the correlation between two functions $f(x,y)$ and $h(x,y)$ is equal to the inverse Fourier transform of the product of the Fourier transforms:

$$f(x,y)*h(x,y)=FT^{-1}[F(\mu,\nu)H^{*}(\mu,\nu)] \quad [3]$$

where $F(\mu,\nu)$ and $H(\mu,\nu)$ are the Fourier transforms of $f(x,y)$ and of $h(x,y)$ respectively, and where H^{*} designates the complex conjugate of H. The ability to carry out and display Fourier transforms in two dimensions, by means of optical systems, is at the root of optical information processing.

One of the main advantages of correlation is that the operations do not require segmentation of the regions of interest. This means that the locations of objects do not have to be segmented from the scene and that the detection is shift-invariant, that is the correlation peaks appear at locations in the scene corresponding to locations of the targets. These advantages are clearer for detection in uncontrolled conditions, for example for detecting vehicles in natural scenes. But they are also useful in security applications, such as identity verification or for detecting defects in assembly lines.

The Optical Fourier Transform

The Fourier transform of eqn [2] is widely used in the field of information processing. The inverse Fourier transform is simply defined as:

$$g(x,y)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}G(\mu,\nu)\mathrm{e}^{i2\pi(\mu x+\nu y)}\mathrm{d}\mu\mathrm{d}\nu \quad [4]$$

We will now discuss how to perform Fourier transforms by means of four different optical setups.

FT Without a Lens

If we illuminate a transparency $U(x_0,y_0)$ with a coherent plane wave, the diffraction pattern we observe at a point d from the input plane is given by the following relation, known as the Fresnel approximation for diffraction (Figure 1):

$$U(x_1,y_1)=\frac{\exp\left(i\dfrac{2\pi d}{\lambda}\right)}{j\lambda d}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}U(x_0,y_0)\times\exp\left\{i\frac{\pi}{\lambda d}[(x_0-x_1)^2+(y_0-y_1)^2]\right\}\mathrm{d}x_0\mathrm{d}y_0 \quad [5]$$

where λ is the wavelength of the light and d is the distance between the diffracting screen and the observed pattern.

In order to use the Fresnel approximation we need only to satisfy the geometrical optics paraxial conditions. If we add an additional approximation, we can further simplify this equation to yield the Fourier transform of $U(x_0, y_0)$. The extra condition is known as the Fraunhofer or far-field approximation, which is only satisfied when the diffracted image is observed far away from the diffracting screen or when the extent of $U(x_0, y_0)$ is very small. Mathematically this condition is expressed by:

$$\frac{\pi}{\lambda d}(x_0^2+y_0^2)\ll 1 \quad [6]$$

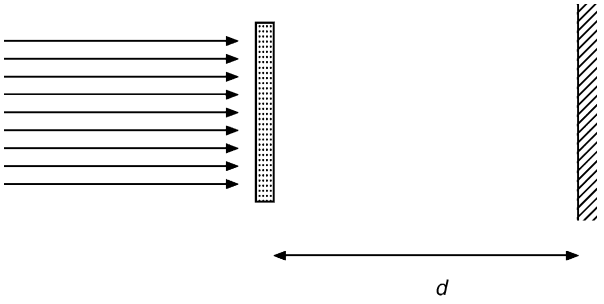

Figure 1 Fresnel diffraction without a lens.

After expanding the squares in the exponentials, there will be three terms: one can go outside the integral and one will be approximately equal to unity so the diffracted pattern becomes

$$U(x_1, y_1) = \frac{\exp\left(i\frac{2\pi d}{\lambda}\right)}{i\lambda d} \times \exp\left[i\frac{\pi}{\lambda d}(x_1^2 + y_1^2)\right] \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U(x_0, y_0) \times \exp\left[-i\frac{2\pi}{\lambda d}(x_0 x_1 + y_0 y_1)\right] dx_0 dy_0 \quad [7]$$

This is the Fourier transform of $U(x_0, y_0)$, scaled by a factor λd, with an extra quadratic phase factor

$$\exp\left[\frac{i\pi}{\lambda d}(x_1^2 + y_1^2)\right]$$

The factor $\exp(i2\pi d/\lambda)/i$ is usually of no importance since it is a phase factor distributed across the output plane. In some applications we only want to know the power spectrum (squared modulus) of the Fourier transform. In such cases the quadratic phase factor disappears because the squared modulus of any complex exponential is equal to 1. Performing a Fourier transform without a lens is possible within the Fraunhofer approximation. But if it is required to obtain the Fourier transform of an image which extends about 1 cm from the optical axis using a coherent He–Ne laser ($\lambda = 632.8$ nm), the condition to be satisfied is $d \gg 496$ m: the required observation distance d is at least a few kilometers. This kind of optical setup is usually impractical, but can fortunately be alleviated by means of lenses.

Object on the Lens

Instead of having only the transparency in the input plane, we place a lens immediately after it as shown in Figure 2. For mathematical simplicity the lens and input plane are superimposed (more realistic cases are considered below). The lens acts as a phase factor

$$\exp\left[-i\frac{\pi}{\lambda f}(x_0^2 + y_0^2)\right]$$

where f is the focal length of the lens. Now in the input plane the object $U(x_0, y_0)$ is multiplied by the phase factor of the lens:

$$U'(x_0, y_0) = U(x_0, y_0)\exp\left[-i\frac{\pi}{\lambda f}(x_0^2 + y_0^2)\right] \quad [8]$$

Inserting this expression into the integral formula for Fresnel diffraction yields the diffraction pattern observed in the focal plane of the lens:

$$U(x_1, y_1) = \frac{\exp\left(i\frac{2\pi f}{\lambda}\right)}{i\lambda f} \times \exp\left[i\frac{\pi}{\lambda f}(x_1^2 + y_1^2)\right] \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U(x_0, y_0) \times \exp\left[-i\frac{2\pi}{\lambda f}(x_0 x_1 + y_0 y_1)\right] dx_0 dy_0 \quad [9]$$

The lens exactly compensates for the other phase factor that was in the integral. This expression for the Fraunhofer approximation is almost the same as before, but the focal length f of the lens replaces the distance d. So by placing a lens immediately after the input plane we can have a much more compact setup since lenses are available with a wide range of focal lengths, usually from a few centimeters to a few meters. Another way to look at this is to consider that the effect of a lens is to bring the pattern at infinity to the focal plane of the lens – except for the phase factor.

Object Before the Lens

Another setup used to perform the Fourier transform is shown in Figure 3, where the lens is placed somewhere between the input and the output planes. Using the Fresnel formula for diffraction it can be

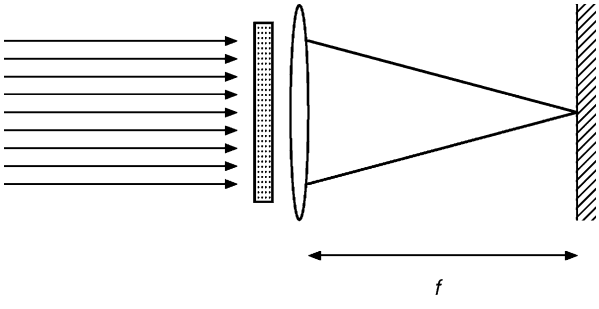

Figure 2 Diffraction with the object on the lens.

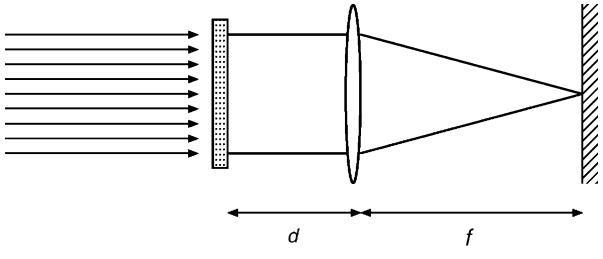

Figure 3 Diffraction with the object before the lens.

shown that the diffraction pattern in the focal plane is:

$$U(x_1, y_1) = \frac{1}{i\lambda f} \times \exp\left[i\frac{\pi}{\lambda f}\left(1 - \frac{d}{f}\right)(x_1^2 + y_1^2) \right] \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U(x_0, y_0) \times \exp\left[-i\frac{2\pi}{\lambda f}(x_0 x_1 + y_0 y_1) \right] dx_0 dy_0 \quad [10]$$

where d is the distance between the input plane and the lens. If we set d equal to the focal length f of the lens, the quadratic phase factor in front in the integral vanishes and we have an exact Fourier transform. This setup with the object and filter in the front and back focal planes of the lens respectively is the one most frequently seen in scientific articles and is known as the *f-f* Fourier transform system.

Object After the Lens

Still another configuration is the one shown in Figure 4, where the lens is placed at a distance d before the input plane. For this configuration the Fresnel diffraction yields the following pattern in the focal plane of the lens:

$$U(x_1, y_1) = \frac{\exp\left[i\frac{\pi}{\lambda d}(x_1^2 + y_1^2) \right]}{i\lambda d} \frac{f}{d} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U(x_0, y_0) \times \exp\left[-i\frac{2\pi}{\lambda d}(x_0 x_1 + y_0 y_1) \right] dx_0 dy_0 \quad [11]$$

Once again the Fourier transform of $U(x_0, y_0)$ is multiplied by a quadratic phase factor. It is interesting to note that, in this case, the Fourier transform is scaled by a factor λd. This can be used to control the scale of the Fourier transform by changing the distance between the lens and the object.

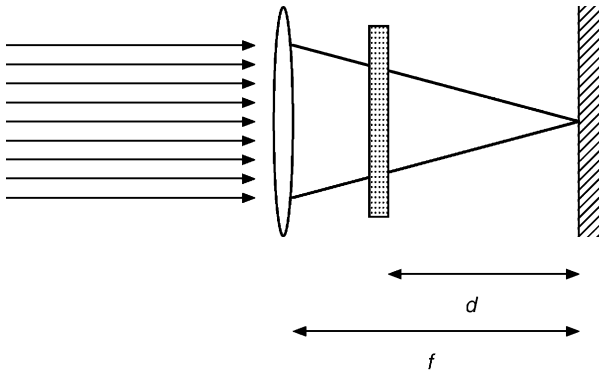

Figure 4 Diffraction with the object after the lens.

Note that although two of the three methods yield Fourier transforms that are accompanied by a quadratic phase factor, the latter is not necessarily an impediment to correlation, contrary to popular belief. Indeed all three configurations have been used for correlation pattern recognition, and each configuration has its advantages.

Optical Correlation

The last section showed how to obtain Fourier transforms by means of an optical setup. The proposed optical setups cannot perform the inverse Fourier transform. Because the Fourier transform and its inverse are very similar, the Fourier transform is performed instead, yielding the mirror image of the correlation:

$$(f * h)(-x, -y) = \mathrm{FT}[F(\mu, \nu)H^*(\mu, \nu)] \quad [12]$$

The correlation can be considered as the result of three operations: a Fourier transform; a product; and an additional Fourier transform. The Fourier transform of a 2D function can be obtained by means of coherent optics. The equivalent of multiplication in optics is transmissivity, so multiplication is accomplished by sending light successively through two superimposed transparencies.

There are two main categories of optical correlators, serial correlators and joint transform correlators.

Serial Correlators

A serial correlator functions in two stages. The first stage performs the Fourier transform of the input image $f(x, y)$, which is multiplied in the Fourier plane with a transparency $H(\mu, \nu)$. The filter $H(\mu, \nu)$ can be a hologram, a spatial light modulator (SLM) or a simple transparency. A second Fourier transform displays in the output plane the correlation of the input image with the impulse response $h(x, y)$, which is the Fourier transform of the filter function $H(\mu, \nu)$.

Serial correlators directly implement the two Fourier transforms and the multiplication operation in a pipelined manner. The input plane and the correlation plane are conjugate planes of the system, that is in the absence of a filter, the output plane displays an inverted image of the input $f(x, y)$. Between those conjugate planes, at the conjugate plane of the source with respect to the first lens, is the Fourier plane where the spatial frequency filter is placed. When the input is illuminated with parallel

light, the frequency plane is at the back focal plane of the first lens. A SLM can be placed in the input plane to feed the images to be correlated; a second SLM can be placed in the Fourier plane to display the filter. The filter is often calculated by a digital computer, and usually takes the form of a hologram if phase information must be used in the filter.

The 4-*f* correlator

The 4-*f* correlator is the most intuitive optical correlator system. We showed above that an *f*-*f* system can be used to optically obtain a Fourier transform (Figure 5). If $f(x, y)$ is in the front focal plane, its Fourier transform $F(\mu, \nu)$ appears at the back focal plane of the first lens. If a filter function $H^*(\mu, \nu)$ is inserted at this point, by means of a SLM or a hologram, then a second *f*-*f* system can perform a second Fourier transform to yield the correlation plane at the back focal plane of the second lens.

Convergent beam correlator

This kind of correlator consists of two conjugate systems. This time, the Fourier transform is obtained by placing the input object in a convergent beam after the first lens. The second lens is placed so that the output plane is conjugate to the input plane, and as before, the filter is placed at the point of convergence of the light after the first lens. It is important to note that this is not the focal plane of the lens, but the conjugate plane of the source of light. In order to have an imaging system between the input and output planes, the distances must satisfy the conjugate relation:

$$\frac{1}{s_0} + \frac{1}{s_i} = \frac{1}{f_2} \qquad [13]$$

where s_i and s_0 are defined in Figure 6. As previously discussed for convergent light, the Fourier transform will have an additional parabolic phase factor. This must be taken into account when constructing the filter H.

This configuration has some advantages over the 4-*f* correlator. By moving the object between the first lens and the filter, it is possible to control the scale of the Fourier transform. And because the first lens is imaging only a single point on the optical axis, only spherical aberration needs to be compensated for. In 4-*f* systems, the first lens must be corrected for all aberrations for the whole input plane, and for a given extent of the input object, the first lens must be larger than that for the convergent system in order to avoid space variance effects. Unfortunately, specially designed expensive lenses are required to correct for those aberrations, so well-corrected Fourier transform lenses for 4-*f* systems are expensive, whereas a simple doublet is sufficient to correct for on-axis spherical aberration, which is all that is required for the convergent light system. In addition, the convergent light system does not require an expensive collimator that is required in the 4-*f* system to obtain the parallel illuminating beam. Aberration correction requirements for the second lens are less stringent

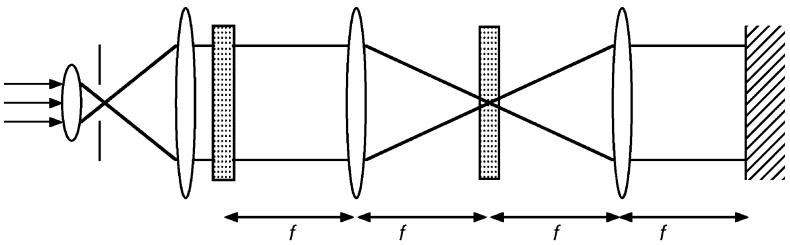

Figure 5 4-*f* correlator setup.

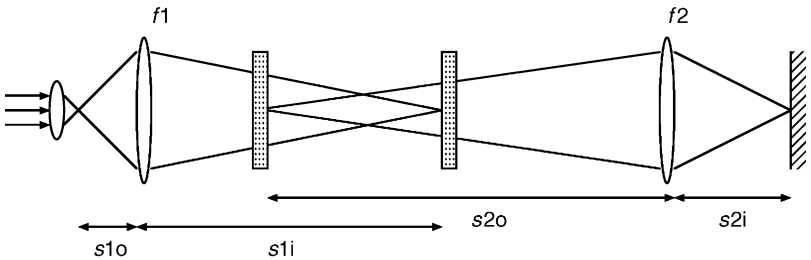

Figure 6 Convergent beam correlator setup.

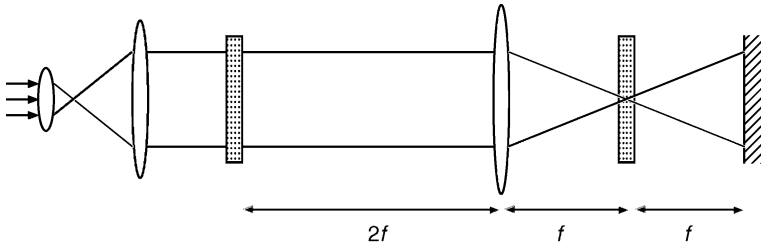

Figure 7 Single lens correlator setup.

than for the first, because in most cases, a slight deformation of the output plane can be acceptable, whereas comparable distortions in the Fourier plane can cause misregistrations between the Fourier transform and the filter that can seriously degrade the correlation.

Divergent beam correlators

Instead of placing the input object in the convergent beam, as in the previous case, another configuration that has been used places the input object in the divergent beam before the first lens. This configuration is rarely seen today, because it exacerbates the space variance and aberration problems of the 4-f system, and the control it allows over the scale of the Fourier transform can be achieved with fewer penalties by means of the convergent light system.

Single lens correlator

Consider an imaging system using only one lens illuminated with a parallel beam of coherent light (Figure 7). The input and output planes are located at distances $2f$ on either side of the lens – the shortest conjugate distances possible. If a filter $H(\mu, \nu)$ is placed at the focal plane of the lens on the object's Fourier transform, the correlation will appear on the output plane. This system requires satisfying impractical conditions: aberration corrections for both the Fourier transform and for the imaging operation, so it is rarely seen.

Filters

Many types of filters can be used for different applications. Table 1 lists some commonly used filters for pattern recognition. The classical matched filter yields the optimum signal to noise ratio in the presence of additive noise. The phase-only filter (POF) is frequently used because of its high discrimination capability. The inverse filter is sometimes used because it theoretically yields very sharp correlation peaks, but is very sensitive to noise, and when the spectrum $F(\mu, \nu)$ has some zeros, the realization of $1/F(\mu, \nu)$ can be impossible. A close relative of the inverse filter is the Wiener filter, which avoids the problem of the inverse filter by introducing a quantity $S(\mu, \nu)$ in the denominator of the filter function. The function $S(\mu, \nu)$ can sometimes be a constant. $H(\mu, \nu)$ is usually chosen to minimize the effect of noise or to optimize some parameter such as the peak to sidelobe ratio, or the discrimination ability of the system.

Table 1 Commonly used filters for image processing

Name	*Filter*
Matched filter	$H_{\mathrm{CMF}}(\mu, \nu) = F(\mu, \nu)$
Phase-only filter	$H_{\mathrm{POF}}(\mu, \nu) = \dfrac{F(\mu, \nu)}{\lvert F(\mu, \nu)\rvert}$
Inverse filter	$H_{\mathrm{INV}}(\mu, \nu) = \dfrac{1}{F(\mu, \nu)}$
Wiener filter	$H_{\mathrm{W}}(\mu, \nu) = \dfrac{F^{*}(\mu, \nu)}{\lvert F(\mu, \nu)\rvert^{2} + S(\mu, \nu)}$

Joint Transform Correlators

In serial transform correlators, the filter is generally a complex function. Spatial light modulators are usually conceived with only one degree of freedom for each pixel, which can be optimized for amplitude modulation or for phase modulation. In order to achieve a fully complex filter, two modulators are required, or some spatial bandwidth of a modulator is sacrificed to encode a computer-generated hologram.

The joint-transform correlator (JTC) does not require a fully complex filter. The filter is stored in the spatial domain so there is usually no need for the computation of a filter in the spectral domain. In the JTC, the correlation of a scene with a reference image is contained in the power spectrum of an input plane consisting of the scene placed side by side with the reference. The correlation terms are revealed when the Fourier transform of the power spectrum is

computed. The joint transform correlation can be summarized in three steps:

1. The scene and the reference are located side by side in the input plane.
2. The Fourier transform of the input plane is computed or carried out optically by one of the methods previously described. The transform intensity is measured and constitutes the joint power spectrum. Some optional enhancements, based on spatial filtering and/or nonlinear processing on the power spectrum, can also be performed.
3. The Fourier transform of this joint power spectrum is carried out, yielding the correlation plane containing the correlation of the reference with the scene.

A mathematical analysis is required to understand the location of the correlation peaks. The side-by-side input scene $s(x, y)$ and reference image $r(x, y)$ are

$$i(x, y) = r(x - x_r, y - y_r) + s(x - x_s, y - y_s) \qquad [14]$$

The joint power spectrum $E(\mu, \nu)$ is equal to the modulus squared of the Fourier transform of the input plane:

$$\begin{aligned} I(\mu, \nu) &= R(\mu, \nu)e^{-i2\pi(\mu x_r + \nu y_r)} + S(\mu, \nu)e^{-i2\pi(\mu x_s + \nu y_s)} \\ E(\mu, \nu) &= \|I(\mu, \nu)\|^2 = \\ &\quad \|R(\mu, \nu)\|^2 + \|S(\mu, \nu)\|^2 \\ &\quad + R(\mu, \nu)S^*(\mu, \nu)e^{-i2\pi[\mu(x_r - x_s) + \nu(y_r - y_s)]} \\ &\quad + R^*(\mu, \nu)S(\mu, \nu)e^{-i2\pi[\mu(x_s - x_r) + \nu(y_s - y_r)]} \end{aligned} \qquad [15]$$

The joint power spectrum contains the Fourier transforms of the autocorrelation of the input scene, the autocorrelation of the reference, the correlation of the scene with the reference and its complex conjugate. The correlation peaks are obtained from the Fourier transform of the joint power spectrum:

$$\begin{aligned} C(x', y') = {} & R_{ss}(x', y') + R_{rr}(x', y') \\ & + R_{sr}(x' - (x_r - x_s),\ y' - (y_r - y_s)) \\ & + R_{sr}(x' + (x_r - x_s),\ y' + (y_r - y_s)) \end{aligned} \qquad [16]$$

where

$$R_{ab}(x', y') = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} a(\xi, \zeta)b^*(\xi - x', \zeta - y')\mathrm{d}\xi\mathrm{d}\zeta \qquad [17]$$

Multiple targets and multiple references

The input scene of the JTC may contain multiple targets. Each target in the scene will correlate with the other targets. The additional correlation peaks can clutter the correlation plane, so some care must be taken when positioning the scene with respect to the reference. Let $s(x, y)$ contain multiple targets $s_i(x, y)$:

$$s(x, y) = \sum_{i=1}^{N} s_i(x - x_i, y - y_i) \qquad [18]$$

The joint power spectrum becomes:

$$\begin{aligned} E(\mu, \nu) = {} & \|R(\mu, \nu)\|^2 + \sum_{i=1}^{N} \|S_i(\mu, \nu)\|^2 + \sum_{i=1}^{N} \sum_{\substack{k=1 \\ i \neq k}}^{N} \\ & \times S_i(\mu, \nu)S_k^*(\mu, \nu)e^{-i2\pi[\mu(x_i - x_k) + \nu(y_i - y_k)]} + \text{C.C.} \\ & + \sum_{i=1}^{N} R(\mu, \nu)S_i^*(\mu, \nu)e^{-i2\pi[\mu(x_r - x_i) + \nu(y_r - y_i)]} + \text{C.C.} \end{aligned} \qquad [19]$$

where C.C. denotes the complex conjugate of the preceding term. The correlation plane will now be:

$$\begin{aligned} C(x', y') = {} & R_{rr}(x', y') + \sum_{i=1}^{N} R_{s_i s_i}(x', y') \\ & + \sum_{i=1}^{N} \sum_{\substack{k=1 \\ i \neq k}}^{N} R_{s_i s_k}(x' - (x_i - x_k),\ y' - (y_i - y_k)) \\ & + \sum_{i=1}^{N} R_{rs_i}(x' - (x_r - x_i),\ y' - (y_{ri} - y_i)) \\ & + \sum_{i=1}^{N} \sum_{\substack{k=1 \\ i \neq k}}^{N} R_{s_k s_i}(x' + (x_i - x_k),\ y' + (y_i - y_k)) \\ & + \sum_{i=1}^{N} R_{s_i r}(x' + (x_r - x_i),\ y' + (y_{ri} - y_i)) \end{aligned} \qquad [20]$$

The second lines of eqns [9] and [20] are the cross-correlation terms between the targets. In order to avoid confusion between reference–target correlations and target–target correlations, special care must be taken in positioning the reference with respect to the scene. All the target–target correlations will be inside a centered box that has twice the length and twice the width of the input scene, so the reference should be placed at least at twice the length or width of the scene.

Multiple targets in the input scene can be viewed as multiple references, and the correlation of multiple

references with multiple targets are all computed simultaneously. This property has led to applications in multiclass pattern recognition problems and in optical neural networks, where each neuron of a layer is coded as a reference object. This is one of the advantages of the JTC compared to serial correlators, since serial correlators are limited to one filter at a time.

Example

Here is an example of joint transform correlation. The input plane is shown in Figure 8a. The plane is composed of the input scene in the top third of the input plane and the reference is placed in the center. This input scene contains two targets. The joint power spectrum is shown in Figure 8b with its pixels mapped to a logarithmic intensity scale. The correlation plane is shown in Figure 8c and d with the central peak truncated. The central peak contains the autocorrelation terms R_{ss} and R_{rr}. On each side of the autocorrelation peak are the cross-correlations between the different targets of the input scene. The correlation between the reference image and the input scene is located in the top part of the correlation plane. The correlation plane is symmetrical with respect to the origin, so the correlation peaks are reproduced on the bottom half of the output plane.

Joint transform correlator architectures

Different architectures have been used for JTCs. Three setups are presented here. This is not an exhaustive list. The simplest optical setup shown in Figure 9 is an optoelectronic implementation of a power spectrum machine. A convergent beam

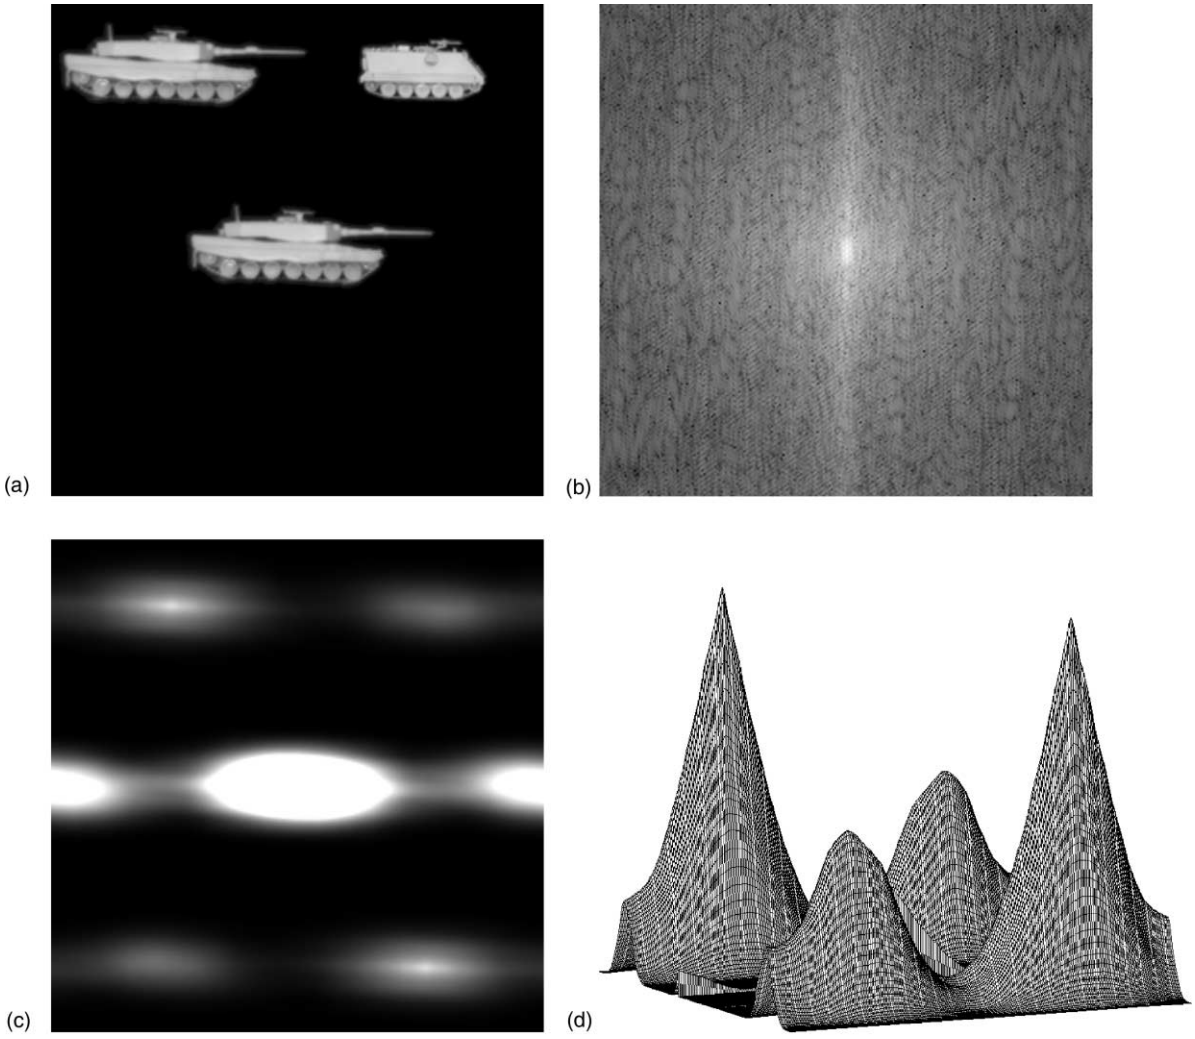

Figure 8 Joint transform correlation example. (a) Input scene; (b) joint power spectrum; (c) correlation plane (top view); (d) correlation plane (mesh view).

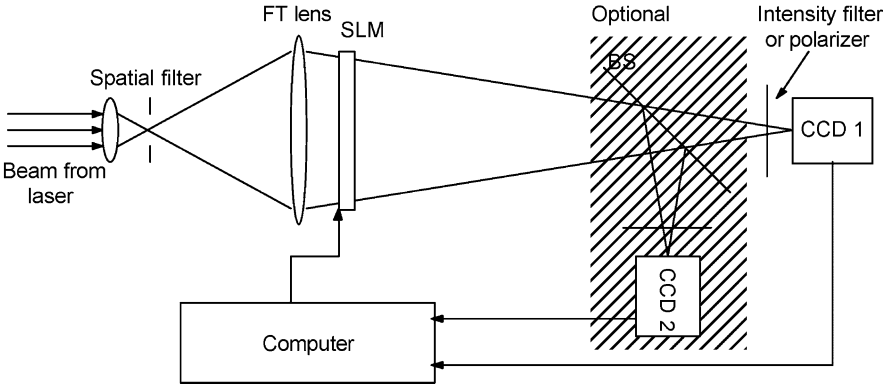

Figure 9 Joint transform correlator implementation as an optical power spectrum machine.

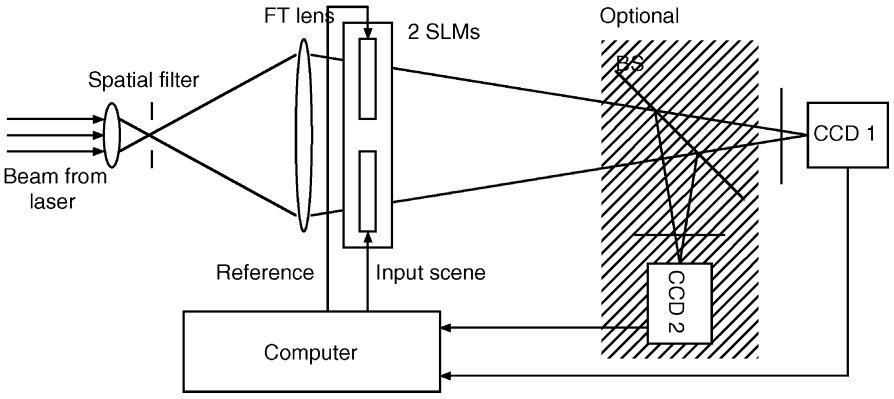

Figure 10 Optical JTC using two SLMs in the input plane.

optical Fourier transform system is used to produce the Fourier transform of an image displayed on a single spatial light modulator (SLM). A CCD camera is placed in the Fourier plane to measure the joint power spectrum. The joint transform correlation is a two-step process: the input plane containing the scene and the reference is first displayed on the SLM, and the camera simultaneously captures the joint power spectrum. In the second step, the joint power spectrum is displayed on the SLM, so the correlation plane is now on the camera. An optional second camera with intensity filters can be added to this setup. In this case, one camera serves to digitize the joint power spectrum during step 1 and the second camera captures the correlation plane at step 2 and transmits it to a display device. This optional configuration is useful to keep both the correlation plane and the joint power spectrum within the dynamic range of their specific cameras.

The setup shown in Figure 9 has two main disadvantages: the correlation is performed in two steps and requires some processing to construct the input plane, and only half of the spatial light modulator can be used to display the input scene. There are alternative setups to alleviate those drawbacks, but they require the use of two or three SLMs. Two modulators can be used in the input plane to simulate a full modulator for the scene, as shown in Figure 10. The original setup can also be doubled with one optical Fourier transform system for the joint power spectrum and one for the correlation plane (Figure 11). With three modulators, it is possible to perform the joint transform correlation in a single step with a full modulator for the input scene.

Comparison to serial transform correlators

The joint transform correlator has some advantages over the serial transform correlator. Since the phase of the Fourier transform is destroyed in the JTC, there are much fewer constraints on the design. So it is advantageous to use an optical convergent beam setup to obtain the Fourier transform. As mentioned before, there is no need for a fully complex spatial light modulator in the joint transform correlator.

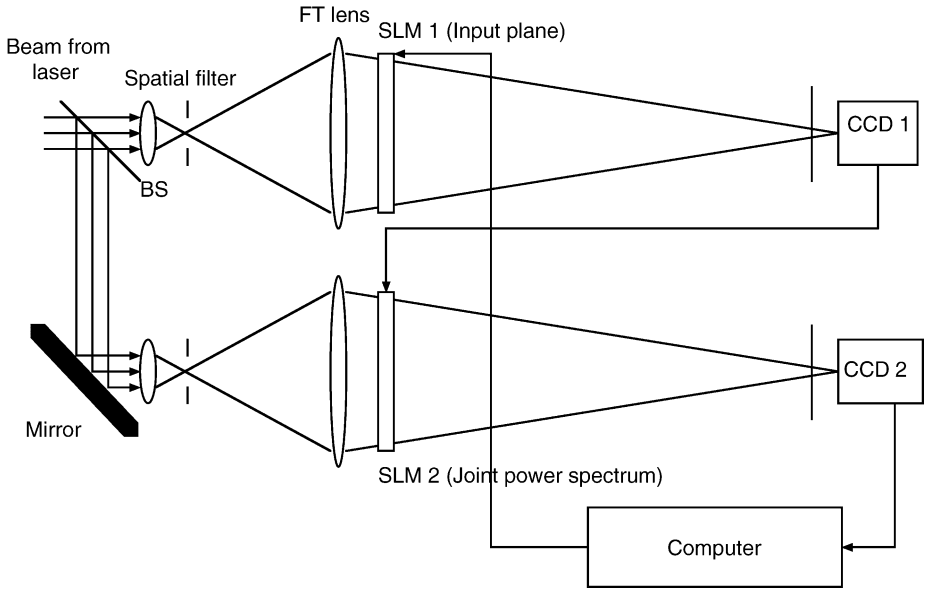

Figure 11 JTC implementation using two power spectrum machines.

This allows the use of commercially available spatial light modulators primarily designed for projectors or for displays, where phase modulation is not required. Since there is a wider market for such devices, they are cheaper.

For pattern recognition, the joint transform correlator has some properties that a serial transform correlator cannot reproduce. Some pattern recognition techniques require a linear combination of multiple amplitude correlations of the scene with different references. This is impossible with serial correlators because only the intensity of the correlation plane is detected. In a JTC, the joint power spectrum is linked to the correlation plane by the Fourier transform. So it is possible to obtain linear combinations of correlation planes by performing the corresponding operations on the joint power spectra. Some recent pattern recognition techniques such as morphological correlation and the sliced orthogonal nonlinear generalized (SONG) correlation, have been optically implemented using a JTC, but the required operations could not be carried out by means of serial optical correlators.

Whereas optical serial transform correlators always carry out linear filtering operations, optical joint transform correlators can be made to carry out nonlinear filtering. This is achieved by imposing a nonlinear characteristic curve on the joint power spectrum, instead of the usual squaring operation inherent to the detection process. The nonlinearity can be intrinsic to the components (saturation, dynamic range) or obtained by introducing electronics between the CCD camera and the second SLM,

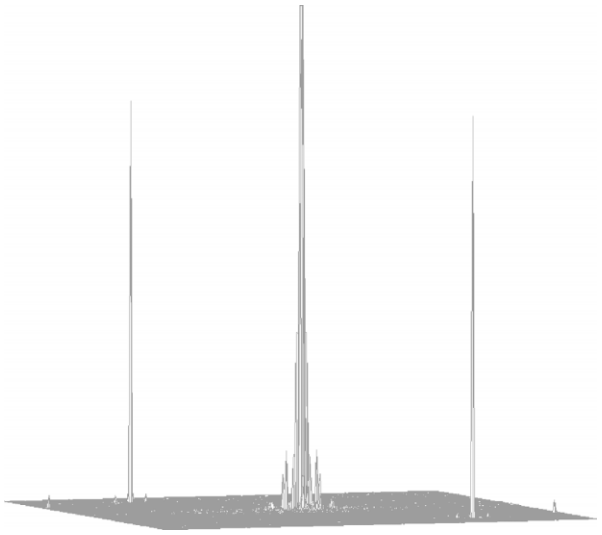

Figure 12 Correlation plane with a logarithmic transformation of the joint power spectrum.

or by using an optically addressed spatial light modulator. Nonlinear processing can enhance the weights of the high frequencies in the correlation, resulting in sharper correlation peaks and improved discrimination. To illustrate this effect, the joint power spectrum of the example of Figure 8 has been modified with a logarithmic transformation:

$$E(\mu, \nu) = \ln\left(1 + \beta \|I(\mu, \nu)\|^2\right) \qquad [21]$$

with $\beta = 0.25$. The correlation plane for the transformed joint power spectrum is shown in Figure 12.

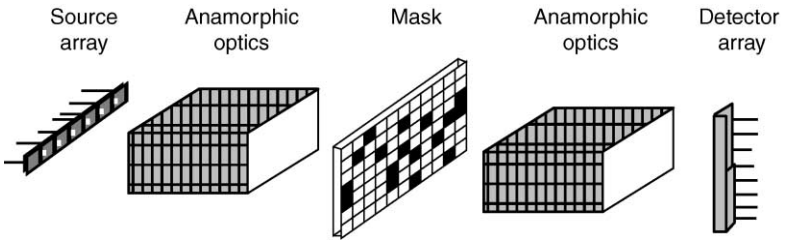

Figure 13 Optical vector–matrix multiplier.

It is clear that the discrimination has improved over that of the previous case.

Optical Vector–Matrix Multiplier

An operation that is frequently required in information processing is the product of a matrix and a vector. This can be accomplished by means on anamorphic optics as shown in Figure 13.

Here the input vector is a set of vertical fans of light from the source array, that are spread out, each over one row of the matrix mask by means of anamorphic optics. The inverse operation is carried out in the second half, so that the vertical array of spots in the output contains the vector–matrix product between the intensities of the source array and the transmissivities of the mask array.

A vector–matrix product can also be carried out by means of a conventional optical correlator as shown in Figure 14.

The input vector **a** is placed in a parallel beam at the focal plane of a conventional 2D correlator. A hologram in the Fourier plane contains a vector array **H**. The vector–matrix product **aH** appears along the axis in the correlation plane.

The above figure shows an input vector $f(x,b)\delta(y-b)$ containing the vector components $f(x1,x2,\ldots,xN)$ arrayed along the horizontal axis x, and shifted a distance a from the horizontal axis. If the Fourier transform of the mask in the filter plane is $h(x,y)$, then the output plane has the distribution:

$$g(x,y)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(\mu,\upsilon)\delta(\mu-b)h(x+\mu,y+\upsilon)\mathrm{d}\mu\mathrm{d}\upsilon \qquad [22]$$

$$g(x,y)=\int_{-\infty}^{\infty} f(\mu,a)h(x+\mu,b-y)\mathrm{d}\mu \qquad [23]$$

$$g(x,b)=\int_{-\infty}^{\infty} f(\mu,b)h(x+\mu,b)\mathrm{d}\mu \qquad [24]$$

$$g(0,b)=\int_{-\infty}^{\infty} f(\mu,b)h(\mu,b)\mathrm{d}\mu \qquad [25]$$

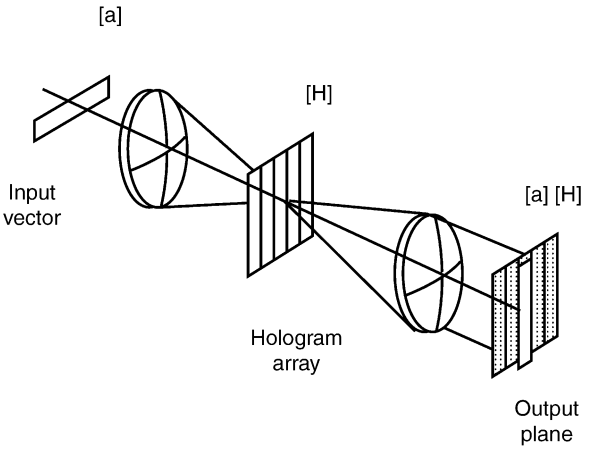

Figure 14 A vector–matrix product using a conventional 2D optical correlator.

So the output value along the y-axis at a distance a from the horizontal axis is equal to the scalar product of the vector $f(x,b)$ with the vector $h(x,b)$. Now if input vectors are stacked up one over the other in the input plane, each one will yield along the output y-axis a value that is the scalar product of the corresponding vector with the vector **h**. The set of values along the y-axis is therefore the vector–matrix product of the matrix constituted by the set of vectors in the input plane, with the vector **h** that is the impulse response of the filter. The cost for this operation is some considerable loss of light, since only the light along the y-axis is used in the output.

Applications of the optical vector–matrix product are optical crossbar, numerical matrix operations such as the solving of linear equations, optical neural networks, spectrum analysis and discrete Fourier transforms.

Conclusion

It has been estimated that serial coherent optical correlators should be able to attain data rates of up to 10^{12} operations per second, using the fastest spatial

light modulators available. Joint transform correlators are somewhat slower, due to the input plane being divided between the object and the reference, to geometrical constraints in placement of targets, and due to the need to use electronics to carry out some of the operations. Until now, speeds have been limited by the data rates at the input, but as the speeds of optically addressed SLMs increase, the problem could be shifted to the output, where the lack of optical high spatial bandwidth threshold devices could cause a bottleneck.

List of Units and Nomenclature

A	Vector or matrix
CCD	Charge coupled device
$F(\mu, \nu)$	Fourier transform of $f(x, y)l$
FT	Fourier transform
FT^{-1}	Inverse Fourier transform
H^*	Complex conjugate of H
JTC	Joint-transform correlator
POF	Phase-only filter
R_{ab}	Correlation between functions a and b
(x, y)	Spatial coordinates
λ	Wavelength of light
(μ, ν)	Spatial frequencies
$*$	Correlation
SLM	Spatial light modulator
SONG	Sliced orthogonal nonlinear generalized correlation

Introduction

Free space optical computing encompasses a vast field, from digital and discrete to analog and hybrid optical computing. This article gives an overview of various algorithms, such as shadow-casting, symbolic substitution to nonlinear optics-based processors. Some of the core devices, such as modulators and nonlinear logic elements, are discussed. The optical computing concepts, originated with nonlinear optics and analog optical computing, are more commonly known as optical signal processing. Now they have culminated into digital optical computing, opening the door to highly specialized parallel computing architecture.

Parallel computation is a direct approach to enhance the speed of digital computations which are otherwise inhibited by the sequential processing bottleneck. Physical limitations – such as limited interconnections, interactions amongst electrons, with the consequent inability to share a data bus simultaneously, and constant propagation delay of electronic circuits – place an upper bound on the speed of the fastest operation possible with an electronic computer, without a modification to the computing architecture. Optics provides an architectural advantage over electronics, due to the fact that the most natural way to use optics lends itself to a parallel implementation. Optical signals propagate in parallel, cross each other without interference (whereas charged electrons interact heavily with each other), have the lowest possible propagation delay of all signals, and can provide million channel free-space interconnections with simple lenses (whereas an unrealistic number of connections are necessary for electrons). Thus, optics is an excellent candidate for implementing parallel computing machines using the 3D space connectivity. While electronic architecture is naturally 2D, optical free space architecture is 3D, exploiting the third dimension of space. The communication bottleneck forces electronic computers to update the computation state space sequentially, whereas the use of optics will empower one to change the entire computation space in parallel.

Historical Perspective

Historically, digital optical computing was proposed as a natural extension of nonlinear optics. Just as transistors, which are nonlinear electronic devices, led to the realization of the computing logic using transistors, it was envisioned that nonlinear optical effects would give rise to optical transistors which would lead to development of optical logic gates. One of the limitations of nonlinear optical device-based computation is the high laser power requirement to demonstrate any nonlinear optical effect.

One of the effects used to demonstrate nonlinearity is to change the refractive index with the incident intensity. In other words, most materials will behave linearly with low optical energy. The refractive index expressed as $n = n_0 + n_2 I$ is nominally linear because the nonlinear co-efficient n_2 is usually very small. In the presence of high power, the $n_2 I$ is significant enough to cause an optical path change by altering the refractive index. When such a medium is placed inside a Fabry–Perot resonator, it will allow one to control the transmission of the filter by changing the incident intensity. Thus, at high power, it shows a nonlinear behavior or bistability. The term optical bistability was coined, which meant the presence of two stable states of output for the same intensity value.

Another development took place at the University of Michigan by the development of a precision optical processor; this was an optical processor which could process radar signals using optics, this is the example of an analog optical computing processor.

A third area which is in between the digital and the analog are the discrete level devices which most often take the form of matrix-based processors. Free space optical matrix vector multipliers are examples of such processors.

The latest field of optical computing research is in the algorithms and architecture area. The motivation here is to develop new algorithms which take advantage of optics. The thing that is lacking is the presence of appropriate device technology that can implement the algorithm in a given architecture. In terms of practical realization, analog optical computing is the most successful one. Adaptive optic processors have found success both in astronomy as well as vision sciences, and more recently in optical imaging through the atmosphere.

Development of free space optical computing has two main driving forces: the technology (device) base and the algorithm base. In this classification, since the field is in its infancy, both device-based classes and architectural (algorithm) classes are listed side-by-side as separate entities, ignoring the natural overlap that may be present in some instances. For example, nonlinear optical devices could be implemented into a variety of architecture that is listed below. Holographic processor is another technology-based class while some other architectures, such as, symbolic substitution may involve use of holograms, but it does not exclude it being a class by itself. The following list gives a classification of optical free space computing:

1. Digital Optical Computing:
   - (a) Pattern coded computing or cellular logic:
     - (i) Optical shadow-casting processor;
     - (ii) Symbolic substitution;
     - (iii) Theta logic based computation.
   - (b) Parallel arithmetic circuits:
   - (c) Hybrid optical computing:
   - (d) Nonlinear optical device based:
   - (e) Threshold logic.
2. Discrete optical computing:
   - (a) Optical fuzzy logic:
   - (b) Optical matrix processors:
     - (i) Vector matrix multiplier;
     - (ii) Differential equation solver;

(iii) Linear algebra processor;
(iv) DFT processor;
(v) Programmable logic array;
(vi) Associative memory processor.
(c) Optical neural network.
3. Analog optical computing:
(a) Adaptive optics processor;
(b) Partially coherent processing (white light processing):
(c) Fourier transform based processor:
(d) Nonlinear contact screen based:
(e) Holographic processors:
(f) Linear optical processors (image differentiation).

We start by discussing some of the device based classes and their underlying concepts: (a) nonlinear optics; (b) SLMs; and (c) hologram based.

Core Device Technologies Used for Free-Space Optical Computing

One of the most difficult challenges of optical computing (OC) is inventing devices that can realize aforementioned key advantages of optics. There exist, however, several key technology areas, where a breakthrough in any one of these will pave the way to real-world optical computing. We discuss here some of the major device technologies that relate to OC.

Spatial light modulator (SLM) converts information from different forms to the optical domain. As a result, SLM is used as an input device to an optical computing system. High contrast ratio, very high speed, and parallel addressing scheme are desirable properties of an SLM as an input device. For example, the SLM could be used to input a 2-dimensional signal or an image into a Fourier transform-based processor. Several applications of SLM are possible:

1. *Optical encoding*: Pattern coded logic can perform logic operations if inputs can be encoded using certain pattern;
2. *Encoding complex filter*: It could encode phase, amplitude or both; and
3. *As phase modulator*: for adaptive optics.

Two types of SLMs are liquid-crystal based and micro-electromechanical (MEM) based. The former uses liquid crystals to change the phase of transmitted or reflected light leading to modulation of phase. Although the most successful commercial application of MEMs is its use in consumer electronics, such as projection TVs or video projectors, in free-space optical computing it can be used as:

(a) an interconnection device;
(b) an SLM for matrix; or
(c) a phase modulating device in AO close loop control of optical phase aberrations or phase only filter.

The heart of the MEMs is tiny electrically controllable mirrors which can steer the incoming beam in a different direction or bend to create a relative optical path difference for the reflected beam.

Algorithms, where an SLM plays a major role, are pattern coded computing, optical matrix processors, adaptive optic processors, partially coherent processing, Fourier transform based processors, and linear optical processors.

Nonlinear Optical Element

A nonlinear optical element is an architecture or device structure which allows for utilization of the nonlinearity of the optical material that produces detectable changes of optical intensity. Figure 1 shows the basic block diagram for an optical computing basic element. To achieve an optical logic gate, one needs a scheme where light can be controlled by light, as current is controlled by current in a transistor. An optical device showing optical bistability can be used for this purpose. Optical bistability is defined as the situation where two different output intensities are possible for a given input intensity.

For example, as shown in Figure 2 below, at the intensity level of C, there are two stable states, one HIGH and one LOW. Just as the transistor has two stable states ON and OFF, the optical bistable device exhibits two states ON and OFF. The fact that such nonlinear behavior could implement logic behavior

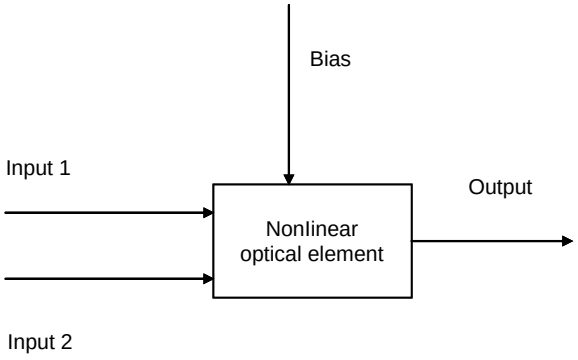

Figure 1 Block diagram of an optical logic gate using nonlinear optical element.

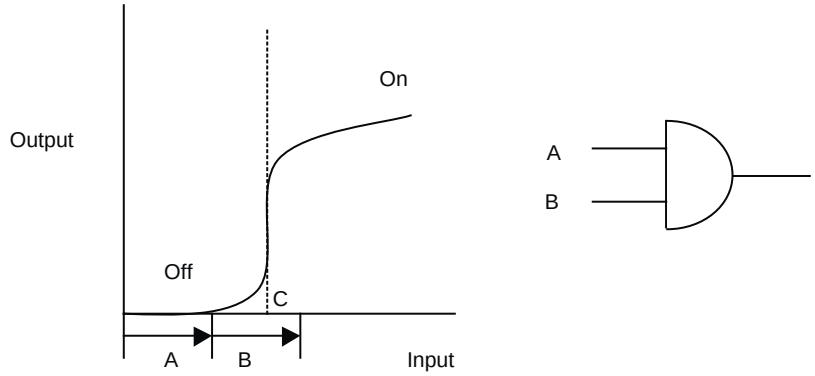

Figure 2 Bistable behavior, a typical AND behavior with inputs A and B.

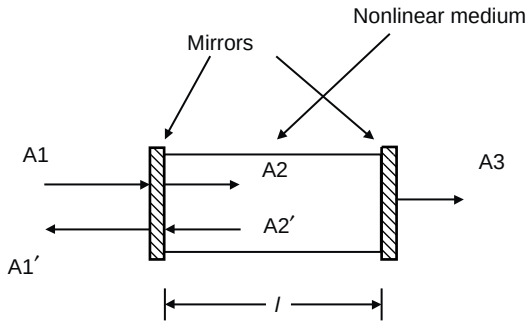

Figure 3 Bistable optical device, nonlinear medium in a Fabry–Perot cavity.

can be explained as follows. Assume that a two input device possesses a nonlinear characteristic as shown in Figure 2. Assume that the input intensity value of 1 is indicated by an intensity level equal to A. When both A and B are equal to 1, then the combined intensity switches the device to HIGH output state. However, if only one input is present, the output will be LOW. Thus, this bistable device acts as a logical AND gate.

To achieve optical bistability, two features are required, namely, nonlinearity and feedback. One way to achieve this is by placing a nonlinear medium in a Fabry–Perot cavity. Figure 3 shows a schematic of these devices. In Figure 3, A_1 is the incident field, A_1' is the reflected field, A_2 and A_2' are the forward and backward fields inside the cavity, respectively, and l is the cavity length.

The coupled wave equation for this system is given by

$$A_2' = \rho A_2 e^{2ikl-\alpha l} \qquad [1a]$$

$$A_2 = \tau A_1 + \rho A_2' \qquad [1b]$$

where, ρ is the amplitude reflectivity and τ is the amplitude transmissivity. The wave vector $k = n\omega/c$ and α is the absorption coefficient. In deriving the above equations, it was assumed that k and α are spatially invariant and real. Solving for A_2, from eqns [1a] and [1b] yields

$$A_2 = \frac{\tau A_1}{1 - \rho^2 e^{2ikl-\alpha l}} \qquad [2]$$

Equation [2] is the so-called Airy's equation which describes the properties of the Fabry–Perot cavity. From eqn [2] it can be seen that if k or α is a sufficiently nonlinear function, this device will show bistability. In general, both k and α can show nonlinearity. Hence optical bistability can be either absorptive or dispersive.

Absorptive Bistability

If the absorption coefficient α depends nonlinearly on the intensity, assuming k is constant, after some manipulation, eqn [2] can be written as

$$I_2 = \frac{TI_1}{[1 - R(1 - \alpha l)]^2} \qquad [3]$$

where, $I_i \propto |A_i|^2$, $T = |\tau|^2$ and $R = |\rho|^2$. In deriving eqn [3], it was assumed that the mirror separation is such that the system is in resonance and $\alpha l \ll 1$. If α depends on the intensity, it can be assumed that it follows the relationship of two level saturable absorbers, for simplicity, which is

$$\alpha = \frac{\alpha_0}{1 + I/I_s} \qquad [4]$$

where, α_0 denotes the unsaturated absorption coefficient, I is the local value of intensity, and I_s is the saturation intensity. Using eqn [4] in eqn [3] yields

$$I_1 = TI_2\left(1 + \frac{C_0}{1 + 2I_2/I_s}\right)^2 \qquad [5]$$

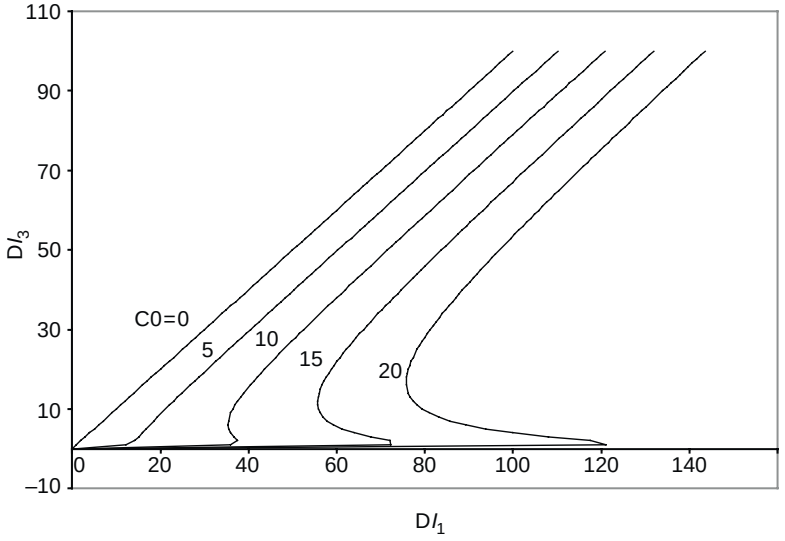

Figure 4 The input–output relationship of absorptive bistability predicted by eqns [5] and [6].

where, $C_0 = R\alpha_0 l/(1-R)$. Also the output intensity I_3 is related to I_2 by

$$I_3 = TI_2 \qquad [6]$$

Using eqns [5] and [6], it can be shown that there can be multiple solutions to the above input–output relationship which predicts the optical bistability. Figure 4 shows a plot of DI_1 versus DI_3, where $D = 2/TI_s$, as a function of various C_0. As can be seen from Figure 4, for a high enough value of C_0, the system possesses multiple solutions.

Dispersive Bistability

The intensity dependence of the refractive index can be written as

$$n = n_0 + n_2 I \qquad [7]$$

If the refractive index n varies nonlinearly with intensity, assuming $\alpha = 0$ and using eqn [7], eqn [2] can be written as

$$A_2 = \frac{\tau A_1}{1-\rho^2 e^{2ikl}} = \frac{\tau A_1}{1-Re^{i\delta}} \qquad [8]$$

where, $\delta = \delta_0 + \delta_2$. δ_0 and δ_2 are given by

$$\delta_0 = \varphi + 2n_0\frac{\omega c}{l}$$
$$\delta_2 = 2n_2 I\frac{\omega c}{l} \qquad [9]$$

where, φ is the phase associated with ρ and the fact that $k = n\omega/c$ is used.

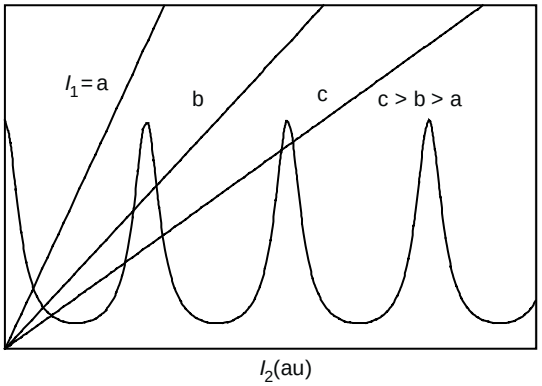

Figure 5 Plots of both sides of eqn [10] as a function of I_2 and for increasing values of input intensity I_1. The oscillatory curve represents the right-hand side of eqn [10] and the straight lines represent the left-hand side with increasing values.

After some manipulation, eqn [8] can be rewritten in terms of intensity as

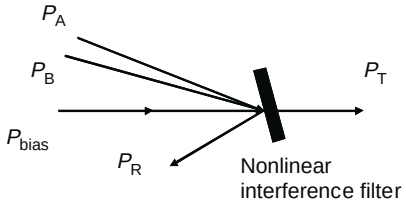
$$\frac{I_2}{I_1} = \frac{1/T}{1+(4R/T^2)\sin^2(\delta/2)} \qquad [10]$$

and

$$\delta = \delta_0 + \left(4n_2\frac{\omega}{c}l\right)I_2 \qquad [11]$$

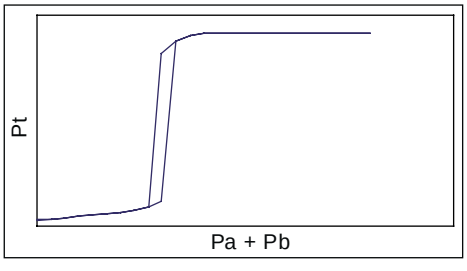
Equation [10] can be solved graphically to show the introduction of bistable behavior as a function of input intensity. Figure 5 shows the plots of both sides of eqn [10] as a function of I_2 and for increasing values of input intensity I_1. The oscillatory curve represents the right-hand side of eqn [10] and the

straight lines represent the left-hand side with increasing values of I_1. It can be readily seen from Figure 5 that at sufficiently high values of I_1, multiple solutions are possible for eqn [10]. This again will give rise to the bistable behavior.



Nonlinear Interference Filters

The optical bistability from the nonlinear interference filters (or etalons) can be used to achieve optical logic gates. The transmission property of these etalons can be modified by another optical beam, known as a bias beam. A typical logic gate and the transmission property are shown in the following figure. If the bias beam is such that, $P_{\text{switch}} - (P_a + P_{\text{bias}}) < P_b$, then the transmitted beam shown in Figure 6b readily follows an AND gate. The truth table for such configurations is shown in Figure 6d.



Four-Wave Mixing

Four Wave Mixing (FWM) can be used to implement various computing functions. Using the photorefractive effect and FWM in a third-order nonlinear optical material, optical phase conjugate beams can be obtained. A schematic of FWM and phase conjugation is shown in Figure 7. The forward pump beam interferes with the probe beam to produce a grating in the photorefractive material. The backward pump beam is then diffracted to produce a beam which retraces the path of the probe beam but has an opposite phase. It can be seen from Figure 7, that the optical phase conjugation can be readily used as an AND logical operator. By using the four-wave mixing, an optical counterpart of transistors has been introduced. FWM have also been used in AND-based optical symbolic substitution (OSS) operations. FWM is also used to produce matched filter-based optical correlators.

Another device showing the optical bistability is the self electro-optic effect device (SEED). SEEDs were used to implement optical logic circuits. The SEEDs are produced by putting multiple quantum wells (MQW) in the intrinsic region of a p-i-n structure. The MQWs are created by placing alternating thin layers of high (barriers) and low (wells) bandgap materials. An electric field is applied to the SEEDs externally. The absorption coefficient is a function of applied bias voltage. When a light beam is incident on these devices, it creates a photocurrent, consequently lowering the bias voltage across the MQW. This, in turn, increases the absorption and when the input optical power is high enough, the system sees a peak absorption and suddenly switches to a lower state and thus shows the bistable behavior. A schematic of SEED is shown in Figure 8.

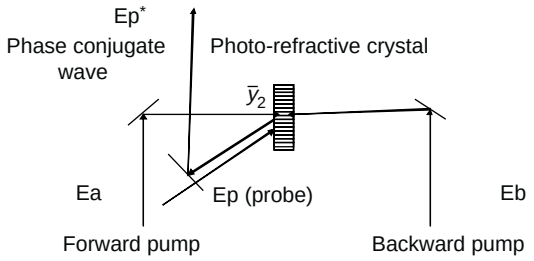

Figure 7 Four-wave mixing setup.

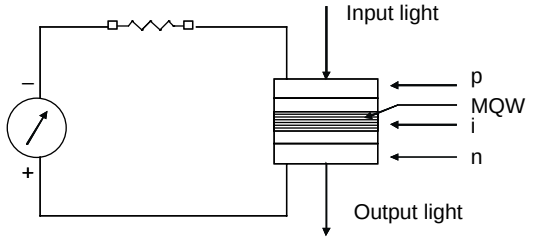

Figure 8 Schematic of self electro-optic effect devices.

Replacing the resistive load by a photodiode, a diode-based SEED (D-SEED) can be constructed, which is analogous to the way diode transistor logic was developed from resistor transistor logic in electronics. Electrically connecting two MQW p-i-n structure symmetric SEEDs (S-SEED) are constructed, which are less sensitive to optical power fluctuations and effectively provide isolation between input and output.

Pattern Coded Optical Computing: Symbolic Substitution or Cellular Logic

This is a keyword which is equivalent to simple digital logic operation. In digital logic, a truth table can describe the relationship between input and output variable. In symbolic substitution logic, this relationship is expressed as a 2D pattern rule. In any specific rule (equivalent to a row in the truth table) of SS logic, a specific 2D pattern is identified and replaced by another pattern. For example, in the case of binary logic, we can express the addition of two binary bits with the following truth table:

Rule number	*Input*		*Output*	
	A	*B*	*C*	*S*
1	0	0	0	0
2	0	1	0	1
3	1	0	0	1
4	1	1	1	0

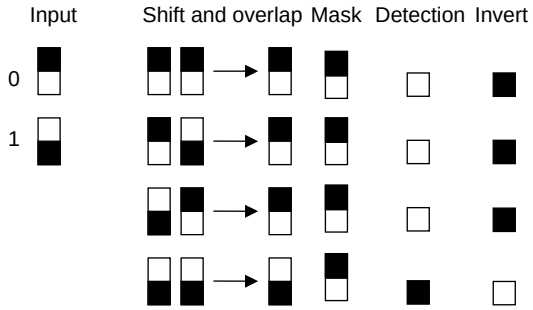

Figure 9 Symbolic substitution example, the two inputs are coded using dual rails. The second column shows the four combinations of inputs (00, 01, 10, and 11). They are shifted and overlapped creating the fourth column. A mask detects the output as a dark pixel appearing through the transparent opening. The dark is inverted to create a detection output.

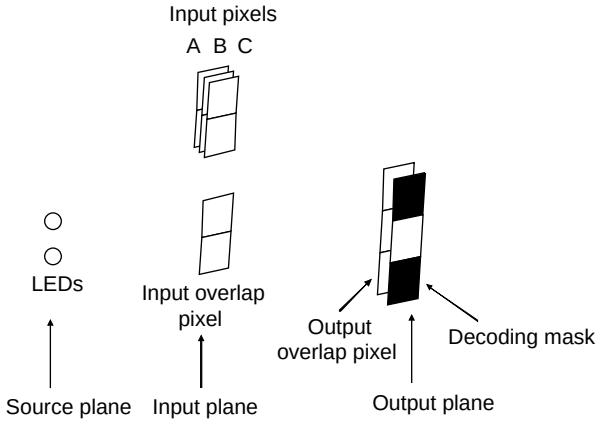
Here A and B are the two digits to be added, C and S are the sum and the carry bit, respectively. To convert this operation to an SS operation, we can say that a two bit binary pattern is identified and replaced by a sum bit and a carry bit. If we now express the above in terms of symbolic substitution, we will say let 0 and 1 be represented by the following 2D symbol. Then the rule for the carry bit generation is shown in Figure 9.

Note that each of these rules has to be implemented individually. However, one can implement these by only generating the 1 output or the zero output, whichever leads to the minimum rule. Here implementing the last rule is convenient, one can make a copy of the whole pattern and then overlap it with its left shift version. This will result in a dark pixel at the origin. This is inverted and then produces a detection output. Natural extension of SS is in signed digit computing, where carry free addition can be achieved, allowing parallel implementation of numerical algorithm using free space optics.

Optical Shadow Casting (OSC)

All digital logic is nonlinear. The nonlinearity of the digital logic is converted into nonlinearity of coding. The OSC system originally proposed by Tanida and Ichioka uses two-dimensional spatially encoded patterns as data input and light emitting diodes (LEDs) as light sources. In the original shadow-casting system, the inputs were represented by vertical and horizontal stripes of opaque and transparent bars. With this system, programmability was attained by changing the LED pattern and it was possible to realize 16 logical operations between two



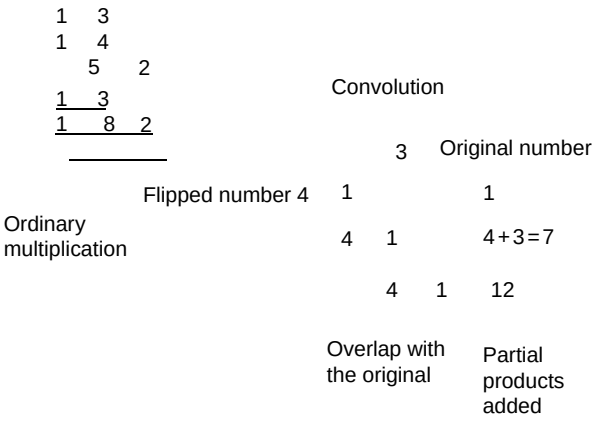


Figure 10 An optical shadow-casting system.

variables as well as a half addition as an example of arithmetic operation. Later, polarized codes were introduced into shadow-casting systems. This improved technique, called the polarization-encoded optical shadow casting (POSC), enabled complex combinational logic units like binary and trinary full adders, as well as image processing applications, to be realized.

The lensless OSC system, as shown in Figure 10, consists of spatially encoded 2D binary pixel patterns as the inputs. The input patterns are kept in close contact at the input plane and the resulting input overlapped pixel pattern is illuminated by a set of LEDs from the source plane. The light originating from each of the LEDs located at the source plane produces a shadow of the input overlap pixel pattern at the output plane. The overlap of these relatively displaced shadows results in an output overlap pixel pattern at the output plane. A decoding mask placed at the output plane is then used to spatially filter and detect the logical output. To prevent crosstalk, specific spacing among the different processing elements must be maintained.

Discrete Processors: Optical Matrix Processor

Most of the discrete optical processing schemes revolve around optical matrix–vector multiplication. Many numerically useful operations such as: (a) linear algebraic operations; (b) signal processing algorithms; (c) Boolean logic; (d) digital multiplication by analog convolution; and (e) neural networks, can be formulated as matrix–vector multiplication. An example of the digital multiplication by analog convolution (DMAC) can be understood by the following numerical example:

The two numbers are convolved as shown above. This is done by reversing one of the numbers (4 1), while keeping the other number in the same order (1 3), then sliding the reversed number to the right, and collecting the element by element products. The second partial products are 4×1 and 1×3 which are then added to give the convolution results. Surprisingly, the weighted number in mixed radix (since numbers that have digits higher than 9, are no longer decimal) has the same value as the product shown in the upper left. It is possible to have fast parallel convolution optically, resulting in fast parallel multiplier. However, an efficient electronic post processor is necessary to convert the mixed radix numbers to the radix of the to-be-multiplied numbers.

A basic optical matrix–vector multiplier is shown in Figure 11. Here the vector, represented by an expanding column of light, is projected onto the 2D matrix, possibly represented by a glass plate or electronically addressable spatial light modulator. As the light representing the vector passes through the transmitting medium, each element of the vector (**I**) gets multiplied by a column of matrix represented by the transmittance of the matrix (T). The product ($\mathbf{I}T$)

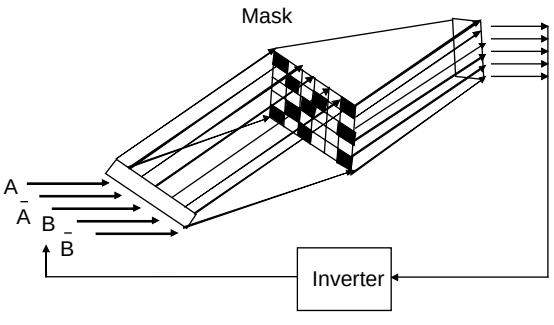

Figure 11 A matrix–vector multiplier.

is integrated horizontally using a cylindrical lens. This leads to an addition operation of the partial products, resulting in the generation of the output product vector. Mathematically:

$$y = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix} \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix}$$

$$= \begin{bmatrix} a_{11}b_1 + a_{12}b_2 + a_{13}b_3 + a_{14}b_4 \\ a_{21}b_1 + a_{22}b_2 + a_{23}b_3 + a_{24}b_4 \\ a_{31}b_1 + a_{32}b_2 + a_{33}b_3 + a_{34}b_4 \\ a_{41}b_1 + a_{42}b_2 + a_{43}b_3 + a_{44}b_4 \end{bmatrix} \quad [12]$$

The above can be achieved if the vector b is expanded as

$$\begin{bmatrix} b_1 & b_2 & b_3 & b_4 \\ b_1 & b_2 & b_3 & b_4 \\ b_1 & b_2 & b_3 & b_4 \\ b_1 & b_2 & b_3 & b_4 \end{bmatrix}$$

and a point-by-point multiplication is performed between the expanded vector and the original matrix. Then the addition is performed by the cylindrical lenses.

Another simple application of vector matrix multiplier is in digital logic, known as programmable logic array (PLA). PLA is an electronic device that consists of a set of AND gates followed by a set of OR gates, which can be organized in AND–OR format suitable for realizing any arbitrary general purpose logic operation. AND logic is performed when light representing a logic level is passed through a transparency representing the other variable; OR is achieved by converging light to a common detector.

$$\text{Assume a function } F = AC + \bar{A}BD + A\bar{B}C \quad [13]$$

where $\bar{A}$ represents the logical inverse of A. Using DeMorgans' theorem in digital logic, this can be expressed as

$$F = \overline{(\bar{A} + \bar{C})} + \overline{(A + \bar{B} + \bar{C})} + \overline{(\bar{A} + B + \bar{C})}$$

$$= \bar{y}_1 + \bar{y}_2 + \bar{y}_2 \quad [14]$$

Now the y_is can be generated by the vector matrix product, as shown below:

$$\text{where } \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix}$$

$$= \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 0 & 0 \end{pmatrix} \begin{pmatrix} A \\ \bar{A} \\ B \\ \bar{B} \\ C \\ \bar{C} \\ D \\ \bar{D} \end{pmatrix} \quad [15]$$

Note here that the AND has been converted to OR, which needs to be inverted and then ORed to generate the function F. A setup shown in Figure 11 can be used to accomplish this. In step 1, the y_is are generated, and then in step 2 they are inverted and summed by a second pass through the same system with a different mask. Other applications of vector–matrix multipliers are in neural networks, where the interconnection weights are represented by the matrix and the inputs are the vector.

Analog Optical Computing

Correlation is a way to detect the presence of signal in additive noise. Optics offer a fast way of performing correlations. The practical motivation of this area comes from the fact that a lens performs a Fourier transform of a two-dimensional signal at its focal plane. The most famous analog optical computing is known as optical matched filter. The theoretical basis of an optical matched filter is in the Fourier theorem of matched filtering which states that the cross correlation between two signals can be formed by multiplying the Fourier transform of the signal and the complex conjugate of the second signal and followed by a subsequent Fourier transform operation. Mathematically:

$$\text{Correlation}(f, g) = \mathrm{F}^{-1}[\mathrm{F}\{f\}^* \text{conjugate}(\mathrm{F}\{g\})] \quad [16]$$

where F represents a Fourier transform operation and F^{-1} represents an inverse transform. Since the lens can easily perform the Fourier transform, and multiplication can be performed by light passing through a medium, the only problem that has to be

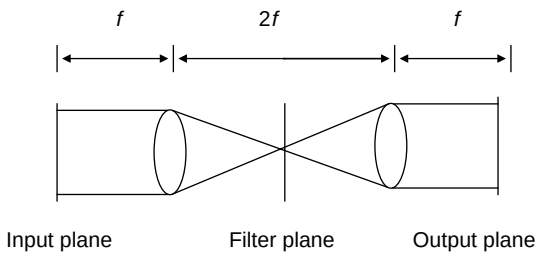

Figure 12 An optical 4-*f* set up. Lenses perform Fourier transform at their focal plane.

solved is to represent the signal and the filter in the optical domain. Since an SLM can represent both the real signal and the complex filter, thus the whole operation can be performed in a 4-*f* setup as shown in Figure 12. The input is displayed in the input plane by an SLM, the first lens performs a Fourier transform. This filter (conjugate F{*g*}) is encoded using another SLM and placed at the filter plane. When light from the F{*f*} passes through the filter, it performs the required multiplication. The second lens performs a second Fourier transform and produces the correlation output at the output plane. Variations of the basic setup exist as a joint transform correlator (JTC) or binary phase-only filter (BPOF). While the JTC achieves the product of the complex domain by adding the two signals and squaring, the BPOF is achieved by simplifying the complex domain filter by numerically approximating it with the binarized phase. Other applications of linear optical processing can be performed in the basic 4-*f* optical setup where filters such as low-pass or high-pass filters, can be set up in the correlation plane.

The hologram base computing treats holograms as a legitimate way of signal transformation from one form to another, just as a lens transforms from one domain to another. Holograms are complex representations that can act on a signal. A lens can be approximated by a hologram, in reality functions of many optical elements, such as lens, grating, prism, and other transformation such as beamsplitting, it can be combined into single computing element known as computer-generated hologram (CGH). The smartness of this type of system depends on how many operations have been replaced by a single CGH.

It is envisioned that optical computing is better suited for special purpose computing rather than general purpose computing. However, the future of optical computing lies in the marriage of appropriate device technology with the right architecture at the right applications. The development of quantum computing may hold new promises for optical computing.

List of Units and Nomenclature

DMAC	Digital multiplication by analog convolution
JTC	Joint transform correlator
OC	Optical computing
PLA	Programmable logic array
QC	Quantum computing
SLM	Spatial light modulator

Incoherent Analog Optical Processors

S Jutamulia, University of Northern California, Petaluma, CA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

After low-cost lasers became widely available, it seemed that incoherent analog optical processing was no longer important. In general, incoherent optical processing has no apparent significant advantages, as compared with its coherent optical counterpart or digital computer processing. However, although nobody now attempts to build an incoherent optical processor, such as an incoherent correlator, most instruments are still operating using incoherent or natural light. These incoherent instruments relate to imaging, including cameras, microscopes, telescopes, projection displays, and lithographic equipment. From this point of view, it is still very important to study the principles of incoherent analog optical processing, in order to further progress or improve the incoherent image.

Incoherent Image Formation

The image formation in a coherent optical system can be explained using the linear system. A perfect point $\delta(x, y)$ in the input plane is imaged in the output plane as the impulse response of the system $h(x, y)$. When the input is only a single point, the output amplitude is simply $h(x, y)$ and the output intensity is $|h(x, y)|^2$. Accordingly, the function of $|h(x, y)|^2$ is called point spread function (PSF).

If we consider that the input object is the collection of a large number of very fine points, under coherent light illumination, the output image will be the collection of the same number of blurred spots. The shape of each blurred spot is $h(x, y)$. If the amplitude function of input object is $f(x, y)$, the amplitude function of output image is

$$o(x, y) = \int\int_{-\infty}^{\infty} f(p, q)h(x - p, y - q)\mathrm{d}p\ \mathrm{d}q \qquad [1]$$

which is a convolution of $f(x, y)$ and $h(x, y)$. The intensity function of output image is

$$|o(x, y)|^2 = \left| \int\int_{-\infty}^{\infty} f(p, q)h(x - p, y - q)\mathrm{d}p\ \mathrm{d}q \right|^2 \qquad [2]$$

According to the convolution theorem, in the Fourier transform domain or frequency domain, we have

$$O(u, v) = F(u, v)H(u, v) \qquad [3]$$

where $O(u, v)$, $F(u, v)$, and $H(u, v)$ are the Fourier transforms of $o(x, y)$, $f(x, y)$, and $h(x, y)$, respectively. $H(u, v)$ is the transfer function of the coherent imaging system. To distinguish it from the incoherent imaging system, it is also called coherent transfer function (CTF).

The same optical imaging system is now illuminated with incoherent light instead of coherent light. The amplitude impulse response is still the same $h(x, y)$, and the point spread function is also the same $|h(x, y)|^2$. Similarly, the input object is the collection of perfect points, and the output image is the collection of blurred images of each point. However, since the illuminating light is incoherent, light from any point in the input object is not coherent with light from any other points. Thus, there is no interference with light from different points. The output image is simply the addition of intensity patterns generated by each point in the input object. The amplitude function of the output image is not computable. However, the intensity function of the output image is

$$|o(x,y)|^2 = \int\int_{-\infty}^{\infty} |f(p,q)|^2 |h(x-p,y-q)|^2 \mathrm{d}p\,\mathrm{d}q \qquad [4]$$

In the frequency domain, we now have

$$O_I(u,v) = F_I(u,v)H_I(u,v) \qquad [5]$$

where $O_I(u,v)$, $F_I(u,v)$, $H_I(u,v)$ are Fourier transforms of $|o(x,y)|^2$, $|f(x,y)|^2$, and $|h(x,y)|^2$, respectively. The intensity impulse response $|h(x,y)|^2$ is the PSF. Note that the index I of O_I, F_I, and H_I denotes intensity. The function $H_I(u,v)$ is now the transfer function of the incoherent imaging system, which is called optical transfer function (OTF).

Referring to Fourier analysis, if $H(u, v)$ is the Fourier transform of $h(x, y)$, the Fourier transform of $|h(x, y)|^2$ is the autocorrelation of $H(u, v)$ as follows:

$$H_I(u, v) = \int\int_{-\infty}^{\infty} H(p, q)H^*(p - u, q - v)\mathrm{d}p\ \mathrm{d}q \qquad [6]$$

The OTF (the function $H_I(u, v)$) is the autocorrelation of CTF (the function $H(u, v)$), which is a complex

function in general. It can be written as

$$\text{OTF} = |\text{OTF}| \exp(i\phi) \quad [7]$$

We can further write

$$\text{MTF} = |\text{OTF}| \quad [8]$$

where MTF stands for modulation transfer function, and

$$\text{PTF} = \phi \quad [9]$$

where PTF stands for phase transfer function.

Measurement of MTF

The MTF of an incoherent imaging system can be measured empirically using an input that is a cosine grating having intensity transmittance function:

$$|f(x)|^2 = 1 + \cos(2\pi a x) \quad [10]$$

where a is the frequency of grating. The output or the image intensity function will be

$$|o(x)|^2 = 1 + m\cos(2\pi a x + \varphi) \quad [11]$$

where m, the contrast, can be measured by

$$m = \frac{|o(x)|^2_{\max} - |o(x)|^2_{\min}}{|o(x)|^2_{\max} + |o(x)|^2_{\min}} \quad [12]$$

In the frequency domain, the Fourier transform of the input function is

$$F_I(u) = \delta(u) + \tfrac{1}{2}\delta(u-a) + \tfrac{1}{2}\delta(u+a) \quad [13]$$

The Fourier transform of the output function will be

$$O_I(u) = F_I(u)\text{OTF}(u) \quad [14]$$

Substitution of eqn [13] yields

$$O_I(u) = \delta(u)\text{OTF}(0) + \tfrac{1}{2}\delta(u-a)\text{OTF}(a) + \tfrac{1}{2}\delta(u+a)\text{OTF}(-a) \quad [15]$$

Notice that

$$\text{OTF}(0) = 1 \quad [16]$$

due to normalization, and

$$\text{OTF}(a) = \text{OTF}(-a) \quad [17]$$

Because OTF is an autocorrelation function, it must be a symmetric function. Substitution of eqns [16] and [17] into eqn [15] yields

$$O_I(u) = \delta(u) + \tfrac{1}{2}\delta(u-a)\text{OTF}(a) + \tfrac{1}{2}\delta(u+a)\text{OTF}(a) \quad [18]$$

Remembering that OTF is a complex function given in eqn [7], we can write

$$\text{OTF}(a) = \text{MTF}(a)\exp(i\phi(a)) \quad [19]$$

Substitution of eqn [19] into eqn [18] yields

$$O_I(u) = \delta(u) + \tfrac{1}{2}\delta(u-a)\text{MTF}(a)\exp(i\phi(a)) + \tfrac{1}{2}\delta(u+a)\text{MTF}(a)\exp(i\phi(a)) \quad [20]$$

The inverse Fourier transform of eqn [20] is

$$|o(x)|^2 = 1 + \text{MTF}(a)\cos(2\pi a x + \phi(a)) \quad [21]$$

By comparing eqn [21] and eqn [11], we find

$$\text{MTF}(a) = m \quad [22]$$

and the PTF

$$\phi(a) = \varphi \quad [23]$$

Therefore, the MTF at frequency $u = a$ of the incoherent imaging system can be measured using eqn [12]. To get the complete MTF(u), the measurement is repeated using cosine gratings with different frequencies. The PTF can also be measured at the same time.

Incoherent Spatial Filtering

In the 4f coherent optical processor, the first lens performs the Fourier transform, and the second lens performs the inverse Fourier transform, as shown in Figure 1. The Fourier transform domain or frequency domain is materialized in the frequency plane that is the back focal plane of the first lens.

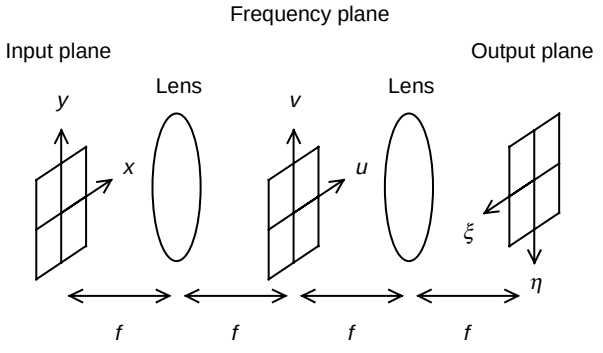

Figure 1 4f coherent optical processor consists of two Fourier transform lenses.

Thus, the Fourier transform of the object can be visualized in the frequency plane. For example, if the object is a grating, we will see its frequency components in the frequency plane. However, if the coherent illumination (e.g., from a laser) is replaced with incoherent illumination (e.g., from a lightbulb), the pattern of Fourier transform in the frequency plane disappears. Does it mean that we can no longer perform spatial filtering? No, we still can perform spatial filtering, although the pattern of Fourier transform is no longer visualized.

Consider that we have a spatial filter in the frequency plane whose physical form can be expressed by the function $H(u, v)$. For illustration, this spatial filter is simply a small one-dimensional window $H(u)$, as shown in Figure 2a. If the 4f optical processor is illuminated with coherent light, the CTF of the system is $H(u)$ itself as shown in Figure 2b. However, if the 4f optical processor is illuminated with incoherent light, we will use OTF instead of CTF in the analysis of linear system. The OTF is the autocorrelation of CTF, which is graphically depicted in Figure 2c. In this example, since the OTF is real and positive, the MTF is identical to the OTF.

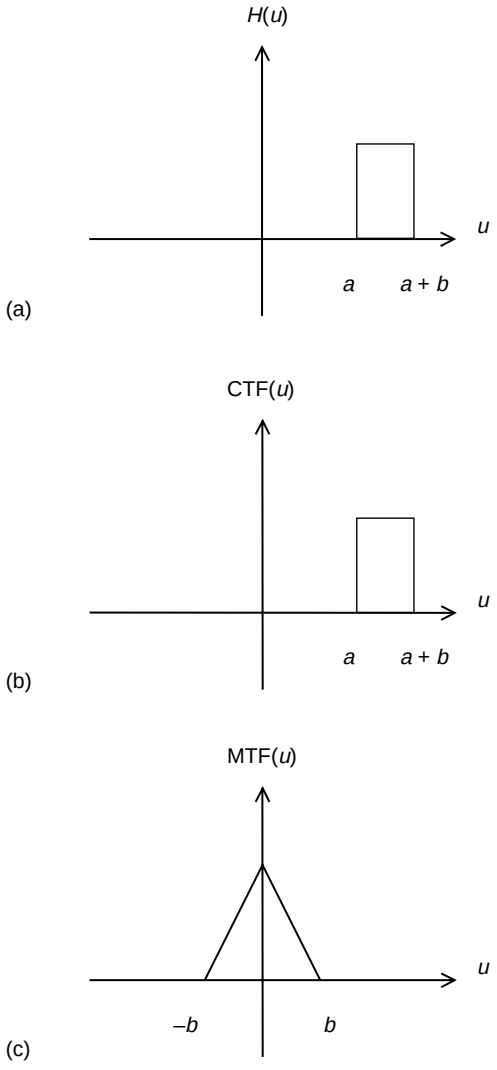

Figure 2 (a) One-dimensional window in frequency plane functions as a spatial filter. (b) CTF and (c) OTF or MTF produced by spatial filter (a).

For simplicity, we analyze and show a one-dimensional filter only in a two-dimensional graph. It certainly can be extended to the two-dimensional filter. And we need a three-dimensional graph to show the two-dimensional autocorrelation.

It is important to note that, although the CTF is a high pass filter that passes frequencies in the band of $u = a$ to $u = a + b$, the MTF is a low pass filter that passes frequencies from $u = -b$ to $u = b$, independent of a. This indicates that an incoherent processor cannot enhance high frequency. It is always a low pass processor. It is interesting to note that the OTF is independent of the location of the filter $u = a$, but it is determined by the width of the filter $\Delta u = b$ only.

Accordingly, an aperture made up of randomly distributed pinholes behaves as a low pass filter in an incoherent imaging system. The cut-off frequency of such a filter can be derived from the diameter of the pinhole, which is equivalent to Figure 2b. The procedure for using this filter is simple. If a camera is used to take a picture, the random pinhole filter can be simply attached to the camera lens. The picture taken will not consist of high-frequency components, because the filter acts like a low pass filter. The low pass filtering can also be done by reducing the aperture of camera. However, by doing so, the light entering the camera is also reduced. The use of a random pinhole filter removes high frequencies without reducing the light intensity. When the random pinhole filter is placed in the frequency plane of a 4f coherent optical processor, it can be used to reduce the speckle noise. Note that the speckle noise is the main drawback in coherent optical processing.

Incoherent Complex Matched Spatial Filtering

Lohmann and Werlich pointed out that the Vander Lugt correlator can also be operated with incoherent light. In the coherent Vander Lugt correlator the correlation term is:

$$o_3(\xi, \eta) = \int\int_{-\infty}^{\infty} f(\alpha, \beta) g^*(\alpha - \xi, \beta - \eta) \mathrm{d}\alpha \mathrm{d}\beta \qquad [24]$$

Its intensity distribution is

$$|o_3(\xi,\eta)|^2 = \left| \int\int_{-\infty}^{\infty} f(\alpha,\beta) g*(\alpha-\xi,\beta-\eta) \mathrm{d}\alpha \mathrm{d}\beta \right|^2 \quad [25]$$

However, when the input object is illuminated with incoherent light instead of coherent light, the intensity distribution of the correlation term becomes

$$|o_3(\xi,\eta)|^2 = \int\int_{-\infty}^{\infty} |f(\alpha,\beta)|^2 |g(\alpha-\xi,\beta-\eta)|^2 \mathrm{d}\alpha \mathrm{d}\beta \quad [26]$$

Equation [26] shows the correlation of $|f(x,y)|^2$ and $|g(x,y)|^2$. Therefore, when $f(x,y)$ is identical to $g(x,y)$, the correlation peak always appears regardless of whether the illumination is coherent or incoherent. However, the detailed structures of the coherent and incoherent correlation outputs are different. Note that the joint transform correlator cannot be operated using incoherent light, since no joint Fourier spectra will be formed.

Depixelization of Projection Display

Recently, a technique to remove the pixel structure from an image projected by liquid crystal projection display has been reported. A liquid crystal projection display must have a pixel structure to form an image. Can we remove this pixel structure from the projected image to obtain a movie-like image? It is well known that a single hole in the frequency plane can perform a coherent spatial filtering, such that the pixel structure will disappear from the output image.

Because of the pixel structure, we get multiple Fourier spectra in the frequency plane. By passing only one spectrum order through the hole in the frequency plane, the pixel structure can be removed as shown in Figure 3.

It is interesting to note that selecting any one of the spectra will produce the image at the same location.

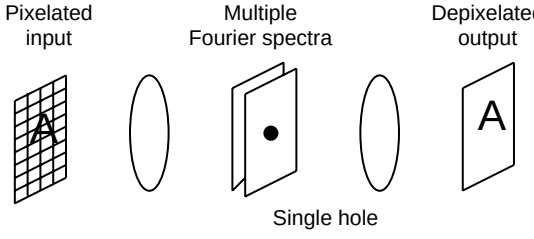

Figure 3 Removal of pixel structure using a single hole in frequency plane. Most of the energy is wasted and the output intensity is dim.

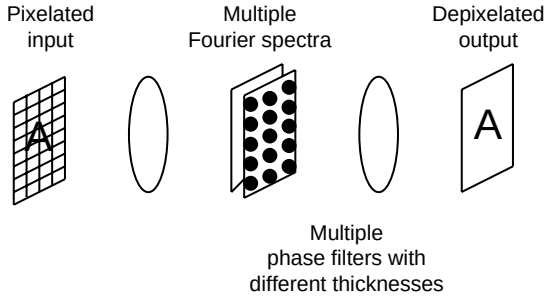

Figure 4 Removal of pixel structure using multiple phase filters with different thickness to cover each Fourier spectrum order. No energy is wasted and the output intensity is very bright.

However, if two spectra are passed, on the top of the produced image, Young interference fringes are also produced. If all spectra are passed, the produced interference fringes are in fact the pixel structure itself. By passing only one spectrum order and blocking most spectrum orders, we lose most of the energy. The projected image will be very dim, although the pixel structure is removed.

To overcome this problem, we may cover each spectrum order with a transparent material having different thickness as shown in Figure 4. Thus, every spectrum order is passed and delayed by a phase filter with a different thickness. If the delay produced by the phase filter is larger than the coherent length of light, every spectrum order is no longer coherent to each other. In other words, the resultant image is the sum of the intensities of all images. As a result, the pixel structure does not appear, and no intensity is lost. For a white light source, since the frequency bandwidth is large, the coherent length is typically on the order of several tens of μm.

This technique can significantly improve the quality of the liquid crystal projection display. Figure 5 shows the experimental result of a depixelated projection image. Figure 5a shows the projected image of an input with pixel structure when no phase filter is applied in the frequency plane. Figure 5b shows the projected image of the same input with pixel structure when phase filters are applied in the frequency plane. The pixel structure is successfully removed as shown in Figure 5b.

Computed Tomography

The computed tomography or CT using X-ray is usually considered beyond optical information processing. However, it is interesting to review the principle of the X-ray CT, since the X-ray source is incoherent, and the CT image reconstruction utilizes Fourier transformation that is commonly used in

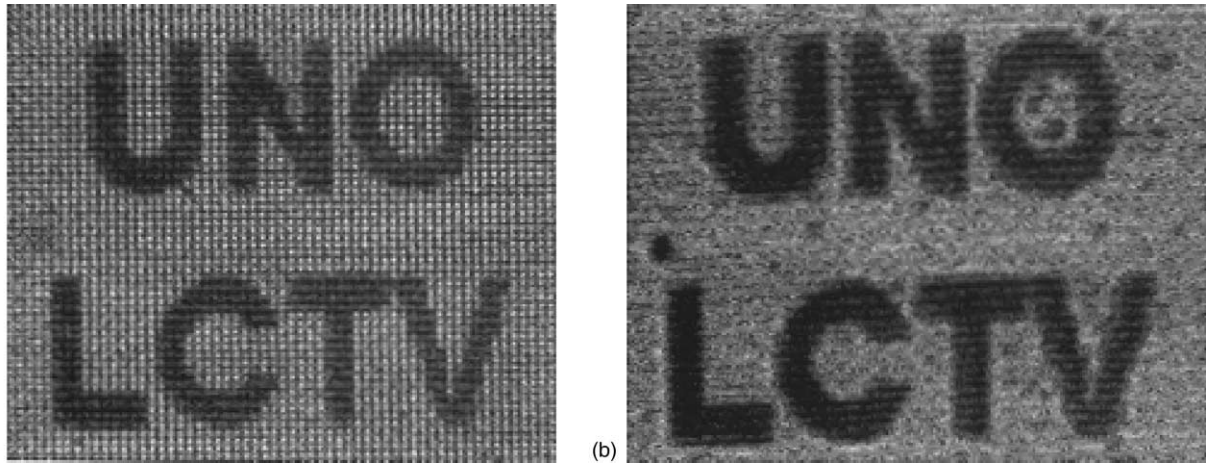

Figure 5 (a) Projected image consists of pixel structure when no phase filter is applied in the frequency plane. (b) Depixelated image is produced when phase filters are applied in the frequency plane.

optical information processing. The X-ray CT is used for taking the cross-section picture of the human body. Note that a conventional X-ray picture only provides a projection instead of a cross-section picture.

Consider the case when an X-ray penetrates through an object characterized by its attenuation coefficient or density function $f(x, y)$ as shown in Figure 6. The detected X-ray intensity is

$$I = I_0 \exp - \left[\int f(x, y) \mathrm{d}s \right] \qquad [27]$$

where I_0 is the original intensity. Equation [27] can be written as

$$\int f(x, y) \mathrm{d}s = -\ln \frac{I}{I_0} \qquad [28]$$

Apparently, we cannot directly measure $f(x, y)$, although we can obtain $\int f(x, y) \mathrm{d}s$ from the measurement of I and I_0. However, we want to get the cross-section picture which is the density function $f(x, y)$. The basic idea is to compute $f(x, y)$ from its Fourier transform $F(u, v)$, and $F(u, v)$ is derived from eqn [28]. $F(u, v)$ can be expressed as

$$F(u, v) = \int \int_{-\infty}^{\infty} f(x, y) \exp[-\mathrm{i}2\pi(ux + vy)] \mathrm{d}x \, \mathrm{d}y \qquad [29]$$

For $v = 0$, eqn (29) becomes

$$F(u, 0) = \int \int_{-\infty}^{\infty} f(x, y) \exp[-\mathrm{i}2\pi ux] \mathrm{d}x \, \mathrm{d}y \qquad [30]$$

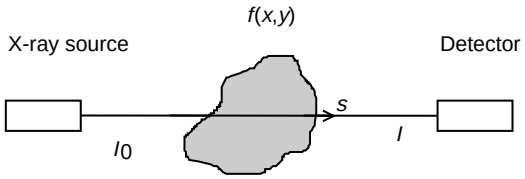

Figure 6 X-ray passes through object having density function $f(x, y)$.

which can be written

$$F(u, 0) = \int_{-\infty}^{\infty} p(x) \exp[-\mathrm{i}2\pi ux] \mathrm{d}x \qquad [31]$$

where

$$p(x) = \int_{-\infty}^{\infty} f(x, y) \mathrm{d}y \qquad [32]$$

The projection function $p(x)$ given by eqn [32] can be obtained using an X-ray parallel beam as shown in Figure 7. Then $F(u, 0)$ can be computed using computer based on eqn [31]. $F(u, 0)$ is the Fourier transform along the u-axis. To get other data, we rotate the coordinate (u, v) to (u', v') by a small angle α. Correspondingly, the coordinate (x, y) is also rotated to (x', y') by the same angle α while the object is not rotated as shown in Figure 8.

From the measurement shown in Figure 8, we can get $p(x')$, which, in turn, provides $F(u', v' = 0)$. By increasing the rotation angle α, we will get other data of $F(u'', v'' = 0)$. The completion of rotation of 180 degrees will give us the data in the frequency domain (u, v) as shown in Figure 9.

After the data $F(u, v)$ is collected, as shown in Figure 9, $F(u, v)$ can be inverse Fourier transformed to

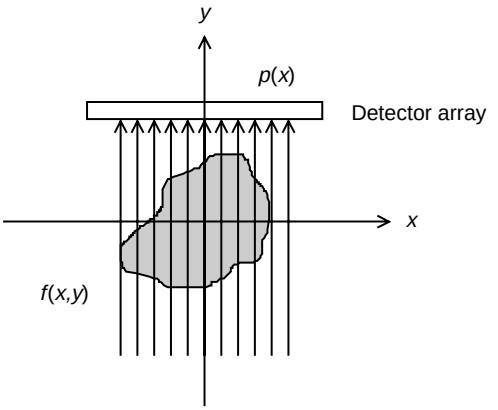

Figure 7 X-ray parallel beam passes through the object to produce projection function $p(x)$.

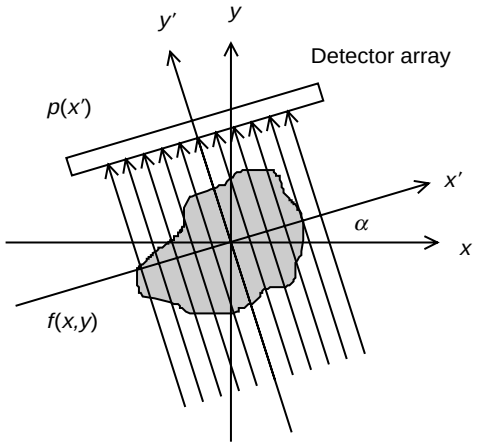

Figure 8 Rotated X-ray parallel beam produces the rotated projection function $p(x')$.

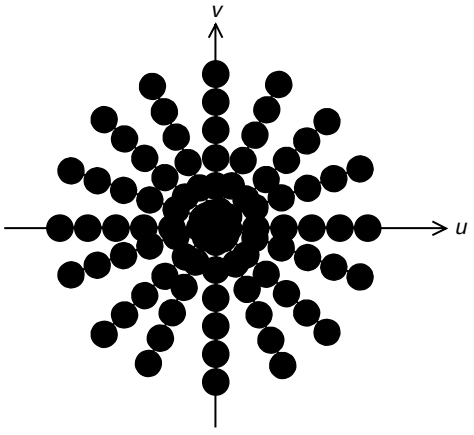

Figure 9 $F(u, v)$ computed from a set of rotated projection functions.

produce $f(x, y)$. There are two approaches in the inverse Fourier transform. The first approach is to interpolate the computed value $F(u, v)$ such that the value of $F(u, v)$, on a regular grid structure, can be defined before an inverse Fourier transform can be taken.

The second approach is to apply polar coordinates, instead of Cartesian coordinates, to the inverse Fourier transform, such that no interpolation in frequency domain (u, v) is required. The inverse Fourier transform in Cartesian coordinates is as follows:

$$f(x, y) = \int\int_{-\infty}^{\infty} F(u, v) \exp[i2\pi(ux + vy)]du\, dv \quad [33]$$

It can be written in polar coordinates as:

$$f(x,y) = \int_0^{2\pi}\int_0^{\infty} F(\rho\cos\phi, \rho\sin\phi) \times \exp[i2\pi\rho(x\cos\phi + y\sin\phi)]|\rho| d\rho\, d\phi \quad [34]$$

where

$$u = \rho\cos\phi \quad [35]$$

$$v = \rho\sin\phi \quad [36]$$

Therefore $f(x,y)$ can be obtained from the collected $F(u,v)$, as shown in **Figure 9**, without further interpolation using eqn [34]. Note that eqns [31], [33], and [34] are computed using a computer program.

Optical Bit-Serial Computing

A D McAulay, Lehigh University, Bethlehem, PA, USA

Why Optical Bit-Serial Computing?

Optical bit-serial computing will lower cost and improve dataflow rates in optical telecommunications and associated computing. Moreover, the electromagnetic immunity of optics will enhance security for computing as well as for communications. Also, absence of sparking with optics enables safe operation, even in hazardous environments.

Currently, optical bit-serial communication involves passing terabits of data per second (10^{12} bps) – thousands of encyclopedias per second – along an optical fiber by switching light of multiple colors on and off, representing '1' and '0' bits respectively. Replacing electronic computing functions, constrained to tens of gigabits per second (10^9 bps), with integrated optics, ones of much higher speed, enables faster flow rates – allowing continuation of the annual doubling of capacity-distance that has occurred since the 1970s. Cost is reduced by eliminating the demultiplexing and multiplexing for optic-electronic-optic (OEO) conversions. Two illustrative areas of optical bit-serial computing for replacing electronic computing functions are described: computing at up to 40 Gbps with semiconductor optical amplifiers (SOAs) and computing at higher bit rates with integrated optic components. Several books address the relevant technical background: free-space optical information processing, optical computer architectures, optical fiber communications, and integrated optics.

Computing with Semiconductor Optical Amplifiers

Semiconductor optical amplifiers, SOAs, allow nonlinear operations (switching, logic) at low power (mW) because of amplification – typically up to 1000. An SOA is a laser diode with antireflection coatings in place of reflecting facets. Light pulses at bit rates in excess of 40 Gbps are amplified by absorbing power from an electronic pump. SOAs are used in the following, at bit rates up to 40 Gbps, for nonlinear operations in cross-gain, cross-phase, or cross-polarization.

SOA-XGM for Logic

Figure 1 shows an SOA in cross-gain modulation (XGM) performing a NOR function. Either A or B inputs at a '1' level, driving the SOA through couplers into saturation, lowering its gain. A continuous wave at C, having a different frequency λ_3, from that of A, λ_1 and B, λ_2, experiences the decrease in gain, resulting in an output '0' level at frequency λ_3. The filter in Figure 1 can be avoided by counter-propagating A and B through the SOA from right to left. XOR gates use interference between two incoming streams of bits (locked to identical frequency, phase, polarization) to correlate headers on internet protocol (IP) address headers – similar to matching zip codes in postal mail routing machines. Bit-serial-adders are constructed from combinations of XOR and NOR gates; subsequently the adders are used to construct ripple-carry-adders for word addition. In addition, NOR gates are used to construct flip-flops; hence registers which form short-term memory.

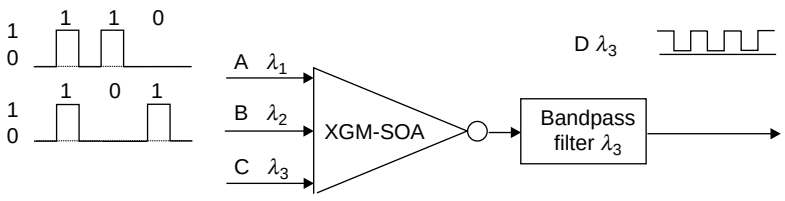

Figure 1 Optical XGM-SOA NOR gate.

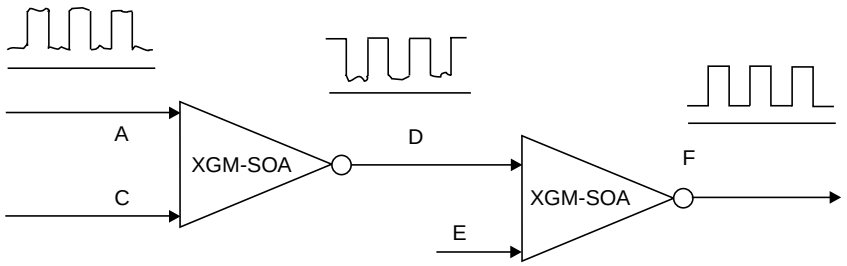

Figure 2 Optical XGM-SOA 2R signal regeneration.

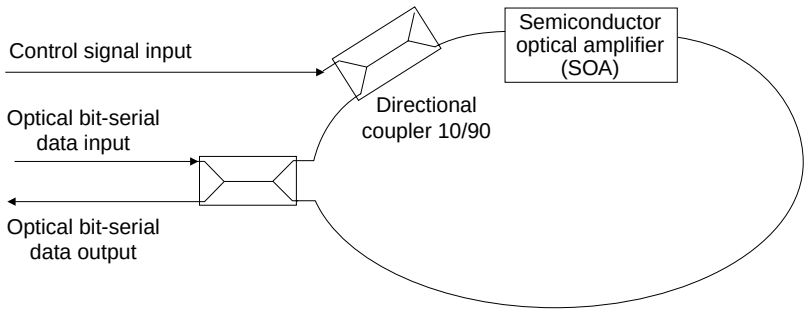

Figure 3 XPM-SOA in Sagnac interferometer for optical manipulation of bits at high data rates.

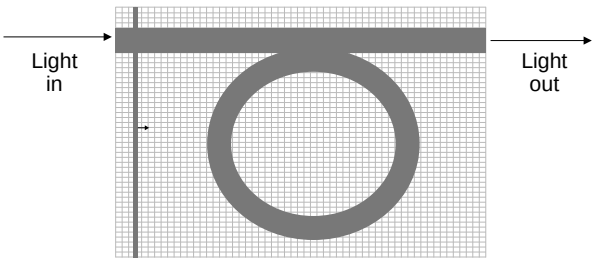

Figure 4 Integrated optic Optiwave layout for microring resonator.

SOA-XGM for Frequency Conversion

Ignoring input B, the bit information in Figure 1 has been transferred from carrier frequency A onto the carrier frequency C, with inversion. This enables switching of signals in wavelength division multiplexing (WDM), for example, color reuse is simplified and a color red is routed to the location where blue was previously routed; this is equivalent to time slot interchangers for switching in time division multiplexing (TDM).

SOA-XGM for 2-R Signal Regeneration

Figure 2 show how two SOAs may be used in sequence to restore signal levels distorted by propagation or computation; reamplification and reshaping (2-R). The '1' level at the output of the first SOA is clipped by gain saturation, removing noise, this becoming the '0' level at the output of the second SOA. The second SOA clips the '1' level at the output.

SOA-XPM with Interferometer

In cross-phase modulation (XPM), the signal at A, Figure 1, changes the phase of carrier for signal C passing through the SOA (signal levels may be less than for XGM). Inclusion of an SOA in an interferometer, Mach–Zehnder or Sagnac, converts phase to intensity for frequency conversion, switching or high-speed bit manipulation. Figure 3 shows a control pulse entering a coupler at the left and providing a control input to the SOA at one frequency. The bits circulating round the loop at a different frequency can be switched on and off by the control pulse, to synchronize or manipulate high bit rate signals or for frequency conversion.

Computing with Integrated Optics

Combining several discrete optical components into a single optical chip is more beneficial than in electronic very large-scale integration (VLSI) because optical connections require greater precision; moreover bit rates are higher because photons, unlike electrons, have no mass or charge (only spin).

Integrated Optic Microring Resonator

Figure 4 shows a microring resonator in an integrated optic chip for optical filtering, light entering at the left couples into the loop. For loop lengths that are a multiple of wavelength, light cycling the loop is in phase and resonance occurs. At resonant frequencies,

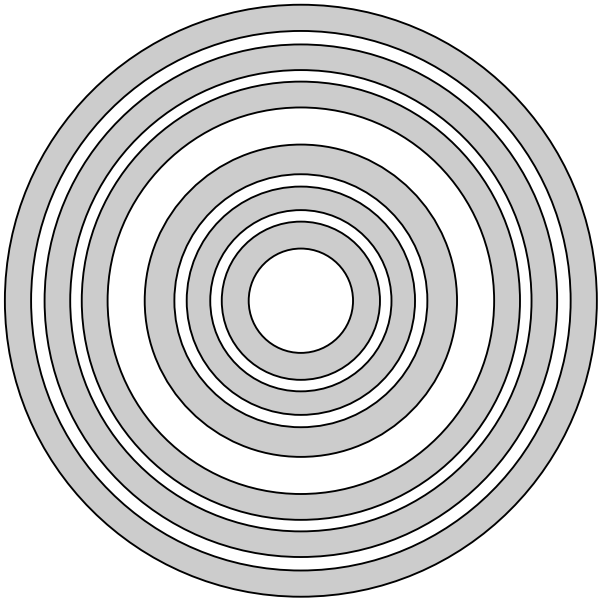

Figure 5 Integrated optic Optiwave layout for Bragg microring resonator.

light exiting the loop is out of phase with that in the linear guide, causing cancellation of the input. As frequency varies away from resonance, light passes and the device acts as a notch filter to block light at the resonant frequencies. With nonlinear Kerr material, low-level light intensity may be used to change a resonant frequency to make a switch.

Bragg Integrated Optic Microring Resonator

Performance is improved by using a Bragg microring resonator, Figure 5, which confines light in the central light colored ring by dielectric mirror reflection from Bragg gratings on either side. The refractive index is less in the ring than in the surrounding regions, in contrast to a conventional waveguide (used in Figure 4) that guides by total internal reflection. The higher reflectivity, smaller ring radius and lower refractive index – these help to reduce power loss, volume, and travel time around the ring. This increases filter selectivity, drives up peak power for enhanced nonlinearity for switching, decreases stored energy for fast response, and increases frequency range (free spectral range, *FSR*). In this case, an equivalent photonic crystal may be more expensive because it requires higher resolution lithography and greater refractive index contrast.

Photonic Crystal Mach–Zehnder Switch

Recently developed photonic crystal technology allows a reduction in integrated optic chip size from centimeters to submillimeters. The 2D or 3D periodic

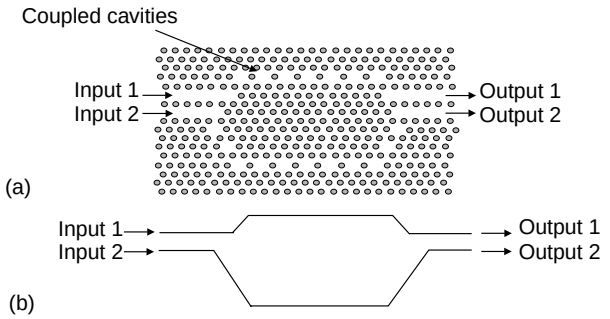

Figure 6 Proposed photonic crystal Mach–Zehnder interferometer.

structure of dielectric variations emulates crystals and provides dielectric mirror reflections in multiple dimensions for lossless waveguide bends, high *Q* resonators, and slowing of wave propagation to enhance effective nonlinearity of materials. Figure 6 shows a proposed 2D photonic crystal Mach–Zehnder interferometer switch in which light is split into two paths by a coupler and propagation velocity is slowed for enhancing nonlinearity by using coupled-resonator optical waveguides (CROWs), in which alternate posts of different dielectric constant remain in the waveguides to form coupled cavities.

Conclusion

Optical bit-serial computing can reduce cost and increase flow-rate for expanding telecommunication network capacity, while providing enhanced security from electromagnetic sabotage and tampering. Advances in integrated optics (microring resonators), progress in optoelectronic components (SOAs), improved materials and fabrication techniques – these technologies enable cost-effective optical bit-serial computing solutions for future telecommunication evolution.

Optical Digital Image Processing

B L Shoop, United States Military Academy, West Point, NY, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Optical approaches to image processing provide a natural method by which to obtain the inherent advantages associated with optics including massive parallelism, high-speed processing, and the inherent compatibility with image formats. Early applications of optics employed analog processing techniques with the most common being the optical Fourier transform, matrix-vector processors, and correlators. Later, advances in digital signal processing (DSP), digital storage, and digital communication systems demonstrated the potential for higher resolution, improved flexibility and functionality, and increased noise immunity over analog techniques and quickly became the preferred method for accurate signal processing. Consequently, optical processing architectures, that incorporated digital processing techniques, were explored. Advances in very large-scale integration (VLSI) electronic circuitry and optoelectronic devices later enabled smart pixel technology, which integrates the programmability and processing of electronic circuitry with the two-dimensional (2D) nature of an optical architecture and made possible a particular realization of optical digital image processing. This chapter describes an application of optical digital image processing, based on smart pixel technology, called digital image halftoning.

Natural images are, by definition, continuous in intensity and color. Halftoning is the process by which a continuous-tone, gray-scale image is converted to one containing only binary output pixels. Halftoning can be thought of as an image compression technique whereby a high-resolution image is transformed to a low-resolution image containing only black-and-white pixels. The transformation from a continuous-tone, gray-scale image to one containing only binary-valued pixels is also similar, in principle, to low-resolution analog-to-digital (A/D) conversion.

An early manual approach to printing continuous-tone images, using only the presence or absence of ink, is the Mezzotint. Ludwig von Siegen (1609–1680), an amateur Dutch printmaker, first invented the mezzotint, or 'half tone process', in 1640. The process later came into prominence in England during the early eighteenth century. Mezzotints are produced on copper plates where the surface of the plate is roughed with a tool called the Mezzotint Rocker, shaped like a wide chisel with a curved and serrated edge. By rocking the toothed edge backwards and forwards over the plate, a rough burr is produced which holds the ink. The dark regions of an image were roughed in a random fashion, while the areas to be lightened were scraped and burnished. This process was found to be especially useful for the reproduction of paintings, due to its ability to capture the subtlest gradations of tone from rich, velvety blacks to glowing highlights. The mezzotint is, therefore, an early artistic predecessor to the modern day halftone.

Optical halftoning has been in use by commercial printers for over 100 years. Commercial halftone screens are based on a discovery made by William Henry Fox Talbot (1800–1877), in 1852. He demonstrated the feasibility of optical halftoning by photographing an image through a loosely woven fabric or 'screen'. In the 1890s, this process came into practical use when the halftone screen, consisting of two ruled glass plates cemented together, became commercially available. Commercial halftone screens produce an effect of variably sized dots on the photographic plate that gives the illusion of a continuous tone image.

Digital image halftoning, sometimes referred to as spatial dithering, is the process of converting an

electronic continuous-tone, gray-scale image to one containing only binary-valued pixels, for the purpose of displaying, printing, or storing the image. The underlying concept is to provide the viewer of the image with the illusion of viewing a continuous-tone image when, in fact, only black and white pixel values are used in the rendering. This process is particularly important in applications such as laser printing, bilevel displays, xerography, and more recently, facsimile.

There are a number of different methods by which this digital image halftoning can be accomplished, which are generally classified as either point or neighborhood processes. A point process is one which computes the output pixel value based strictly on some characteristic of the corresponding input pixel. In contrast, a neighborhood process computes a single output pixel based on a number of pixels in a neighborhood or region of the input image. Ordered dither, which is considered a point process, produces an output by comparing a single continuous-tone input value against a deterministic periodic array of threshold values. If the value of the input pixel under consideration is greater than the corresponding threshold value, the corresponding output pixel is rendered white. If the intensity is less that the threshold, it is rendered black. Dispersed-dot ordered dither is a subset of ordered dither in which the halftone dots are of a fixed size while clustered-dot ordered dither uses variable-sized dots and simulates the variable-sized dots of a printer's halftone screen in the rendering. Among the advantages of point process halftoning, in general and ordered dither halftoning specifically, are simplicity and speed of implementation. The primary disadvantage is that ordered dither produces patterns in the halftoned image, which are visually undesirable.

In contrast, halftoning using the error diffusion algorithm, first introduced by Floyd and Steinberg in 1975, employs neighborhood operations and is currently the most popular neighborhood process. In this approach to halftoning, the output pixel value is determined, not solely by the value of the input pixel and some deterministic pattern, but instead by a weighted average of values from pixels in a neighborhood surrounding the specific pixel being computed. Here, the error of the quantization process is computed and spatially distributed or diffused within a local neighborhood in order to influence future pixel quantization decisions within that neighborhood and thereby improve the overall quality of the halftoned image. In classical unidirectional error diffusion, the image is processed sequentially, proceeding from the upper-left to the lower-right. Starting in the corner of the image, the first pixel is thresholded and the quantizer error is calculated. The error is then diffused to neighboring pixels that have not yet been processed according to the scaling and interconnect defined by the error diffusion filter. The remainder of the pixels in the image are subsequently processed with each quantizer input, now being the algebraic sum of the corresponding original input pixel intensity and the weighted error from previously processed pixels. While error diffusion produces halftone images of superior quality, the unidirectional processing of the algorithm continues to introduce visual artifacts that are directly attributable to the algorithm itself.

In an effort to overcome the implementation constraints of serial processing and improve overall halftone image quality, a number of different parallel architectures have been investigated, including several based on neural network algorithms. While neural network approaches can provide distinct advantages in improved halftone image quality, they also present challenges to hardware implementations, including speed of convergence and the physical interconnect requirements. These challenges, in addition to the natural compatibility with imaging media, provide the motivation for developing optical image processing architectures for these types of applications.

The Error Diffusion Algorithm

Figure 1 shows a block diagram of the error diffusion architecture used in digital image halftoning. The input image is represented as $x_{m,n}$, $w_{m,n}$ is the impulse response of a 2D causal, unity gain error diffusion filter, and the output quantized image is described by $y_{m,n} \in \{-1, 1\}$. The quantizer $q[u_{m,n}]$ provides the one-bit thresholding functionality necessary to convert each analog input pixel to a low-resolution digital output pixel. The quantizer error $\varepsilon_{m,n}$ is computed as the difference between the output and input to the quantizer and distributed to adjacent pixels according to the weighting and interconnection specified by the error diffusion filter. The unity gain constraint ensures

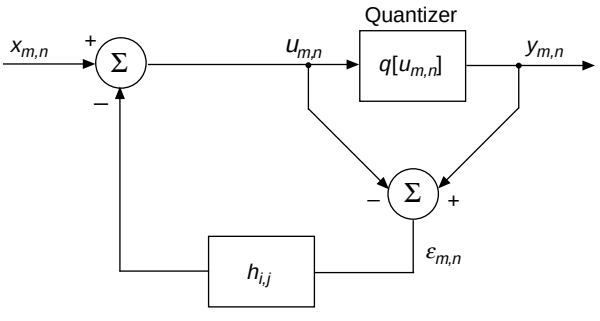

Figure 1 Block diagram of recursive error diffusion architecture.

that no amplification or attenuation of the error signal occurs during the error diffusion process and preserves the average intensity of the image.

In this architecture, the error associated with the quantizer decision at spatial coordinates (m, n) is diffused within a local 2D region to influence adjacent quantization decisions. All of the state variables in this architecture are scalar values since this architecture represents a recursive algorithm in which each pixel in the image is processed sequentially. In the general case, where $w_{m,n}$ is assumed to be a 2D finite impulse response (FIR) filter with coefficients that span a region of support defined by $R_{m,n}$, the quantizer input state $u_{m,n}$ can be written as

$$u_{m,n} = x_{m,n} - \sum_{i,j \in R_{m,n}} w_{i,j} \varepsilon_{m-i,n-j} \qquad [1]$$

Here, $w_{i,j} = 0$, for all $i = j$, since the error signal is diffused spatially within the region of support $R_{m,n}$ and does not influence the pixel under consideration. In this unidirectional error diffusion, the 2D error diffusion filter is therefore noncausal. Figure 2 shows the impulse response of several popular error diffusion filters that have been used in rectangular grid architectures. Figure 2a shows the original error diffusion filter weights developed by Floyd and Steinberg. They argued that the four weights were the smallest number of weights that would produce good halftone images. Figure 2b is a filter that contains a larger region of support developed by Jarvis, Judice, and Ninke in 1976. Finally, the filter in Figure 2c, developed by Stucki, contains the same region of support with coefficients that are a multiple of 2 for digital compatibility and computational efficiency. Here, '•' represents the pixel being processed and the weights describe the local region over which the error is diffused. The normalization factors ensure that the filter coefficients sum to one and therefore meet the unity gain criterion.

To understand the effect of error diffusion and its impact on the quantizer error, it is instructive to describe the effect of error diffusion mathematically. Consider the relationship between the quantizer error $\varepsilon_{m,n} \equiv y_{m,n} - u_{m,n}$ and the overall quantization error $\hat{\varepsilon}_{m,n} \equiv y_{m,n} - x_{m,n}$ in the frequency domain. If we assume that the error is uncorrelated with the input and has statistical properties consistent with a white process, z-transform techniques can be applied to show that the feedback architecture provides the following noise-shaping characteristics:

$$H_{\text{ns}}(z_1, z_2) \equiv \frac{\hat{E}(z_1, z_2)}{E(z_1, z_2)} = 1 - W(z_1, z_2) \qquad [2]$$

Here, $\hat{E}(z_1, z_2)$, $E(z_1, z_2)$, and $W(z_1, z_2)$ represent the z-transforms of $\hat{\varepsilon}_{m,n}$, $\varepsilon_{m,n}$, and $w_{m,n}$, respectively. Equation [2] shows that the noise-shaping characteristic of the error diffusion architecture is directly related to the spectral characteristics of $W(z_1, z_2)$. Appropriate selection of $W(z_1, z_2)$ can spectrally shape the quantizer noise in such a way that minimizes the effect of the low-resolution quantization process on the overall halftoning process. An error diffusion filter with low-pass spectral characteristics produces an overall noise-shaping characteristic $1 - W(z_1, z_2)$, which has the desired high-pass frequency characteristics. This noise-shaping function suppresses the quantization noise within those frequencies occupied by the image and spectrally shapes the noise to high frequencies, which are less objectionable to the human visual system. Circular symmetry is another important characteristic in the error diffusion filter since the human visual system is particularly sensitive to directional artifacts in the image.

In the following qualitative description of digital image halftoning, a 348×348 natural image of the Cadet Chapel at West Point was selected as the test image. This image provides a variety of important image characteristics, with regions of uniform gray-scale, edges, and areas with fine detail. This image was scanned from a high-resolution black and white photograph at 150 dots per inch (dpi) and then printed using a 300 dpi laser printer.

Figure 3 shows the test image of the Cadet Chapel rendered using dispersed-dot ordered dither and results in 256 gray-levels at 300 dpi. Figure 4 shows the halftone image of the Cadet Chapel using the error diffusion algorithm and the Floyd–Steinberg filter coefficients shown in Figure 2a. The unidirectionality of the processing and the causality of the diffusion filter result in undesirable visual artifacts in the halftone image. These include directional hysteresis, which is manifested as 'snakes' running from upper-left to lower-right, and transient behavior near boundaries, which appears as 'shadows' below and to the right of sharp-intensity changes. The directional

$$\left(\frac{1}{16}\right)\times \begin{array}{ccc} & \bullet & 7 \\ 3 & 5 & 1 \end{array}$$

(a)

$$\left(\frac{1}{48}\right)\times \begin{array}{ccccc} & & \bullet & 7 & 5 \\ 3 & 5 & 7 & 5 & 3 \\ 1 & 3 & 5 & 3 & 1 \end{array}$$

(b)

$$\left(\frac{1}{42}\right)\times \begin{array}{ccccc} & & \bullet & 8 & 4 \\ 2 & 4 & 8 & 4 & 2 \\ 1 & 2 & 4 & 2 & 1 \end{array}$$

(c)

Figure 2 Three common error diffusion filters used in rectangular grid architectures. (The '•' represents the origin.)

hysteresis is particularly objectionable in uniform gray intensity areas such as the cloud structure in the upper-left of Figure 4. Similar artifacts are also present in images halftoned using the error diffusion algorithm and other causal diffusion kernels. The logical conclusion to draw from this limited, qualitative analysis is that if we could diffuse the error symmetrically and simultaneously process the entire image in parallel, we could reduce some of these visual artifacts and thereby improve overall halftone image quality.

Figure 3 Original gray-scale image of the Cadet Chapel rendered using dispersed-dot ordered dither.

Figure 4 Halftone image of the Cadet Chapel produced using the error diffusion algorithm and the Floyd–Steinberg weights.

The Error Diffusion Algorithm and Neural Networks

The popularity of the neural network-based approach to signal and image processing lies in the ability to minimize a particular performance metric associated with a highly nonlinear system of equations. Specifically, the problem of creating a halftone image can be cast in terms of a nonlinear quadratic optimization problem where the performance measure to be minimized is the difference between the original and the halftone images.

The Hopfield-Type Neural Network

Tank and Hopfield first proposed a mathematical description of the functionality of the neural processing network for signal processing applications. Figure 5 shows an electronic implementation of a four-neuron architecture. Here, a single neuron is comprised of both a standard and inverting amplifier and the synapses or neural interconnections are represented by the physical connections between the input and output of the amplifiers. If the input to amplifier i is connected to the output of amplifier j by a resistor with resistance $R_{i,j}$, the amplitude of the connection $T_{i,j}$ is the conductance $1/R_{i,j}$.

The dynamic behavior of an N-neuron Hopfield-type neural network can be described by the following system of N nonlinear differential equations:

$$c\frac{\mathrm{d}u_i(t)}{\mathrm{d}t} = -u_i(t) + \sum_j T_{i,j}\Im[u_j(t)] + x_i \qquad [3]$$

where $i = 1, 2, \ldots N$, $\Im[\cdot]$ is a monotonically increasing sigmoid function, x_i is an input vector containing N

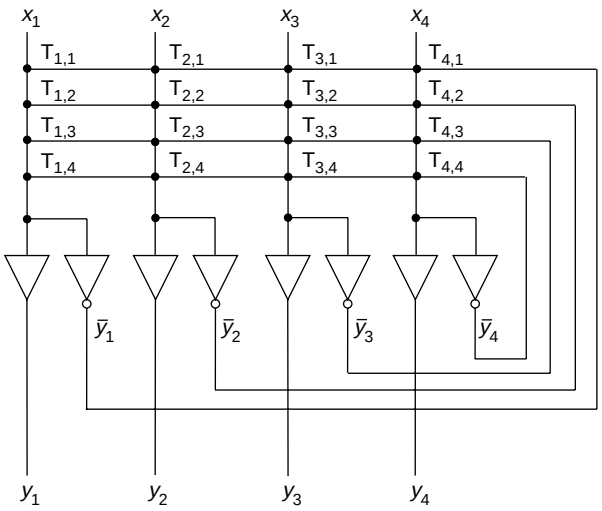

Figure 5 Electronic realization of a four-neuron Hopfield-type neural network.

elements, and c is a scaling factor. In equilibrium, eqn [3] implies that

$$u_i = x_i + \sum_j T_{i,j}\Im[u_j] \qquad [4]$$

Hopfield showed that when the matrix of interconnection weights $\mathbf{T}$ is symmetric with zero diagonal elements and the high-gain limit of the sigmoid $\Im[\cdot]$ is used, the stable states of the N functions $y_i(t) = \Im[u_j]$ are the local minima of the energy function:

$$E = -\frac{1}{2}\mathbf{y}^{\mathrm{T}}\mathbf{T}\mathbf{y} - \mathbf{x}^{\mathrm{T}}\mathbf{y} \qquad [5]$$

where $\mathbf{y} \in \{-1, 1\}$ is the N-vector of quantized states. As a result, if the neural network can be shown to be stable, as the network converges the energy function is minimized. In most neural network applications, this energy function is designed to be proportional to a performance metric of interest and therefore as the network converges, the energy function and consequently the performance metric is also minimized.

The Error Diffusion Neural Network

An understanding of the operation and characteristics of the Hopfield-type neural network can be applied to the development and understanding of a 2D extension of the error diffusion algorithm. Figure 6 shows an electronic implementation of a four-neuron error diffusion-type neural network, where the individual neurons are represented as amplifiers and the synapses by the physical connections between the input and output of the amplifiers.

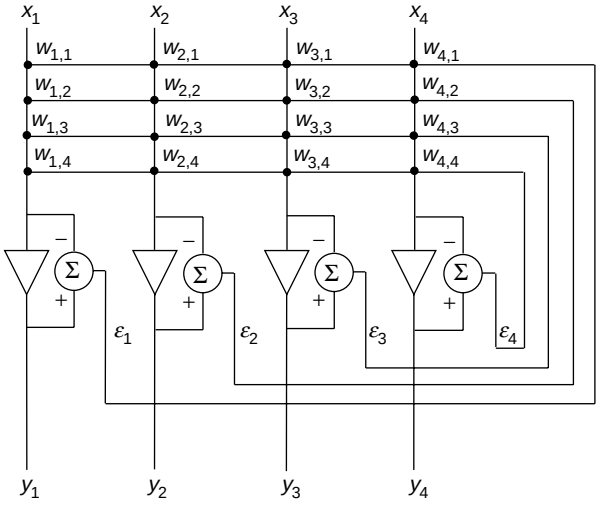

Figure 6 Four-neuron electronic implementation of the error diffusion neural network.

In equilibrium, the error diffusion neural network can be shown to satisfy

$$\mathbf{u} = \mathbf{W}(\mathbf{y} - \mathbf{u}) + \mathbf{x} \qquad [6]$$

Here, $\mathbf{u}$ is the state vector of neuron inputs, $\mathbf{W}$ is a matrix containing the interconnect weights, $\mathbf{x}$ is the input state vector, and $\mathbf{y}$ is the output state vector. For an $N \times N$ image, $\mathbf{W}$ is an $N^2 \times N^2$ sparse, circulant matrix derived from the original error diffusion weights $w_{m,n}$. If we define the coordinate system such that the central element of the error diffusion kernel is $(i, j) = (0, 0)$, then the matrix $\mathbf{W}$ is defined as $W(i, j) = -w[(j - i) \text{ div } N, (j - i) \bmod N]$ where:

$$x \text{ div } y = \left\lfloor \frac{x}{y} \right\rfloor \text{ if } xy \geq 0 \text{ or } \left\lceil \frac{x}{y} \right\rceil \text{ if } xy < 0 \qquad [7]$$

An equivalence to the Hopfield network can therefore be described by

$$\mathbf{u} = \mathbf{A}(\mathbf{W}\mathbf{y} + \mathbf{x}) \qquad [8]$$

where $\mathbf{A} = (\mathbf{I} + \mathbf{W})^{-1}$. Effectively, the error diffusion network includes a pre-filtering of the input image $\mathbf{x}$ by the matrix $\mathbf{A}$ while still filtering the output image $\mathbf{y}$ but now with a new matrix, $\mathbf{AW}$. Recognizing that $\mathbf{AW} = \mathbf{I} - \mathbf{A}$ and adding the arbitrary constant $k = \mathbf{y}^{\mathrm{T}}\mathbf{y} + \mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{x}$, we can write the energy function of the error diffusion neural network as

$$\hat{E}(x, y) = \mathbf{y}^{\mathrm{T}}\mathbf{A}\mathbf{y} - 2\mathbf{y}^{\mathrm{T}}\mathbf{A}\mathbf{x} + \mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{x} \qquad [9]$$

This energy function is a quadratic function, which can be factored into

$$\hat{E}(x, y) = [\mathbf{B}\underbrace{(\mathbf{y} - \mathbf{x})}_{\text{error}}]^{\mathrm{T}}[\mathbf{B}\underbrace{(\mathbf{y} - \mathbf{x})}_{\text{error}}] \qquad [10]$$

where $\mathbf{A} = \mathbf{B}^{\mathrm{T}}\mathbf{B}$. From eqn [10] we find that as the error diffusion neural network converges and the energy function is minimized, so too is the error between the output and input images.

If the neurons update independently, the convergence of the error diffusion network is guaranteed if

$$\forall k : [\mathbf{AW}]_{k,k} \geq 0 \qquad [11]$$

We find in practice, that even in a synchronous implementation, the halftoned images converge to a solution, which results in significantly improved halftone image quality over other similar halftoning algorithms.

The Error Diffusion Filter

The purpose of the error diffusion filter is to spectrally shape the quantization noise in such a way that the

quantizer error is distributed to higher spatial frequencies, which are less objectionable to the human visual system. In this application, a feedback filter for the error diffusion neural network was designed using conventional 2D filter design techniques resulting in the 7×7 impulse response shown in Figure 7. Figure 8 shows the same image of the Cadet Chapel halftoned using the error diffusion neural network algorithm and the 2D error diffusion filter shown in Figure 7. There is clear improvement in halftone image quality over the image produced using sequential error diffusion in Figure 4. Notice particularly the uniform distribution of pixels in the cloud formation in the upper-left of Figure 8. Also noteworthy is the improvement around the fine detail portions of the tree branches and next to the vertical edges of the chapel.

Smart Pixel Technology and Optical Image Processing

The concept underlying smart pixel technology is to integrate electronic processing and individual optical devices on a common chip, to take advantage of the complexity of electronic processing circuits and the speed of optical devices. Arrays of these smart pixels then allow the advantage of parallelism that optics provides. There are a number of different approaches to smart pixel technology that differ primarily in the kind of opto-electronic devices, the type of electronic circuitry, and the method of integration of the two. Common opto-electronic devices found in smart pixels include: light-emitting diodes (LEDs); laser diodes (LDs); vertical cavity surface emitting lasers (VCSELs); multiple quantum well (MQW) modulators; liquid crystal devices (LCDs); and photodetectors (PDs). The most common types of electronic circuitry are silicon-based semiconductors such as complementary metal oxide semiconductors (CMOS) and compound semiconductors such as gallium arsinide (GaAs)-based circuitry. There are a number of different approaches to smart pixels, which generally differ in the way in which the electronic and optical devices are integrated. Monolithic integration, direct epitaxy, and hybrid integration are the three most common approaches in use today.

Smart pixel technology provides a natural methodology by which to implement optical image processing architectures. The opto-electronic devices provide a natural optical interface while the electronic circuitry provides the ability to perform either analog or digital computation. It is important to understand that any functionality that can be implemented in electronic circuitry can be integrated into a smart pixel architecture. The only limitations arise from physical space constraints imposed by the integration of the opto-electronic devices with the electronic circuitry. While smart pixels can be fabricated with digital or analog circuitry, the smart pixel architecture described subsequently uses mixed-signal circuitry.

A Smart Pixel Implementation of the Error Diffusion Neural Network

A smart pixel hardware implementation of the error diffusion neural network provides the potential to simultaneously achieve the computational complexity of electronic circuitry and the parallelism and high-speed switching of optics. The specific smart pixel architecture described here integrates MQW modulators called self electro-optic effect devices (SEEDs) with silicon CMOS

VLSI circuitry, using a hybrid integration approach called flip-chip bonding. This type of smart pixel is commonly referred to as CMOS-SEED smart pixel technology.

To provide an example of the application of smart pixel technology to digital image halftoning, a 5×5 CMOS-SEED smart pixel array was designed and fabricated. The CMOS circuitry was produced using a 0.5 μm silicon process and the SEED modulators were subsequently flip-chip bonded to silicon circuitry using a hybrid integration technique. The central neuron of this new smart pixel array consists of approximately 160 transistors while the complete 5×5 array accounts for over 3,600 transistors. A total of 50 optical input/output channels are provided in this implementation.

Figure 9 shows the circuitry associated with a single neuron of the smart pixel error diffusion neural network. All state variables in each circuit of this architecture are represented as currents. Beginning in the upper-left of the circuit and proceeding clockwise, the input optical signal incident on the SEED is continuous in intensity and represents the individual input analog pixel intensity. The input SEED at each neuron converts the optical signal to a photocurrent and subsequently, current mirrors are used to buffer and amplify the signal. The width-to-length ratio of the metal oxide semiconductor field effect transistors (MOSFETs) used in the CMOS-SEED circuitry provide current gain to amplify the photocurrent. The first circuit produces two output signals: $+I_u$ which represents the state variable $u_{m,n}$ as the input to the quantizer and $-I_e$ which represents the state variable $-\varepsilon_{m,n}$ as the input to the feedback differencing node. The function of the quantizer is to provide a smooth, continuous threshold functionality for the neuron that produces the output signal I_{out}, corresponding to the output state variable $y_{m,n}$. This second electronic circuit is called a modified wide-range transconductance amplifier and produces a hyperbolic tangent sigmoidal function when operated in the sub-threshold regime. The third circuit takes as its input I_{out}, produces a replica of the original signal, and drives

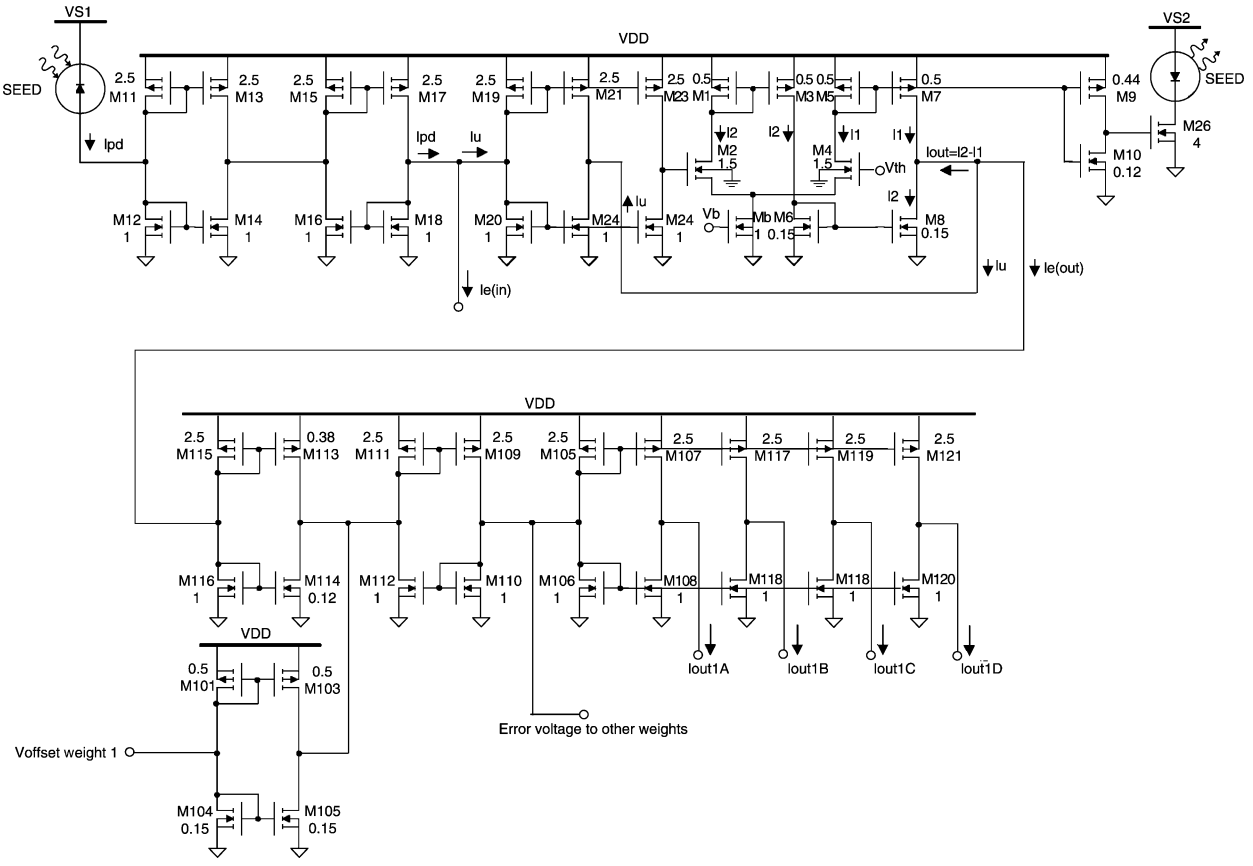

Figure 9 Circuit diagram of a single neuron and a single error weight of the 5×5 error diffusion neural network based on a CMOS-SEED-type smart pixel architecture. the output optical SEED. In this case, the output optical signal is a binary quantity represented as the presence or absence of light. When the SEED is forward-biased, light is generated through electroluminescence. The last circuit at the bottom of the schematic implements a portion of the error weighting and distribution function of the error diffusion filter. The individual weights are implemented by scaling the width-to-length ratio of the MOSFETs to achieve the desired weighting coefficients. The neuron-to-neuron interconnections are accomplished using the four metalization layers of the 0.5 μm silicon CMOS process. In this design, the error diffusion filter was limited to a 5×5 region of support because of the physical constraints of the circuitry necessary to implement the complete error diffusion neural network in silicon circuitry. The impulse response of the 5×5 filter used in this particular smart pixel architecture is shown in Figure 10. The error weighting circuitry at the bottom of Figure 9 represents only the largest weight (0.1124) with interconnects to its four local neighbors ($I_{\text{outA}} - I_{\text{outD}}$).

Figure 10 Error diffusion filter coefficients used in the 5×5 CMOS-SEED error diffusion architecture. ('•' represents the origin.)

Figure 11 shows a photomicrograph of a 5×5 error diffusion neural network, which was fabricated using CMOS-SEED smart pixels. Figure 12 shows a photomicrograph of a single neuron of the 5×5 CMOS-SEED neural network. The rectangular features are the MQW modulators while the silicon circuits are visible between and beneath the modulators. The MQW modulators are approximately 70 μm × 30 μm and have optical windows, which are 18 μm × 18 μm.

Simulations of this network predict individual neuron switching speeds of less than 1 μs, which corresponds to network convergence speeds capable of providing real-time digital image halftoning. Individual component functionality and dynamic operation of the full 5×5 neural array were both experimentally characterized. Figure 13 shows CCD images of the operational 5×5 CMOS-SEED smart pixel array. The white spots show SEED MQW modulators emitting light. Figure 13a shows the fully functioning array while Figure 13b shows the 5×5 CMOS-SEED neural array under 50% gray-scale input. Here 50% of the SEED modulators are shown to be in the *on*-state demonstrating correct operation of the network and the halftoning architecture.

Both the simulations and the experimental results demonstrate that this approach to a smart pixel implementation of the error diffusion neural network provides sufficient accuracy for the digital halftoning application. The individual neuron switching speeds also demonstrate the capability for this smart pixel hardware implementation to provide real-time halftoning of video images.

Image Processing Extensions

Other image processing functionality is also possible by extending the fundamental concepts of 2D, symmetric error diffusion to other promising image processing applications. One important application includes color halftoning while other extensions include edge enhancement and feature extraction. In the basic error diffusion neural network, the error diffusion filter was specifically designed to produce visually pleasing halftoned images. Care was taken to ensure that the frequency response of the filter was circularly symmetric and that the cutoff frequency was chosen in such a way as to preserve image content. An analysis of the error diffusion neural network shows that the frequency response of this filter directly shapes the frequency spectrum of the output halftone image and therefore directly controls halftone image content. Other filter designs with different spectral responses can provide other image processing features such as edge enhancement, which could lead to feature extraction and automatic target recognition applications.

Introduction

An artificial neural network (ANN) is a nonlinear signal processing system based on the neural processes observed in animals. Usually they have multiple inputs and often multiple outputs also. Conventionally, each input sends its signal to many neurons, and each neuron receives signals from many inputs. The neuron forms an intermediate sum of weighted inputs and transforms that sum, according to some nonlinearity, to form an output signal. Often the output signal from one neuron is used as the input signal for another in feed forward, feedback, or mixed mode complex neural networks.

ANNs are of value in helping us understand how biological neural networks perform and in a variety of technical applications, most of which involve pattern association. An auto-associative neural network, that associates patterns with themselves, can have useful noise cleanup or pattern completion properties. A hetero-associative neural network is often used in pattern recognition to associate input patterns with preselected class labels.

Neural Networks – Natural and Artificial

The most primitive one-celled organisms have no nerve cells, but they do exhibit various chemical means for interacting with their environments, within their own cells, and among individuals of the same or different types. As organisms increased in size, a common chemical environment became impractical, and nerves arose as a means for long-distance communication within larger organisms. One thing seen in evolution is that widespread useful adaptations are often modified but seldom discarded. Thus, it should not be surprising to find that chemical interactions play a major role in the most complex thing we know of – the human brain. Chemicals play a huge role in making us who we are, setting our moods, and so forth. Realizing this, in the late twentieth century, psychiatrists started to make serious progress in treating mental diseases through the use of chemistry.

There are a variety of processes that we use as humans, but the primary means is neural. Only some animals and no plants have neurons, but soon after neurons evolved, they began to concentrate in special regions of the body that developed into primitive brains. Not only were there many neurons, but also they were densely and complexly interconnected to form neural networks.

Neural networks did not replace chemical interactions, they used and supplemented them. Chemical communication across the synaptic cleft dominates communication between networks, but the neural networks also control chemical production and distribution within the brain, and those chemicals change the behavior of the neurons that cause their secretion. The functioning of real brains is incredibly complex, possibly irreducibly complex in terms of current mathematics and logic.

These things are noted to avoid a confusion that is distressingly common. Technologists produce simplified ANNs and then try to interpret the behavior of brains in those terms. Quite often, ANNs yield useful insight into brain behavior but seldom offer a detailed account of them. Reality is far more complex than any ANN. Current mathematics provides no means

to describe continuous sets of events, each of which both causes and is caused by the others.

ANNs themselves have grown much more complicated as well. Starting out as simple, feed-forward, single-layer systems, they rapidly became bidirectional and even multilayered as well. Higher-order neural networks processed the input signals before inserting them into the neural network. Pulse coupled neural networks (PCNNs) arose that more closely modeled the pulsations in real brains. Learning was broken into learning with instruction, following example, and self-organizing, the latter leading to self organized maps and adaptive resonance theory, and many related subjects. These are but crude pointers to the wealth and variety of concepts now part of the ANN field.

The history of ANNs is both complicated and somewhat sordid. This is not the occasion to retrace the unpleasant things various members of this community have done to others in their quests for stature in the field. One result of that history is a dramatically up-and-down pattern of interest in and support for ANNs. The first boom followed the development of a powerful single-layer neural network called the Perceptron by its inventor Rosenblatt. Perceptrons were biologically motivated, fast, and reasonably effective; so interest in the new field of ANNs was high. That interest was destroyed by a book on the field arguing that Perceptrons were only linear discriminants and most interesting problems are not linearly discriminable. Ironically, the same argument has been made about optical Fourier correlators, and it is true there as well. But optical processing folk largely ignored the problem and kept working on it. Sociologists of science might enjoy asking why reactions differed so much in the two fields. Funding and interest collapsed and the field went into hibernation.

It was widely recognized that multilayer ANNs would comprise nonlinear discriminants, but training them presented a real problem. The simple rewards and punishment of weights depending on performance was easy when each output signal came from a known set of weighted signals that could be rewarded or punished jointly, according to how the output differed from the sought-after output. With a multilayer perceptron, credit assignment of inner layers is no longer simple. It was not until Werbos invented 'backward error propagation' that a solution to this problem was available and the field started to boom again. Also key to the second boom were enormously popular articles by Hopfield on rather simple auto- and hetero-associative neural networks. Basically, those networks are almost never used, but they were of great value in restarting the field. In terms of research and applications, we are still in that second boom, that began during the 1980s.

> An ANN is a signal processor comprised of a multiplicity of nodes which receive one or more input signals and generate one or more output signals in a nonlinear fashion wherein those nodes are connected with one or two way signaling channels.

Note also that biological inspiration is no longer a part of the definition. Most ANNs used for association are only vaguely related to their biological counterparts.

Optical Processors

Optics is well-suited for massive parallel interconnections, so it seems logical to explore optical ANNs. The first question to address is "Why bother to use optical processors at all?" as electronic digital computers seem to have everything:

- Between the writing of this article (on an electronic computer) and its publication, the speed of electronic computers will almost double and they will become even cheaper and faster.
- They can have arbitrary dynamic range and accuracy.
- Massively improved algorithms also improve their speed. For instance, the wonderful fast Fourier transform (FFT) that opticists have used to simulate optics for decades has been replaced by an even faster fastest Fourier transform in the West (FFTW). And for wavelets, the fast wavelet transform (FWT) is even faster.

Optical processors, on the other hand, have severely limited analog accuracy and few analog algotectures or archirithms. They are specialized systems (equivalent in electronics, not to computers but to application specific integrated circuits (ASICs)). They are usually larger and clumsier than electronic systems and always cost more.

There are several reasons why optics may still have a role in some computations. First, many things on which we wish to perform computations are inherently optical. If we can do the computations optically before detection, we can avoid some time and energy and sensitivity penalties inflicted, if we first detect the signals then process them electronically, and then (sometimes) convert them back to optics. Examples include spectroscopy and optical communication.

Second, pure optics is pure quantum mechanics. Input of data and setup of the apparatus is experiment preparation. Readout of data is classical measurement. Nature does the rest free of charge. There is a unitary transformation from input to output that

requires no human intervention and is, in fact, destroyed by human intervention. Those intermediate (virtual) computations require no energy and no time, beyond the time taken for light to propagate through the system. Speed and power consumption are limited only by the input and output. This applies for everything from Fourier optics to digital optics to logic gates. Thus, optics can have speed and power consumption advantages over electronics.

Third, if quantum computers involving entanglement ever emerge, they may well be optical. Such computers would be used for nondeterministic solutions of hard problems. That is, they would explore all possible paths at once and see which one does best. This is something we can already do electronically or optically for maze running (using classical, not quantum entanglement) means.

Fourth, most optical processors are analog, which is sometimes superior to digital. In those cases, we would still have to choose between analog optics and analog electronics, of course.

So, optical processing (like all other processing) is a niche market. But some of the niches may be quite large and important. It is not a universal solution, but neither is digital electronics.

The Major Branches of Optical Processing and Their Corresponding Neural Networks

Every branch of optical processing leads to its own special purpose optical neural networks, so those branches become a good place to start an article such as this one.

Optical Linear Algebra

Many neural network paradigms use linear algebra followed by a point-by-point nonlinearity in each of multiple stages. The linear operation is a matrix–vector multiplication, a matrix–matrix multiplication, or even a matrix–tensor multiplication. In any case, the key operations are multiplication and addition – operations very amenable to performance with analog optics. With effort, it is possible to combine simple electronics with analog optics operating on non-negative signals (the amount of light emitted from a source, the fraction of light passing through a modulator, etc.) to expand to real or even complex numbers. With even more effort, we can use multiple analog non-negative signals to encrypt a digital signal, allowing digital optical processors. Almost all optical neural networks using linear algebra use only real numbers. In most of these, the real number is encoded as a positive number and a negative number. Data are read in parallel using spatial light modulators (SLMs), source arrays, acousto-optic modulators, etc. They are operated upon by other SLMs, acousto-optic systems, and so forth. Finally, they are detected by individual detectors or detector arrays. The required nonlinearities are then done electronically. It is a theory that holds for all linear algebraic processes up to computational complexity $O(N^4)$ that they can be performed with temporal complexity $O(N^0)$ if the extra dimensions of complexity are absorbed in space, up to $O(N^2)$ through 2D arraying and in fanin/fanout, the ability of multiple beams of light to be operated upon in parallel by the same physical modulator – this has the same complexity as the 2D array of modulators, namely $O(N^2)$. Thus, we can invert a matrix, an order $O(N^4)$ for an $N \times N$ matrix, $O(N^0)$ in time, that is, independently of the size of N, as long as that matrix is accommodated by the apparatus. This offers a speed electronics cannot match.

Most of the optical neural networks of the mid-1980s had optical vector–matrix multipliers at their heart. Most were a few layers of feed forward systems, but by the 1990s feedback had been incorporated as well. These are typically N inputs connected to N outputs through an $N \times N$ matrix, with N varying from 100 to 1000. With diffuser interconnection and a pair of SLMs, it is possible to connect an $N \times N$ input with an $N \times N$ output using N^4 arbitrary weights, but that requires integrating over a time up to N^2 intervals. Most of the N^4-dimensional matrices can be approximated well by fewer than N^4 terms using singular value decomposition (SVD) and (as this version of the interconnection uses outer products), that reduces the number of integration times considerably in most cases. We have shown, for instance, that recognizing M target images can be accomplished well with only M terms in the SVD.

Coherent Optical Fourier Transformation

It took opticists several years, during the early 1960s, to realize that if Fourier mathematics was useful in describing optics, optics might be useful in performing Fourier mathematics. The first applications of optical Fourier transforms were in image filtering and particularly in pattern recognition. Such processors are attractive not only for their speed but also for their ability to locate the recognized pattern in 1D, 2D, or even 3D. It was soon obvious that a Fourier optical correlator was a special case of a single layer perceptron. Of course, it inherits the weaknesses of a single layer perceptron too. Soon, workers had added

feedback to create a winner-takes-all type of auto-associative optical neural network, a system that associated images with themselves. This proved useful in restoring partial or noisy images. It was not until 2003 that we learned how to make powerful hetero-associative networks with Fourier optical systems. This creates a nonlinear discrimination system that maintains the target location and generalizes well from a few samples of multiple classes to classify new data quite accurately.

Imaging

Imaging is the central act of optics and might seem to be of little value in optical processing. But multiple imaging (with lenslets, self-focusing fibers, holograms, and the like) has been the basis of numerous optical neural networks. Multiple imaging is a nonrandom way of distributing information from one plane to the next. Diffusers have also been used to produce fully interconnected optical neural networks. If each broad image point contains the whole image (something easily arranged with a diffuse hologram), then we have an auto-associative memory. Different such auto-associative networks can be superimposed in a single hologram. Then feedback after nonlinear image filtering can be used to make a general auto-associative memory.

Even deliberately poor imaging has been used. A blurred or out-of-focus image can accomplish the lateral signal spreading needed to facilitate a PCNN. These networks are substantially more like real brain networks than those discussed so far. It starts with a 2D array of integrate-and-fire units. The firing rate of each depends only in the incident power (how long integration to the thresholding firing takes). But if the fired signal is spread to its neighbors, the firing of a neighbor can hasten any unit's firing. This causes firings to synchronize and results in 'autowaves' of firing patterns moving across the 2D plane. Thus an incident 2D image is converted to a 3D signal – the two spatial dimensions and time. This results, for all but some very simple cases, in a chaotic signal occupying a strange attractor. It is interesting but not very revealing in itself. But suppose we 'integrate out' either the two spatial dimensions or the time dimension. If we integrate out the spatial dimensions, we are left with a time signal. Its strange attractors are remarkably useful in pattern recognition, because they are more syntactic than statistical (in pattern recognition terms). They describe the shape as similar, independently of the size, rotation, perspective, or even shading of the pattern! If we integrate out the time dimension, we restore the original image – almost. In fact, we can use this aspect of PCNNs for optimum blind segmentation of images. The autowaves can be made to 'leave tracks' so they can be reversed, which allows them to solve maze problems nondeterministically, because they can take all the paths. When the first wave exits, we simply retrace it to find the shortest path through the maze – a prototypical nondeterministic polynomial operation.

Holograms

Holograms are the most general, complex, and flexible means of light manipulation so far invented. Naturally, they have many applications in optical neural networks. One such application is the interconnection of each of an $N \times N$ array of inputs to each of an $N \times N$ array of outputs with its own unique connection strength (weight in the language of neural networks). The practical limit seems to be around $N = 1000$, yielding 10^{12} weights, roughly the same number as in the human brain! The brain, however, is not fully interconnected, so this produces an entirely different type of neural network. The resulting network would have fixed weights, but it could perform a variety of useful operations and be both forward and backward connected.

Special on-axis holograms, called diffractive optical elements, can be mass manufactured very effectively and inexpensively to perform tasks such as multiple imaging.

Photorefractive Neural Networks

A very complex thing happens when a pattern of fringes, such as those that form an interference pattern for hologram recording, strike materials such as lithium niobate, strontium barium niobate, gallium arsenide, and many others that fall into this category of 'photorefractive' materials. Of course, 'photo' refers to light and 'refractive' refers to the speed of light in a material – the speed of light in a vacuum divided by the index of refraction. These materials are photoconductive, so the light releases charge carriers in what would otherwise be an electrical insulator. The periodic charge pattern sets up a periodic space charge within the material. But the material is also electro-optic, that is, its index of refraction changes with applied electric field, thus generating a periodic index of refraction grating in the material. Finally, that index of refraction pattern (a phase hologram) diffracts the incoming light. Usually, but not always, a steady-state situation is reached after time that depends on the material and the photon density, although chaos can arise under some conditions. This makes for a dynamic

hologram, one that can change or adapt over time as the input pattern changes. Once a satisfactory photorefractive hologram is formed, it can be stabilized (fixed) if desired. Most optical neural network uses envision a dynamic situation with changing interconnections.

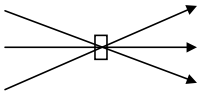
What has not been discussed above is that the index of refraction varies with the light's electric field vector cubed, so photorefractives provide a convenient way to accomplish such nonlinear operations as winner-takes-all.

Sometimes, we can record holograms with photorefractives that cannot be recorded by conventional holograms in conventional materials. To explain this, a hologram is a transducer between two optical wavefronts – usually called the reference and object beams. If the reference beam is incident on the hologram, it is (fully or partially) converted into the object beam. If the precisely reversed (phase conjugated) reference beam is incident on it, the precisely reversed (phase conjugated) object beam is derived from it. Likewise, the object wavefront (or its phase conjugate) produces the reference wavefront (or its phase conjugate). The hologram is made by recording the interference pattern between the two wavefronts: the reference and object beams. The ability of two wavefronts to form a temporally stable interference pattern at some point in space is called the mutual coherence of those wavefronts. Usually, both wavefronts are derived from the same laser beam to make achieving high mutual coherence possible. And, of course, both beams must be present to form an interference pattern. In some cases of photorefractive holograms, all of those conditions can be violated. The two wavefronts can derive from two sources that are different in wavelength, polarization, etc., and need not be simultaneously present. This phenomenon, called mutual phase conjugation, converts each wavefront into the phase conjugate of the other, but for effects due to any differences in wavelength and polarization. This allows new freedoms that have been exploited in optical neural networks.

Photorefractive materials also tend to be piezoelectric. It has been found that up to about 20 totally independent reflective holograms can be stored with different applied electric field in lithium niobate. Changing electric fields so changes the fringe spacings and indices of refraction, that only one of those holograms has any appreciable diffraction efficiency at any one electric field value. The result is an electrically selectable interconnection pattern. The same hologram can contain the information needed for many neural networks or multiple layers of fewer of them. There is no need, in general, to have more than an input layer, an output layer, and two intermediate or hidden layers.

Others have used photorefractive material to implement learning in neural networks. In biological neural networks the synaptic strengths (the weights between neurons) continue to adapt. With photorefractive holograms, we can achieve this in an optical ANN.

As previously discussed, a key development in the history of ANNs was a way to train multilayer neural networks and thus accomplish nonlinear discrimination. The first, and still most popular, way to do this is called backward error propagation. Several groups have been implemented in photorefractive optical neural networks.



Conclusions

Essentially every major type of neural network has been implemented optically. Every major tool of optics has found its way into these optical neural networks. Yet, it remains the case that almost every neural network used for practical applications is electronic. The mere existence proof of a use for optical neural networks may be what the field needs to move forward from the demonstration stage to the application stage. The tools exist and there are niches where optics seems more appropriate than electronics. Hopefully, the next review of the field will include a number of commercial successes. Nothing spurs science better than the funds that follow successful applications.

List of Units and Nomenclature

Adaptive resonance theory (ART)	Another self-organized neural net categorizer that works by mutual adjustment between bottom-up and top-down neural connections.
Computational complexity	The measure of how the number of required calculations scales with the problem size, usually denoted by N. The scaling is represented by the Big O form of (N), where $f(n)$ shows how it scales asymptotically (large N). Problems that scale as $O(N^P)$ are said to be of polynomial complexity. Unfortunately, some of the most important problems have exponential complexity.

Fanin/Fanout
: Beams of light (unlike beams of electrons or holes) do not interfere with one another, so many of them can be modulated by the same physical elements quite independently, so long as they can be identified. This is usually done by sending the different beams in at different angles, giving rise to the words fanin and fanout, as suggested by the drawing below:

Self organized maps (Kohonen networks)
: A means of self-organization of inputs into (normally 2D) maps wherein every concept falls into some category and the categories themselves develop out of application of the Kohonen's algorithm and user-selected parameters applied to the given data.

Singular value decomposition (SVD)
: Any matrix can be broken into (decomposed) a weighted sum of simpler, rank-one matrices. The simplest such decomposition (in the sense of fewest number of terms) is the SVD. The weights are the singular values and are indicators of the importance of that term in the decomposition.

Spatial light modulator (SLM)
: A 1D or 2D array of elements under electronic or optical control that change some property of the light incident on them. Usually, it is the index of refraction in some direction that is changed. That change can be used to modulate the amplitude, the polarization, or the phase of the light.

Introduction

This article describes the requirements placed on astronomical instruments and the methods used to achieve them, making reference to generic techniques described elsewhere in this encyclopedia. It is limited in scope to electromagnetic radiation with wavelengths from the atmospheric cutoff in the ultraviolet (0.3 μm) to the point in the near-infrared where the technology changes radically (5 μm), taking in the transition from uncooled to cooled instruments at ~1.7 μm. Thus, it excludes the extreme UV and X-ray regimes, where standard optical techniques become ineffective (e.g., requiring grazing incidence optics) and all mid-infrared, sub-mm, THz, and radio-frequency instruments. Terrestrial telescopes are the main focus but space-borne telescopes are subject to similar design considerations, except that the diffraction limit of the optics may be achieved at short wavelengths. Adaptive optics (AO), of increasing importance in astronomy and almost essential for the next generation of extremely large telescopes (ELTs), is covered elsewhere in this encyclopedia.

Astronomical Data

The purpose of astronomical instruments is to measure the following properties of photons arriving on or near to the Earth and brought to a focus by an astronomical telescope:

(i) direction of arrival;
(ii) energy;
(iii) polarization state; and
(iv) time of arrival.

In practice, these properties cannot be measured simultaneously, requiring the following generic classes of instrument:

- *Imagers* to measure (i) and, if equipped with ultra-low-noise detectors, (iv);
- *Spectrographs* to measure (ii), although some can be configured to do a good job on (i) as well. *Integral field spectrographs* can measure (i) and (ii) simultaneously; and
- *Polarimeters* for (iii) plus (i) and *spectropolarimeters for* (iii) plus (ii).

In principle, energy-resolving detectors, such as arrays of superconducting tunnel-junction devices (STJs) can replace (i), (ii), and (iv).

These must interface to the telescope which provides a focal surface with an image scale which is approximately constant over the field. Currently, almost all telescopes are based on the Cassegrain or Ritchy-Chretien reflecting configurations, comprising a large curved primary mirror (M1) which defines the collecting aperture (diameter D_T) and a curved secondary mirror (M2). This feeds the Cassegrain focus via a hole in M1 in line with the central obstruction caused by M2, or the Nasmyth focus if a tertiary (usually plane) mirror is added to direct light from M2 along the elevation axis to a location in which the gravity vector changes only in rotation about the optical axis. For the Cassegrain focus, the full range of change in the gravity vector is experienced as the telescope tracks objects during long exposures or slews between targets. It is also possible to dispense with M2 and mount the

instrument directly at the focus of M1 (prime focus), although this imposes severe restrictions on the mass and size of the instrument. An alternative mounting for instruments is via optical fibers. The input, with any fore-optics required to couple the telescope beam into the fiber, is mounted at the appropriate focus while the output, possibly several tens of meters distant, is mounted where the instrument is not subjected to variations in the gravity vector.

The useful field of view (FOV) of the telescope is determined by how rapidly the image quality degrades with radius in the field; restrictions on the size of the Cassegrain hole and the space set aside for the star trackers required for accurate guiding and auxiliary optics involved in target acquisition, AO, etc.

Typical telescope parameters are shown in Table 1, of which the last two entries are speculative examples of ELTs. The table also lists the diffraction limit of the telescopes and the limits imposed by seeing, with and without the effects of the telescope structure and enclosure, and approximate limits for performance with AO which approaches the diffraction limit in the infrared.

Instrument Requirements

Efficiency

Almost all astronomical observations are of very faint objects or require very high signal-to-noise (SNR) to extract the desired subtle information. The former, for example, might reveal the initial phase of galaxy or star formation, while the latter could reveal the mix of elements in the big bang or uncover changes in fundamental constants on cosmological timescales ($\sim 10^{10}$ years). The term 'efficiency' has several components:

(i) Throughput of the optical system, including the efficiency of the optical components (lenses or mirrors), dispersers, filters, and also detectors and also includes losses due to transmission/reflection, diffraction, scattering, and vignetting by internal obstructions;
(ii) Noise from all sources: the detector, including time-independent (read-noise) and time-dependent (dark-current) components; thermal emission from the instrument, telescope, enclosure and sky; straylight (see above), and electronic interference;
(iii) Efficient use of the instrument and telescope to maximize the fraction of the time spent accumulating useful photons instead of, say, calibrating; reconfiguring the instrument; or acquiring targets;
(iv) Parallelizing the observations so that the same instrument records data from many objects at the same time. This is discussed further below.

Angular Resolution

The required angular resolution is summarized in Table 2 for key features in galaxies. The resolutions currently achievable with AO systems (with severe restrictions on sky coverage pending routine availability of laser beacons), or without, are shown in bold. Finer resolution is possible using interferometric techniques, but is limited to a handful of bright stars.

Table 2 Typical requirements for angular resolution and single-object field of view

Target	*Distance*[a]	*Active nucleus*		*Star cluster (10 pc)*	*Visible extent*
		Central engine (10 AU)	*Dynamical core (0.5 pc)*		
Milky Way	8 kpc	1 mas	10″	4′	
Local group galaxy (M31)	800 kpc	0.01 mas	100 mas	3″	100″
Distant galaxy	>1 Gpc	10^{-5} mas	0.1 mas	2 mas	0.5–2″
Cluster of galaxies	>1 Gpc				3′
Cosmological structure	>1 Gpc				~1°

[a]1 pc = 3.1×10^{16} m.

Field of View and Multiplexing

The FOV of an individual observation must be sufficient to cover the angular extent of the object with the minimum number of separate pointings of the telescope. As well as minimizing the total observation time, this reduces photometric errors caused by changes in the ambient conditions (e.g., flexure, thermal effects, and changes in the sky background). (Photometry is the measurement of the flux density received from an astronomical object, usually done with the aid of an imager employing filters with standardized broad passbands. Spectrophotometry is the same but in the much narrower passbands obtained by dispersing the light.) The last column of Table 2 indicates the required size of FOV. It is also highly desirable to observe many objects simultaneously since most studies require large statistically homogenous samples. The precise requirement depends on the surface number density of potential targets and the sampling strategy adopted to create the sample. Cosmological studies of the large-scale distribution of galaxies and clusters emphasize the size of the field ($\geq 0.5°$), since the targets may be sparsely sampled, while studies of clustered objects (galaxies or stars) aim to maximize the surface density of targets (≤ 1000 arcmin^{-2}) within a modest FOV (~5′).

Spectral Resolution

The required energy resolution is specified in terms of the spectral resolving power, $R \equiv \lambda/\delta\lambda$, where $\delta\lambda$ is the resolution in wavelength defined usually in terms of the Rayleigh criterion. One of the main data products required in astrophysics is the velocity along the line of sight (radial velocity) obtained through measurement of the wavelength of a known spectral feature (emission or absorption line). This may be determined to an accuracy of:

$$\delta v = \frac{Qc}{R} \qquad [1]$$

where Q is the fraction of the width of the spectral resolution element, $\delta\lambda$, to which the centroid can be determined. This is limited by either the SNR of the observation of the line via $Q \approx 1/\mathrm{SNR}$, or by the stability of the spectrograph via:

$$Q = \frac{\Delta x}{\chi}\left(\frac{\mathrm{d}\chi}{\mathrm{d}x}\right) \qquad [2]$$

where χ is the angular width of the slit measured on the sky and $\delta\chi/\mathrm{d}x$ is the image scale at the detector. Δx is the amount of uncorrectable flexure in units of the detector pixel size. This is the part of the motion of the centroid of the line which is not susceptible to modeling with the aid of frequent wavelength calibration exposures. Typically, $\Delta x \approx 0.2$ pixels is achievable (roughly 3 μm at the detector or 10 μm at the slit for an 8 m telescope) implying $Q \approx 1/30$ for a typical $(\mathrm{d}\chi/\mathrm{d}x) = 0.1–0.2''$/pixel and $\chi = 0.5–1''$. Table 3 gives typical requirement for R and the value of Q required to achieve it, given the spectral resolution obtainable for different types of current spectrograph. Extrasolar planet studies require very high stability.

Some spectral observations require very accurate measurements of the shape of the spectral features to infer the kinematics of ensembles of objects which are individually not resolvable (e.g., stars in distant galaxies, gas in blackhole accretion disks). Other applications require accurate measurements of the relative flux of various spectral features within the same spectrum (e.g., to reveal abundances of elements or different types of star).

Optical Principles

Imaging

The simplest type of imager consists of a detector, comprising a 2D array of light-sensitive pixels (Table 4) placed at a telescope focal surface without any intervening optics except for the filters required for photometry. Although maximizing throughput, this arrangement removes flexibility in changing the image scale since the physical size of pixels (typically 15–25 μm) is fixed. Thus the Gemini telescopes

[a]Quantum efficiency varies strongly over quoted wavelength range.

($D_T = 8$ m) provides an uncorrected image scale of 25–40 mas/pixel at its sole F/16 focus. Although well-suited to high-resolution observations with AO, this is inappropriate for most observations of faint galaxies where 100–200 mas/pixel is required. This arrangement also provides limited facilities for defining the wavelength range of the observations since there is no intermediate focal surface at which to place narrowband filters, whose performance is sensitive to field angle and are, therefore, best placed at an image conjugate. There is also no image of the telescope pupil at which to place a cold stop to reject the external and instrumental thermal radiation which is the dominant noise source at $\lambda > 1.5$ μm.

The alternative is to use a focal-reducer consisting of a collimator and camera. The auxiliary components (filters, cold-stops, Fabry–Perot etalons, etc.) then have an additional image and pupil conjugate available to them and the image scale may be chosen by varying the ratio of the camera and collimator focal lengths. The extra complexity of optics inevitably reduces throughput but, through the use of modern optical materials, coatings such as Sol–Gel and the avoidance of internally obstructed reflective optics, losses may be restricted to 10–20% except at wavelength shorter than ~0.35 μm. An imaging focal reducer is a special case of the generic spectrograph described in the next section.

Spectroscopy

Basic principles

Astronomical spectrographs generally employ plane diffraction gratings. The interference between adjacent ray paths as they propagate through the medium is illustrated in Figure 1. From this, we obtain the grating equation:

$$m\rho\lambda = n_1 \sin\alpha + n_2 \sin\beta \equiv G \qquad [3]$$

where α and β are the angles of incidence and diffraction respectively, $\rho = 1/a$ is the ruling density, λ is the wavelength, and m is the spectral order. The refractive indices in which the incident and diffracted rays propagate are n_1 and n_2 respectively.

The layout of a generic spectrograph employing a plane diffraction grating in a focal reducer arrangement is shown in Figure 2. The spectrograph re-images the slit onto the detector via a collimator and camera. The disperser is placed in the collimated beam close to a conjugate of the telescope pupil.

A field lens placed near the focus is often incorporated in the collimator for this purpose.

The geometrical factor, G, defined in the equation is constrained by the basic angle of the spectrograph:

$$\psi = \alpha - \beta \qquad [4]$$

which is the (normally fixed) angle between the optical axes of the collimator and camera. $\psi = n\pi$, corresponds to the Littrow configuration (for integer n).

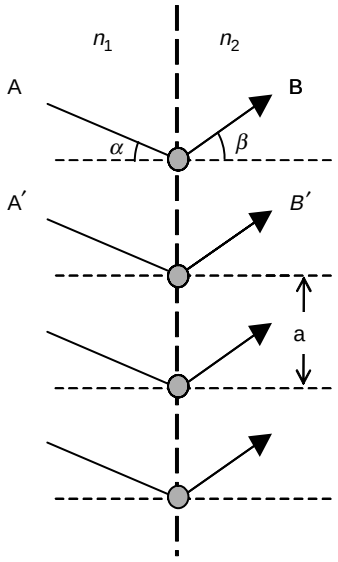

Figure 1 Derivation of the grating equation by consideration of the optical path difference between neighboring ray paths AB and A′B′.

Considering the case of a diffraction grating in vacuo, differentiation of the grating equation with respect to the diffracted angle yields the angular dispersion:

$$\frac{d\lambda}{d\beta} = \frac{\cos\beta}{m\rho} \qquad [5]$$

from which the linear dispersion is obtained by considering the projection of $d\beta$ on the detector, dx:

$$\frac{d\lambda}{dx} = \frac{d\lambda}{d\beta}\frac{d\beta}{dx} = \frac{\cos\beta}{m\rho f_2} \qquad [6]$$

where f_2 is the focal length of the camera (see Figure 2).

In the diffraction-limited case, where the slit is arbitrarily narrow, the resolving power is given simply by the total number of rulings multiplied by the spectral order:

$$R^* = m\rho W \qquad [7]$$

where w is the length of the disperser as defined below. But in astronomy, it is usually determined by the width of the image of the slit, s, projected on the detector, s'. By conservation of Etendue:

$$s' = s\frac{F_2}{F_1} \qquad [8]$$

where F_1 and F_2 are the collimator and camera focal ratios, respectively. The spectral resolution of the spectrograph is simply the width of this expressed in

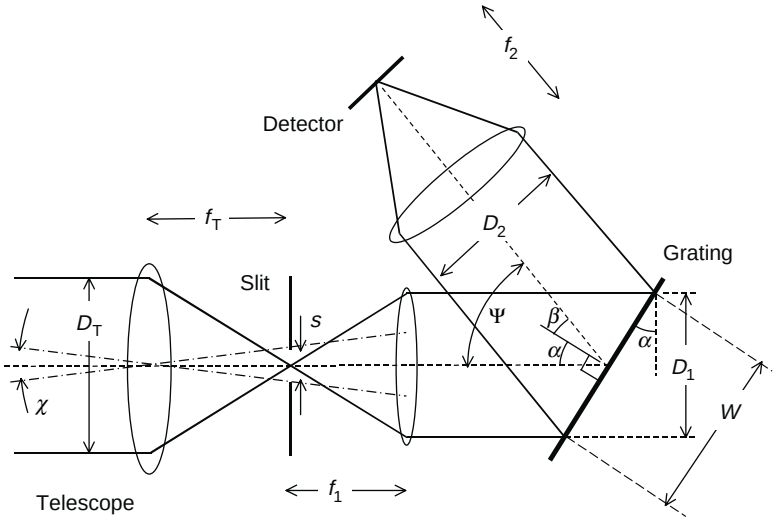

Figure 2 Generic spectrograph employing a plane diffraction grating. Note that according to the sign convention implicit in Figure 1, the diffraction angle, β, is negative in this configuration.

wavelength units:

$$\delta\lambda = \left(\frac{d\lambda}{dx}\right)s' = \frac{\cos\beta}{m\rho f_2}s\frac{F_2}{F_1} = \frac{sD_1\cos\beta}{m\rho D_2 f_1} \quad [9]$$

The length of the intersection between the collimated beam and the plane of the grating (not necessarily the actual physical length of the grating) is

$$W = \frac{D_2}{\cos\beta} = \frac{D_1}{\cos\alpha} \quad [10]$$

Using this to eliminate $\cos\beta$, the spectral resolution becomes

$$\delta\lambda = \frac{s}{m\rho F_1 W} \quad [11]$$

and the resolving power is

$$R \equiv \frac{\lambda}{\delta\lambda} = \frac{m\rho\lambda F_1 W}{s} = G\frac{F_1 W}{s} \quad [12]$$

where G is the quantity defined in eqn [3]. Note that R is now independent of the details of the camera. This expression is useful for the laboratory since it is expressed in terms of the parameters of the experimental apparatus; but, for astronomy, it is more useful to express the resolving power in terms of the angular slit width, χ, and the telescope aperture diameter, D_T, via:

$$s = \chi f_T = \chi F_T D_T = \chi F_1 D_T \quad [13]$$

since the collimator and telescope focal ratios are the same if the spectrograph is directly beam-fed from the telescope. Note that even if the telescope focal surface is re-imaged onto the slit, the expression for the resolving power still holds due to the conservation of Etendue in the re-imaging optics. Thus the resolving power is

$$R = \frac{m\rho\lambda W}{\chi D_T} = \frac{GW}{\chi D_T} \quad [14]$$

Note that the resolving power obtained with a nonzero slit width is always less than the theoretical maximum, $R \leq R_*$, for wavelengths:

$$\lambda < \lambda_* = \chi D_T \quad [15]$$

Thus, long-wavelength applications may approach the theoretical limit; in which case they are said to be diffraction-limited. If so, the resolving power is independent of the slit width, simplifying the interface to different telescopes. For a nondiffraction-limited spectrograph, the resolving power obtained depends on the aperture of the telescope to which it is fitted.

Optical configuration

The non-Littrow configuration shown in Figure 2 introduces anamorphism into the recorded spectra such that a monochromatic image of the slit mask is compressed in the dispersion direction by a factor:

$$A = \frac{D_2}{D_1} = \frac{\cos\beta}{\cos\alpha} \quad [16]$$

which varies, depending on the choice of angles required to place the chosen wavelength on the detector using eqns [3] and [4].

Practical configurations that maximize R, do so by increasing $W = D_1/\cos\alpha$. This implies maximizing $\cos\beta$, since $\psi = \alpha - \beta$, which results in $A > 1$. This is known as the grating-to-camera configuration since the grating normal points more towards the camera than to the collimator. The grating-to-collimator configuration may also be used at the penalty of lower R but does permit a smaller camera. Thus the camera aperture must be oversized in the dispersion direction since $D_2 > D_1$. The Littrow configuration is rarely used with reflective designs when large FOV is required because of internal vignetting and consequent light loss. However, it can be used effectively with transmissive dispersers.

If the disperser is replaced by a plane mirror (or if the disperser is removed in a transmissive system), the system acts as a versatile imager, with $A = 1$. This also facilitates target acquisition which requires that the telescope attitude be adjusted until the targets are aligned with apertures cut in an opaque mask placed at the input of the spectrograph. These apertures (normally slits) are usually oversized in the direction perpendicular to the dispersion to allow the spectrum of the sky to be recorded directly adjacent to that of the target to permit accurate subtraction of the background.

The slit width is chosen by trading off the desire to maximize the amount of light entering the instrument from the target (but not so much as to admit excessive background light) and the need to maximize spectral resolving power, R, by reducing the slit width, χ, according to eqn [14].

Since $|G| \leq 2$, the maximum attainable resolving power, according to eqn [14], is determined chiefly by the telescope aperture and angular slitwidth. The only important parameter of the spectrograph is the illuminated grating length, W. Therefore, maintaining the same resolving power as the telescope aperture increases, requires W to increase in direct proportion. Because of limits placed on the geometry by the need to avoid obstructions, etc., this means that both the collimated beam diameter and the size of the disperser must increase. This is one of the major

problems in devising instruments for ELTs. Current instruments on 8 m telescopes feature collimated beam diameters of $D_1 \approx 150$ mm. For ELTs, the implied sizes are 0.5–2 m, requiring huge optics, accurately co-aligned mosaics of dispersing elements, and enormous support structures to provide the required stability. A simple calculation indicates that the ruling stylus for a classically ruled diffraction grating would have to cover a thousand kilometers without significant wear unless the disperser was made from smaller pieces.

Choice of dispersing element

Astronomical spectrographs mostly use surface-relief diffraction (SL) gratings. These are ruled with groove densities $50 < \rho < 3000\ \text{mm}^{-1}$.

Blazing diffraction gratings. The intensity of the multibeam interference pattern from N rulings of finite width is given by

$$I = \left(\frac{\sin^2 N\phi}{\sin^2 \phi}\right)\left(\frac{\sin^2 \theta}{\theta^2}\right) \qquad [17]$$

where 2ϕ is the phase difference between the center of adjacent rulings and θ is the phase difference between the center and edge of a single ruling. To be useful for astronomy, the peak in this pattern, determined by the second term, must coincide with a useful order, such as $m = 1$, rather than zero order. This can be done by introducing a phase shift into the second term, which represents the diffraction of a single ruling, such that:

$$\theta = \frac{\pi \cos\gamma}{\rho\lambda}(\sin i - \sin r) \qquad [18]$$

where the groove angle, γ, is the angle by which the facets are tilted with respect to the plane of the grating. With the aid of Figure 3, it can be seen that $i = \alpha - \gamma$ and $r = \gamma - \beta$ so that the maximum efficiency, which occurs when $\theta = 0$, corresponds to $i = r$, which is equivalent to simple reflection from the facets, and $\alpha + \beta = 2\gamma$.

Thus, through this process of blazing, the grating eqn [3], at the blaze wavelength, λ_B, becomes:

$$\rho m \lambda_B = 2\sin\gamma\cos\frac{\psi}{2} \qquad [19]$$

where ψ, is given by eqn [4] using the identity: $\sin x + \sin y \equiv 2\sin\left(\frac{x+y}{2}\right)\cos\left(\frac{x+y}{2}\right)$. Thus, the resolving power at blaze is obtained from eqns [10], [14], and [19] as:

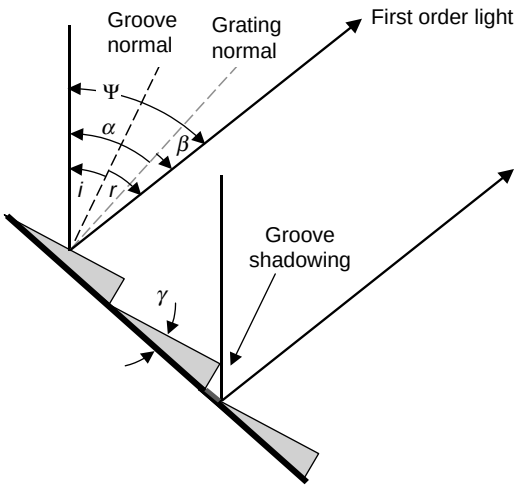

Figure 3 Blazing of ruled diffraction grating.

$$R_B = \frac{2D_1}{\chi D_T}\frac{\sin\gamma\cos(\psi/2)}{\cos(\gamma + \psi/2)} \qquad [20]$$

Use of grisms. An alternative configuration uses transmission gratings. The advantage here is that the collimator and camera can share the same optical axis in a straight-through configuration with unit anamorphism, $A = 1$, which does not require oversizing of the camera. The same phase-shift can be applied as before by making the facets into prisms with the required groove angle. However, this would only allow zero-order to propagate undeviated into the camera so an additional prism is required with vertex angle $\phi = \gamma$ to allow first-order light to pass undeviated into the camera. This composite of blazed transmission grating and prism is called a grism (Figure 4).

The grating equation (eqn [3]) is modified for a grism in the blaze condition to $m\rho\lambda_B = (n-1)\sin\phi$ since $\alpha = -\beta = \phi$ and $n_1 \equiv n, n_2 = 1$. Noting that $\psi = 0$, the resolving power at blaze is then:

$$R_B = \frac{D_1}{\chi D_T}(n-1)\tan\phi \qquad [21]$$

where n is the refractive index of the prism and grating material. Due to problems such as groove shadowing (illustrated for reflection gratings in Figure 3), these lack efficiency when $\phi \gtrsim 30°$ restricting their use to low-resolution spectroscopy.

Use of volume phase holographic gratings. A newer alternative to surface-relief (SR) dispersers are volume phase holographic (VPH) gratings in which

the interference condition is provided by a variation of refractive index of a material such as dichromated gelatine, n_g, which depends harmonically on position inside the grating material as:

$$n_g(x,z) = \bar{n}_g + \Delta n_g \cos[2\pi\rho_g(x\sin\gamma + z\cos\gamma)] \qquad [22]$$

where ρ_g is the density of the lines of constant n_g and $\bar{n}_g$ and Δn_g are the mean refractive index and its modulation amplitude, respectively (Figure 5). These are described by the same grating (eqn [3]), as before leading to an identical expression for the resolving power at blaze, where $m\rho\lambda_B = 2\sin\alpha$, to that of a blazed plane diffraction grating in the Littrow configuration (eqn [20]):

$$R_B = \frac{D_1}{\chi D_T} 2\tan\alpha \qquad [23]$$

Unlike SR gratings, the blaze condition of VPH gratings may be varied by changing the basic angle of the spectrograph, $\psi = 2(\gamma+\alpha)$, although this is often mechanically inconvenient. They may also be sandwiched between prisms to provide the necessary incident and diffraction angles while retaining the advantage of a straight-through configuration, to form an analogue of a grism, sometimes termed a vrism. Unlike grisms, these are not constrained by groove shadowing and so can be efficient at relatively high dispersion, subject to the constraint imposed by the size of the device.

Use of echelle gratings. Another option to increase the resolving power is to use a coarse grating in high order via the use of an echelle format. The resolving power in the near-Littrow configuration in which it is usually operated, is given by eqn [20] with $\psi = 0$.

$$R_B = \frac{D_1}{\chi D_T} 2\tan\gamma \qquad [24]$$

where γ is the groove angle.

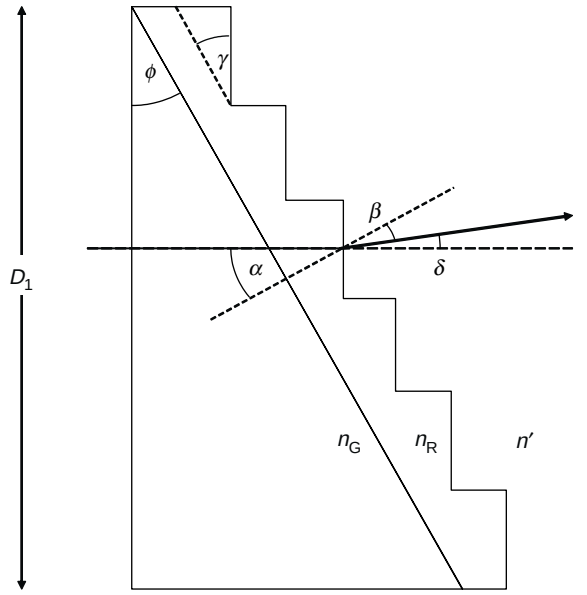

Figure 4 Typical configuration of a grism. The prism vertex and groove angles are chosen for maximum efficiency on the assumption that refractive indices, $n_G = n_R = n$ and $n' = 1$. The blaze condition occurs when $\delta = 0$. In this configuration, $\phi = \gamma = \alpha$.

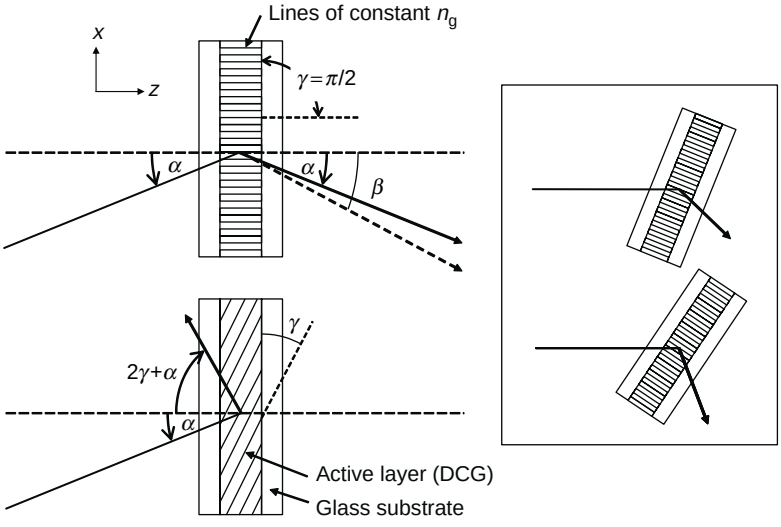

Figure 5 Various configurations of volume phase holographic gratings. The blaze condition is when $\beta = \alpha$. The inset shows how the blaze condition may be altered by changing the basic angle of the spectrograph.

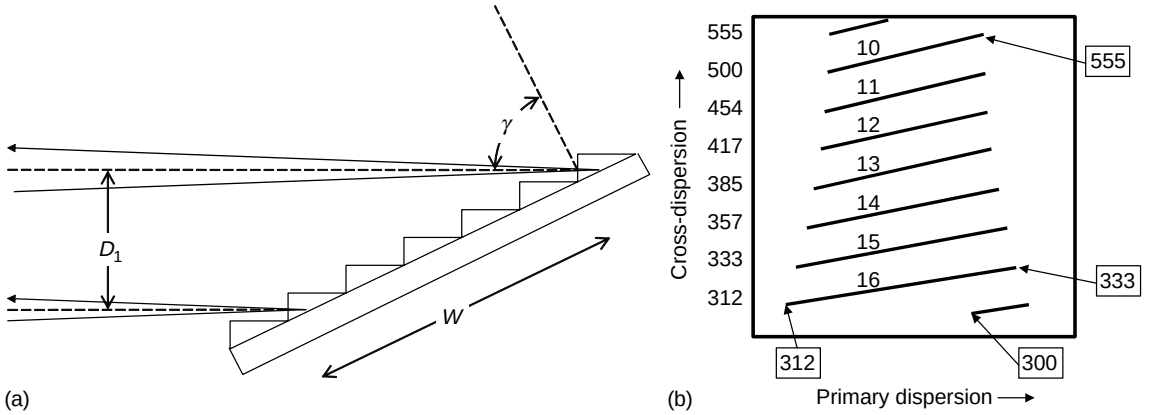

Figure 6 (a) Basic layout of an Echelle grating used in a near-Littrow configuration. (b) Illustrative cross-dispersed spectrogram showing a simplified layout on the detector. The numbers 10–16 label the different spectral orders. The numbers labeling the vertical axis are the wavelength (nm) at the lowest end of each complete order. Other wavelengths are labeled for clarity. For simplicity the orders are shown evenly spaced in cross-dispersion.

In the configuration shown in Figure 6, R is maximized by increasing W. This also means that $G = m\rho\lambda$ is large. In order to avoid excessively high ruling densities, the grating may be used in high orders. However, this presents the problem of order overlap since the wavelength in order m occurs in the same place as wavelength $\lambda_n = (m/n)\lambda_m$ in order n. Limiting the observation to a single order via the use of order-sorting filters is one solution while another is to use cross-dispersion via a chain of prisms or a grating with dispersion perpendicular to that of the echelle to separate the orders out. This option severely curtails the use of such spectral formats in multi-object spectroscopy.

Increasing resolving power using immersed gratings. All the methods of using diffraction gratings discussed so far are subject to various geometric constraints which ultimately limit the maximum obtainable resolving power by placing limits on W (e.g., in eqn [14]). These may be partly overcome by optically coupling the dispersers to immersing prisms. This can lead to a doubling of the resolving power in some cases.

Use of prisms. The final method of dispersion is to use a prism. This has the advantage that, since it does not work by multibeam interference, the light is not split into separate orders which removes the problem of order-overlap and improves efficiency. However, it does not produce the high spectral resolution required for some applications and the dependency of dispersion on λ is often markedly nonlinear.

From a consideration of Fermat's principle, it can be shown that the resolving power of a prism is:

$$R = \frac{\lambda t}{\chi D_{\mathrm{T}}}\left(\frac{\mathrm{d}n}{\mathrm{d}\lambda}\right) \qquad [25]$$

where t is the baselength of the prism. Using modern materials, $R \lesssim 300$ may be obtained. The problem of the nonlinearity in dispersion can be alleviated by the use of composite materials with opposite signs of dispersion.

Multiobject spectroscopy (MOS)

As discussed above, there is great value in increasing the multiplex gain. This can be done in two ways:

(i) *Increasing the number of apertures in the slit mask (Multislits)*. This requires that each slit is carefully cut in the mask because, although the telescope attitude (translation and rotation) may be adjusted to suit one aperture, errors in the relative positions of slits cannot be compensated since the image scale is fixed. Each aperture produces a spectrum on the detector and the mask designer must ensure that the targets and their matching slits are chosen to avoid overlaps between spectra and orders. This has the effect of limiting the surface density of targets which can be addressed in one observation. Passband filters can be used to limit the wavelength range and reduce the overlap problem. This option requires superior optics able to accommodate both a wide FOV and large disperser.

(ii) *Using optical fibers (Multifibers)*. A number of fibers may be deployed at the telescope focus to

direct light from the various targets to a remote spectrograph whose input focus consists of one or more continuous pseudoslits. These are made up of the fiber outputs arranged in a line. The continuous nature of the slit means that spectral overlap is avoided without restricting the surface density of addressable targets; although there is a limit imposed by the distance of closest approach of the fibers. The method of deploying the fiber inputs may be a plugplate consisting of pre-cut holes into which encapsulated fibers are manually plugged, or a pick-and-place robot which serially positions the fiber inputs at the correct location on a magnetized field plate. The latter is highly versatile but mechanically complex with a significant configuration time that may erode the actual on-target integration time.

The two systems have contrasting capabilities (Figure 7). The multislit approach provides generally better SNR since the light feeds into the spectrograph directly, but is compromised in terms of addressable surface density of targets, by the need to avoid spectral overlap and in FOV by the difficulty of the wide-field optics. A current example of this type of instrument, GMOS, is shown in Figure 8 and described in Table 5. The multifiber approach is limited in SNR by modal noise in the fibers and attendant calibration uncertainties and the lack of contiguous estimates of the sky background. However, it is easier to adapt to large fields since the spectrograph field can be much smaller than the field over which the fiber inputs are distributed. In summary, multislit systems are best for narrow-but-deep surveys while the multifiber systems excels at wide-but-shallow surveys. Fiber-fed instruments may further prove their worth in ELTs where technical problems may require that these bulky instruments are mounted off the telescope (see below for further discussion).

Of paramount importance in MOS is the quality of the background subtraction as discussed above. Traditionally, this requires slits which sample the sky background directly adjacent to the object. An alternative is nod-and-shuffle (va-et-vient) in which nearby blank regions are observed alternately with the main field using the same slit mask by moving the telescope (the nod). In the case of CCDs, the photo-generated charge from the interleaved exposures is stored temporarily on the detector by moving it to an unilluminated portion of the device (the shuffle). After many repeats on a timescale less than that of variations in the sky background (a few minutes), the accumulated charge is read out, incurring the read-noise penalty only once. Although requiring an effective doubling of the exposure time and an

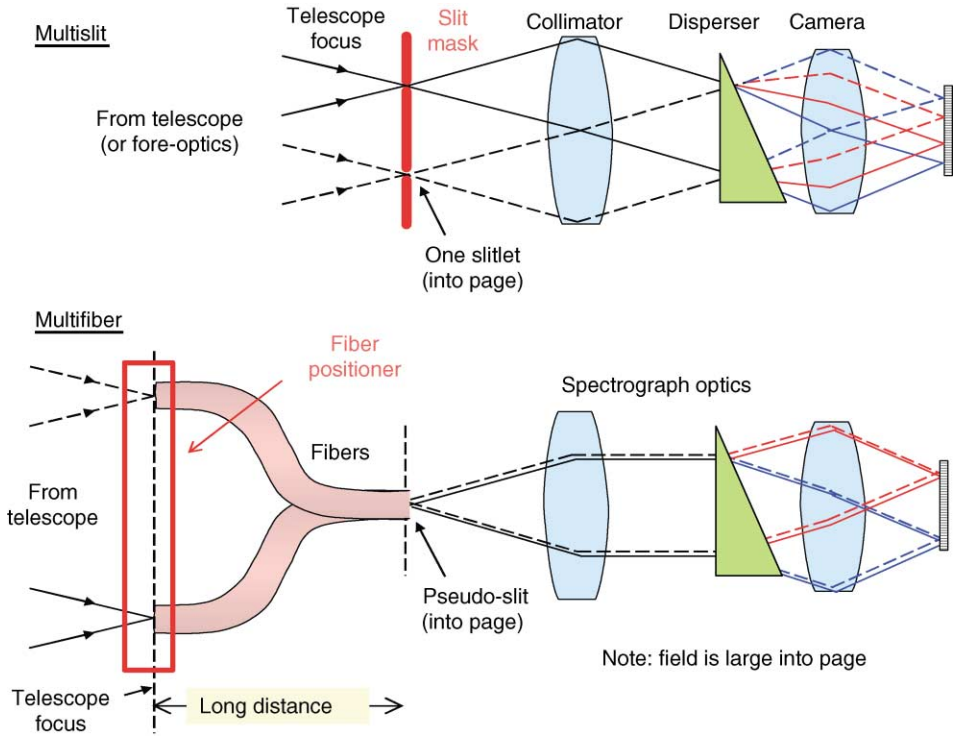

Figure 7 Illustration of the difference between the multislit and multifiber approaches to multi-object spectroscopy.

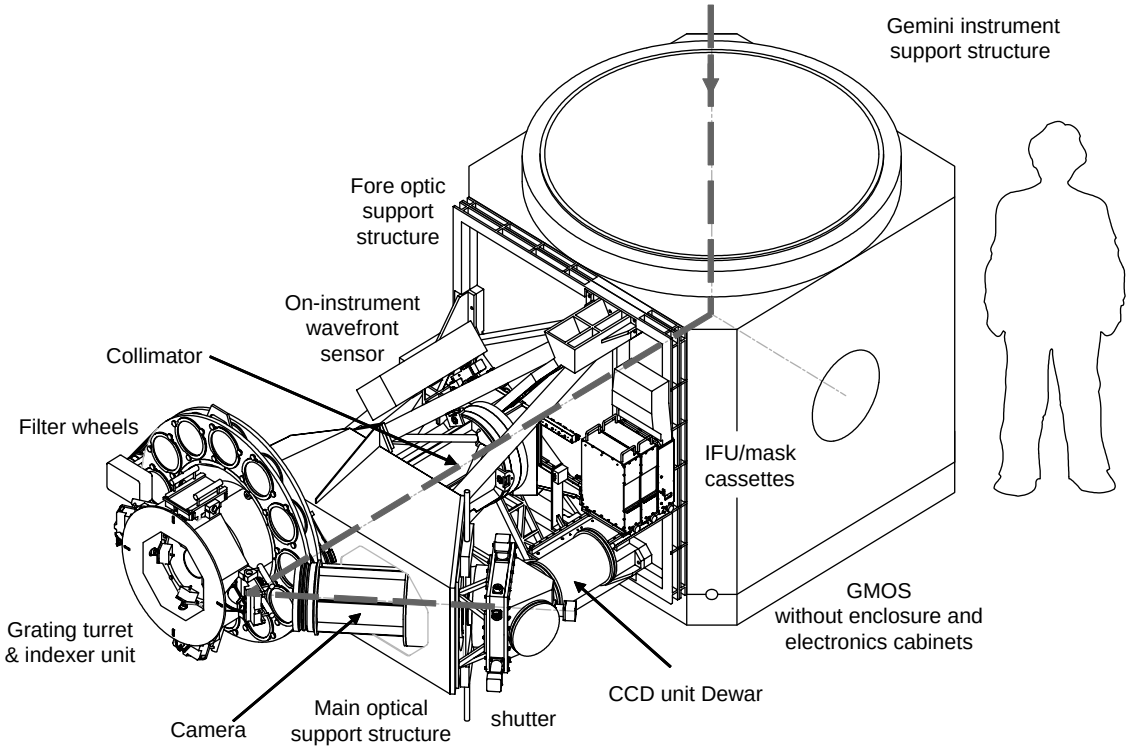

Figure 8 The Gemini Multiobject Spectrograph (GMOS). One of two built for the two Gemini 8-m telescopes by a UK–Canadian consortium. It includes an integral field capability provided by a fiber-lenslet module built by the University of Durham. The optical configuration is the same as shown in **Figure 2**. It is shown mounted on an instrument support unit which includes a mirror to direct light from the telescope into different instruments. The light path is shown by the red dashed line. The slit masks are cut by a Nd-YAG laser in 3-ply carbon fiber sheets. See **Table 5** for the specification.

Table 5 Main characteristics of the Gemini multiobject spectrographs

Image scale	72 mas/pixel	FOV	$5.5' \times 5.5'$
Detector	CCD with 13.5 μm pixels Format: $3 \times (4608 \times 2048)$	Slit/mask configuration	$\leq$ few $\times$ 100 slits of width $\geq 0.2''$
Wavelength range	Total: 0.4–1.0 μm Simultaneous: $\leq$ 1 octave	Integral field unit	$1500 \times 0.2''$ samples in 50 sq.$''$
Spectral resolving power	$R \leq 5000$ with $0.5''$ slit	Dispersion options	3 gratings + mirror for imaging

increase in the size of the detector, this technique allows the length of the slits to be reduced since no contiguous sky sample is required, thereby greatly increasing the attainable multiplex gain if the number density of potential targets is sufficiently high.

Integral field spectroscopy (IFS)

IFS provides a spectrum of each spatial sample simultaneously within a contiguous FOV. Other approaches provide the same combination of imaging and spectroscopy but require a series of nonsimultaneous observations. Examples include imaging through a number of narrow passband filters with different effective wavelength and spectroscopy with a single slit which is stepped across the object. Other such techniques are Fabry–Perot, Fourier-transform and Hadamard spectroscopy. Since the temporal variation of the sky background is a major limitation in astronomy of faint objects, IFS is the preferred technique for terrestrial observations of faint objects, but nonsimultaneous techniques are preferable in certain niche areas, and relatively more important in space where the sky background is reduced.

The main techniques (**Figure 9**) are as follows:

(i) *Lenslets*. The field is subdivided by placing an array of lenslets at the telescope focus (or its conjugate following re-imaging fore-optics) to form a corresponding array of micropupils. These are re-imaged on the detector by a focal

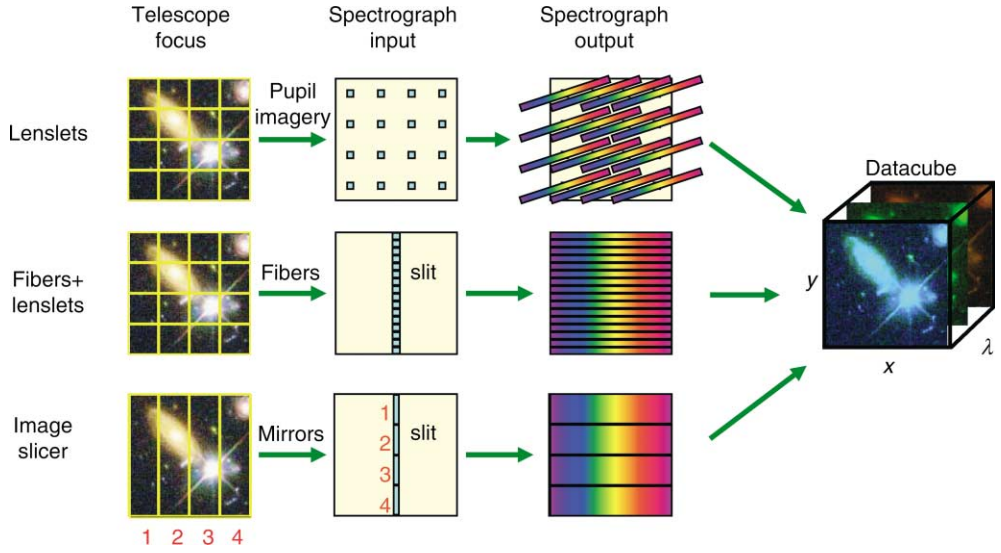

Figure 9 Main techniques of integral field spectroscopy.

reducer using a conventional disperser. The spectra are, therefore, arranged in the same pattern as that of the lenslet array. Spectral overlap is reduced by angling the dispersion direction away from the symmetry axes of the lenslet array and by the fact that the pupil images are smaller than the aperture of the corresponding lenslet.

(ii) *Fibers + lenslets*. The field is subdivided as in (i) but the pupil images are relayed to a remote spectrograph using optical fibers which reformat the field into linear pseudoslits. This avoids the problem of overlap, allowing a greater length of spectrum than in (i), but is more complex since the arrays of fibers and lenslets must be precisely co-aligned and are subject to modal noise in the fibers.

(iii) *Image slicer*. The field is subdivided in only one dimension by a stack of thin slicing mirrors placed at a conjugate of the telescope focus (Figure 10). Each mirror is angled so as to direct light to its own pupil mirror which re-images the field to form part of a linear pseudoslit. Thus the slices into which the image is divided are rearranged end-to-end to form a continuous slit at the spectrograph input. Unlike the other techniques, this retains spatial information along the length of each slice. This is dispersed by conventional means via a focal-reducer. An additional optic is often required at the image of each slice at the slit to reimage the micropupil images produced by the slicing mirrors onto a common pupil inside the spectrograph. In principle this is the most efficient of the three methods since the one-dimensional slicing produces fewer diffraction losses in the spectrograph than the two-dimensional division used by the others, and minimizes the fraction of the detector surface which must be left unilluminated in order to avoid cross-talk between noncontiguous parts of the field. However the micromirrors are difficult to make since they require diamond-turning or grinding in metal or glass with a very fine surface finish (typically with RMS ~ 1 nm for the optical and ~ 10 nm in the infrared). This sort of system is, however, well-matched to cold temperatures, since the optical surfaces and mounts may be fabricated from the same material (e.g., Al) or from materials with similar thermal properties.

The data are processed into a datacube whose dimensions are given by the two spatial coordinates, x, y, plus wavelength. The datacube may be sliced up in ways analogous to tomography to understand the physical process operating in the object.

Spectropolarimetry and Polarimetry

Spectropolarimetry and polarimetry are analogous to spectroscopy and imaging, where the polarization state of the light is measured instead of the total intensity. Like IFS, spectropolarimetry is a photon-starved (i.e., limited in SNR by photon noise) area which benefits from the large aperture of current and projected telescopes.

The Stokes parameters of interest are I, Q, and U. V is generally very small for astronomical objects.

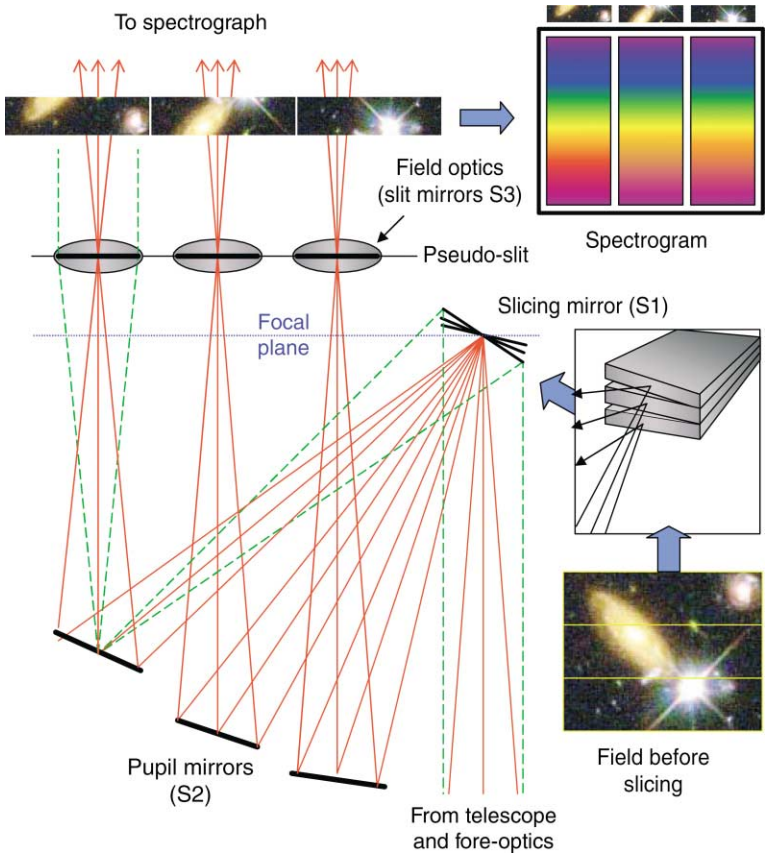

Figure 10 Principle of the advanced image slicer. Only three slices are shown here. Real devices have many more, e.g., the IFU for the *Gemini Near-Infrared Spectrograph* has 21 to provide a $5'' \times 3''$ field with $0.15'' \times 0.15''$ sampling. Reproduced from Content R (1997) A new design for integral field spectroscopy with 8 m telescopes. *Proceedings SPIE* 2871: 1295–1305.

From these, the degree and azimuthal angle of linear polarization are obtained as:

$$\pi_{\mathrm{L}} = \left(\frac{Q^2 + U^2}{I^2}\right) \qquad \psi = \frac{1}{2}\arctan\left(\frac{U}{Q}\right) \qquad [26]$$

The Stokes parameters may be estimated using a modified spectrograph with a rotatable achromatic half-wave retarder, characterized by the angle of rotation about the optical axis, θ, placed before the instrument and a polarizing beamsplitter which separates the incident beam into orthogonal polarization states (Figure 11). The two states are recorded simultaneously on different regions of the detector. The separation is achieved usually through the angular divergence produced by a Wollaston prism placed before the disperser or through the linear offset produced by a calcite block placed before the slit. The intensity as a function of the waveplate rotation angle, $S(\theta)$, is recorded for each wavelength and position in the spectrum or image. The Stokes parameters for each sample are then given by

$$\begin{aligned}
\frac{Q}{I} &= \frac{S(0) - S(\pi/2)}{S(0) + S(\pi/2)} \\
&= \left\langle \frac{A_1 - \omega_{AB}B_1}{A_1 + \omega_{AB}B_1}, \frac{A_2 - \omega_{AB}B_2}{A_2 + \omega_{AB}B_2} \right\rangle \\
\frac{U}{I} &= \frac{S(\pi/4) - S(3\pi/4)}{S(\pi/4) + S(3\pi/4)} \\
&= \left\langle \frac{C_1 - \omega_{CD}D_1}{C_1 + \omega_{CD}D_1}, \frac{C_2 - \omega_{CD}D_2}{C_2 + \omega_{CD}D_2} \right\rangle \\
I &= S(0) + S(\pi/2) \\
&= \left\langle \frac{A_1 + \omega_{AB}B_1}{\eta_{A1}}, \frac{A_2 + \omega_{AB}B_2}{\eta_{A2}} \right\rangle \text{ etc.}
\end{aligned} \qquad [27]$$

where A and B are the signals (functions of position and/or λ) recorded with the waveplate at $\theta = 0$ and $\theta = \pi/2$ and the subscripts 1 and 2 refer to the two polarization states produced by the beamsplitter.

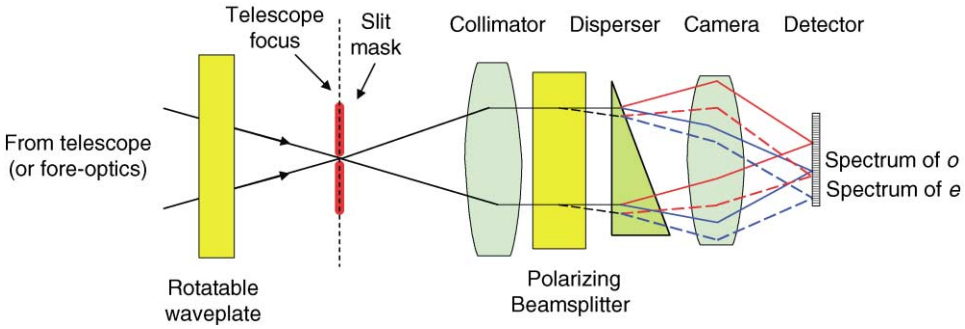

Figure 11 Schematic layout of spectropolarimeter using a polarizing beamsplitter in the collimated beam (e.g., a Wollaston prism producing *e*- and *o*-states) to produce separate spectra for orthogonal polarization states on the detector. Alternative configurations in which the two polarizations have a linear offset (e.g., a calcite block) may be used in which case the beamsplitter is placed before the slit.

Likewise, C and D are a pair of observations taken with $\theta = \pi/4$ and $\theta = 3\pi/4$. The angled brackets indicate a suitable method of averaging the quantities inside. The factors ω_{AB} and ω_{CD} are estimated as

$$\omega_{AB} = \sqrt{\frac{A_1 A_2}{B_1 B_2}} \qquad \omega_{CD} = \sqrt{\frac{C_1 C_2}{D_1 D_2}} \qquad [28]$$

and η_{A1} is a single calibration factor for polarization state 1 of observation A, etc. One problem is instrumental polarization caused by oblique reflections from telescope mirrors upstream of the polarizing waveplate, such as the fold mirror external to GMOS (see Figure 8). This must be carefully accounted for by taking observations of stars with accurately known polarization. The dispersing element is also likely to be very strongly dependent on the polarization state of the incident light with widely different efficiency as a function of wavelength. Although this effect is cancelled out using the procedure described above, it introduces a heavy toll in terms of SNR reduction.

Technology Issues

Use of Optical Fibers in Astronomy

As discussed above, optical fibers are commonly used in astronomy for coupling spectrographs to wide, sparsely sampled FOVs in the case of MOS, or small contiguously sampled FOVs in the case of IFS. For both applications, the most important characteristics are:

(i) *Throughput*. Near-perfect transmission is required for wavelength intervals of ~1 octave within the overall range of 0.3–5 μm. For MOS, a prime focus fiber feed to an off-telescope spectrograph implies fiber runs of several tens of meters for 8 m telescopes, increasing proportionally for ELTs. For IFS, runs of only ~1 m are required for self-contained par-focal IFUs. For $\lambda < 2.5$ μm, fused silica is a suitable material, although it is not currently possible to go below ~0.35 μm, depending on fiber length. Newer techniques and materials may improve the situation. For $\lambda > 2.5$ μm, alternative materials are required, such as ZrF4 and, at longer wavelengths, chalcogenide glasses, but these are much more expensive and difficult to use than fused silica.

(ii) *Conservation of Etendue*. Fibers suffer from focal ratio degradation, a form of modal diffusion, which results in a speeding up of the output beam with respect to the input. Viewed as an increase in entropy, it results in a loss of information. In practice, this implies either reduced throughput, as the fiber output is vignetted by fixed-size spectrograph optics, or a loss in spectral resolution if the spectrograph is oversized to account for the faster beam from the fibers. This effect may be severe at the slow focal ratios pr oduced by many telescopes ($F > 10$) but is relatively small for fast beams ($F < 5$). Thus, its effect may be mitigated by speeding up the input beam by attaching lenslets directly to the fibers, either individually (for MOS) or in a close-packed array (for IFS). If the spectrograph operates in both fiber- and beam-fed modes (e.g., Figure 8), it is also necessary to use lenslets at the slit to convert the beam back to the original speed.

(iii) *Efficient coupling to the telescope*. This requires that the fibers are relatively thick to match the physical size of the sampling at the telescope focus which is typically $\chi_s = 0.1''$ for IFS and $\chi_s = 2''$ for MOS. By conservation of Etendue, the physical size of the fiber aperture is

$$d_f = \chi_s D_T F_f \qquad [29]$$

where F_f is the focal ratio of the light entering the fiber and D_T is the diameter of the telescope aperture. Using the above values with $F_f = 4$, as required to maintain Etendue, implies $15 < d_f < 300$ μm for an 8 m or $60 < d_f < 1200$ μm for a 30 m telescope. Except at the lower end, this implies the use of multimode (step-index) fibers. However, the need in IFS to oversize the fibers to account for manufacturing errors and current requirements of $\chi_s \geq 0.2''$ to produce sufficient SNR in a single spatial sample gives a practical limit of $d_f > 50$ μm which is in the multimode regime.

Recently, the use of photonic crystal fibers in astronomy has been investigated. These, together with other improvements in material technology may improve the performance of optical fibers, which will be of special relevance to ELTs where, for example, there will be a need to couple very fast beams into fibers.

Cooling for the Near-Infrared

As shown in Figure 12, it is necessary to cool instruments for use in the infrared. This is to prevent thermal emission from the instrument becoming the dominant noise source. The minimum requirement is to place a cold stop at a conjugate of the telescope pupil. However, much of the rest of the instrument requires cooling because of the nonzero emissivity of the optics. The telescope also requires careful design. For example, the Gemini telescopes are optimized for the NIR by undersizing M2 so that the only stray light entering the final focal surface is from the cold night sky.

Irrespective of the thermal background and wavelength, all detectors (see Table 4), require cooling to reduce internally generated noise to acceptable levels. For the CCDs used in the optical, the cryogen is liquid nitrogen, but for the infrared, cooling with liquid helium is required.

Structure

As discussed above, the necessity for instruments to scale in size with the telescope aperture cannot be achieved by simply devising a rigid structure, since the required materials are generally not affordable (instruments on 8 m telescopes cost roughly €/$ 5–15 M, including labor). Furthermore, the stability also depends critically on the mounting of the individual optical elements, where the choice of material is constrained by the need for compliance with the optical materials. The solution adopted for GMOS was to design the collimator and camera mounting so that variations in the gravity vector induce a translation in each component orthogonal to the optical axis without inducing tilts or defocus. Therefore, the only effect of instability is a translation of the image of the slit on the detector. Since the slit area is rigidly attached to the telescope interface, the image of a celestial object does not move with respect

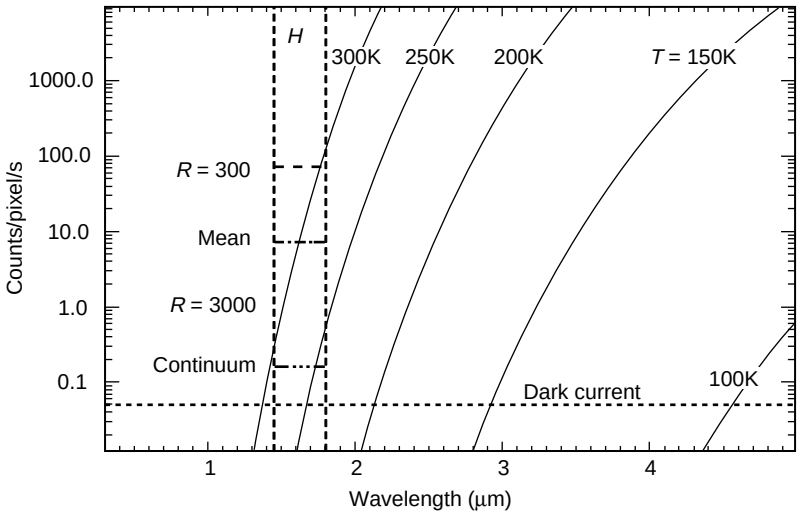

Figure 12 Illustration of the need for cooling in NIR instruments. This is modeled for the case of a spectrograph on an 8 m telescope with $0.2'' \times 0.2''$ sampling with both throughput and total emissivity of 50%. The curves indicate the cumulative thermal background for wavelengths shortward of that shown on the scale. For comparison, a typical dark current is shown for NIR detectors (see Table 4). Also shown is the background from the night sky for the case of the *H*-band, for two values of spectral resolution, *R*. The mean sky background level is shown for both values of *R*. For $R = 3000$, the continuum level found between the strong, narrow OH-lines which make up most of the signal is also shown. To observe in the *H*-band, cooling to $-40\,^{\circ}$C is required for high spectral resolution, but is unnecessary at low resolution. At longer wavelengths, fully cryogenic cooling with liquid nitrogen is generally required.

to the slit providing that the telescope correctly tracks the target. The motion of the image of the slit on the detector is then corrected by moving the detector orthogonal to the optical axis to compensate. Taking account of nonrepeatable motion in the stucture and the detector mounting, it proved possible to attain the desired stability in open-loop by measuring the flexure experienced with the control system turned off, making a look-up table to predict the required detector position for each attitude setting (elevation and attitude) and applying the correction by counting pulses sent to the stepper motors which control the detector translation.

Some instruments require much greater stability than GMOS does. The flexure-control outlined above may be augmented by operation in closed-loop so that nonrepeatable movements may be accounted for. However, this ideally requires a reference light source which illuminates the optics in the same way as the light from the astronomical target and which is recorded by the science detector without adversely impacting the observation. Alternatively, partial feedback may be supplied by repeated metrology of key optical components such as fold-mirrors.

One strategy to measure radial velocities to very small uncertainities (a few meters per second) is to introduce a material (e.g., iodine) into the optical path, which is present throughout the observations. This absorbs light from the observed object's continuum at one very well-defined wavelength. Thus, instrument instability can be removed by measuring the centroid of the desired spectral line in the object relative to the fixed reference produced by the absorption cell. However, flexure must still be carefully controlled to avoid blurring the line during the course of a single exposure.

Mounting of instruments via a fiber-feed remotely from the telescope, at a location where they are not subjected to variations in the gravity vector, is a solution for applications where great stability is required. But, even here, care must be taken with the fore-optics and pickoff system attached to the telescope, and to account for modal noise induced by changes in the fiber configuration as the telescope tracks.

Finally, the instrument structure has other functions. For cooled instruments, a cryostat is required inside which most of the optical components are mounted. For uncooled instruments, careful control of temperature is needed to avoid instrument motion due to thermal expansion. This requires the use of an enclosure which not only blocks out extraneous light, but provides a thermal buffer against changes in the ambient temperature during observations and reduces thermal gradients by forced circulation of air.

Ellipsometry

Introduction

Ellipsometry measures a change in polarization as light reflects from or transmits through a material structure. The polarization-change is represented as an amplitude ratio, Ψ, and a phase difference, Δ. The measured response is dependent on optical properties and thickness of each material. Thus, ellipsometry is primarily used to determine film thickness and optical constants. However, it is also applied to the characterization of composition, crystallinity, roughness, doping concentration, and other material properties associated with a change in optical response.

Interest in ellipsometry has grown steadily since the 1960s as it provided the sensitivity necessary to measure nanometer-scale layers used in microelectronics. Today, the range of applications has spread to basic research in physical sciences, semiconductor, data storage, flat panel display, communication, biosensor, and optical coating industries. This widespread use is due to increased dependence on thin films in many areas and the flexibility of ellipsometry to measure most material types: dielectrics, semiconductors, metals, superconductors, organics, biological coatings, and composites of materials.

This article provides a fundamental description of ellipsometry measurements along with the typical data analysis procedures. The primary applications of ellipsometry are also surveyed.

Light and Materials

Ellipsometry measurements involve the interaction between light and material.

Light

Light can be described as an electromagnetic wave traveling through space. For ellipsometry, it is adequate to discuss the electric field behavior in space and time, also known as polarization. The electric field of a wave is always orthogonal to the propagation direction. Therefore, a wave traveling along the z-direction can be described by its x- and y-components. If the light has completely random orientation and phase, it is considered unpolarized. For ellipsometry, we are interested in the case where the electric field follows a specific path and traces out a distinct shape at any point. This is known as polarized light. When two orthogonal light waves are in-phase, the resulting light will be linearly polarized (Figure 1a). The relative amplitudes determine the resulting orientation. If the orthogonal waves are 90° out-of-phase and equal in amplitude, the resultant light is circularly polarized (Figure 1b). The most general polarization is 'elliptical', which combines orthogonal waves of arbitrary amplitude and phase (Figure 1c). This is how ellipsometry gets its name.

Materials

Two values are used to describe optical properties, which determine how light interacts with a material.

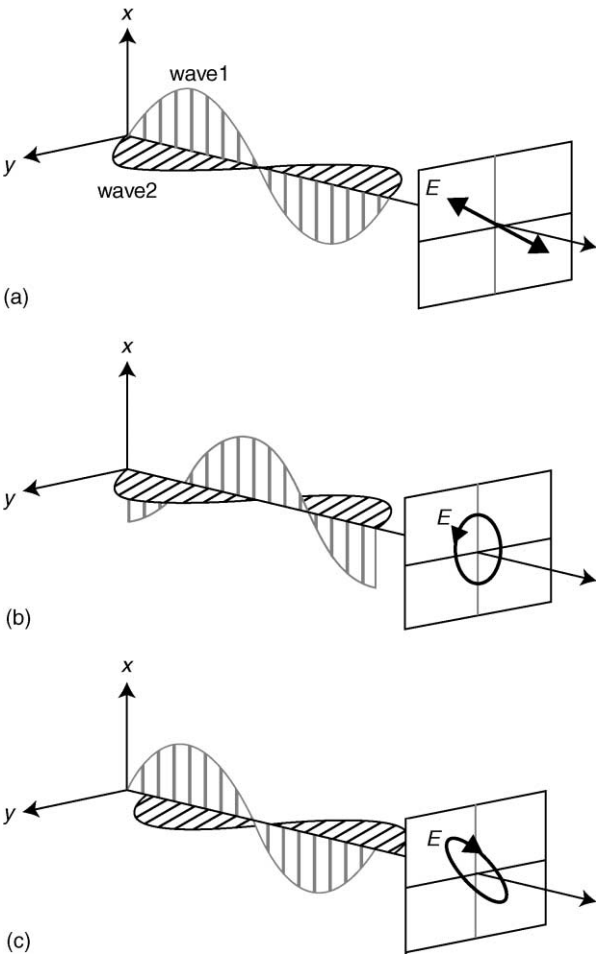

Figure 1 Orthogonal waves combine to demonstrate polarization: (a) linear; (b) circular; and (c) elliptical.

They are generally represented as a complex number. The complex refractive index ($\tilde{n}$) consists of the index (n) and extinction coefficient (k):

$$\tilde{n} = n + ik \quad [1]$$

Alternatively, the optical properties can be represented as the complex dielectric function:

$$\tilde{\varepsilon} = \varepsilon_1 + i\varepsilon_2 \quad [2]$$

with the following relation between conventions:

$$\tilde{\varepsilon} = \tilde{n}^2 \quad [3]$$

The index describes the phase velocity for light as it travels through a material compared to the speed of light in vacuum, c:

$$v = \frac{c}{n} \quad [4]$$

Light slows as it enters a material with higher index. Because frequency remains constant, the wavelength will shorten. The extinction coefficient describes the loss of wave energy to the material. It is related to the absorption coefficient, α, as:

$$\alpha = \frac{4\pi k}{\lambda} \quad [5]$$

Light loses intensity in an absorbing material, according to Beer's Law:

$$I(z) = I(0)\, e^{-i\alpha z} \quad [6]$$

Thus, the extinction coefficient relates how quickly light vanishes in a material. These concepts are demonstrated in Figure 2, where a light wave travels from air into two different materials of varying properties.

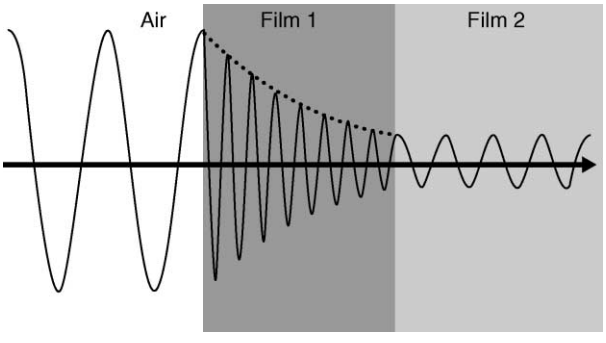

Figure 2 Wave travels from air into absorbing Film 1 and then transparent Film 2. The phase velocity and wavelength change in each material depending on index of refraction (Film 1: $n = 4$, Film 2: $n = 2$).

The optical constants for TiO_2 are shown in Figure 3 from the ultraviolet (UV) to the infrared (IR). The optical constants are wavelength dependent with absorption ($k > 0$) occurring in both UV and IR, due to different mechanisms that take energy from the light wave. IR absorption is commonly caused by molecular vibration, phonon vibration, or free-carriers. UV absorption is generally due to electronic transitions, where light provides energy to excite an electron to an elevated state. A closer look at the optical constants in Figure 3 shows that real and imaginary optical constants are not independent. Their shapes are mathematically coupled together through Kramers–Krönig consistency. Further details are covered later in this article.

Interaction Between Light and Materials

Maxwell's equations must remain satisfied when light interacts with a material, which leads to boundary conditions at the interface. Incident light will reflect and refract at the interface, as shown in Figure 4. The angle between the incident ray and sample normal

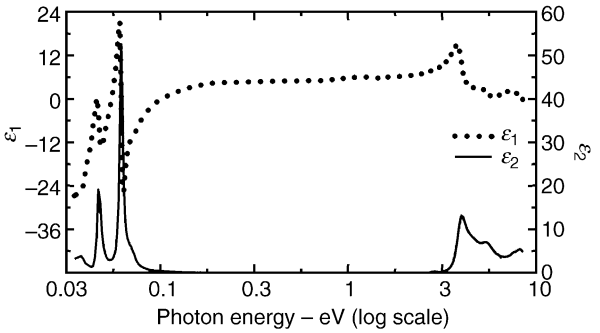

Figure 3 Complex dielectric function for TiO_2 film covering wavelengths from the infrared (small eV) to the ultraviolet (high eV).

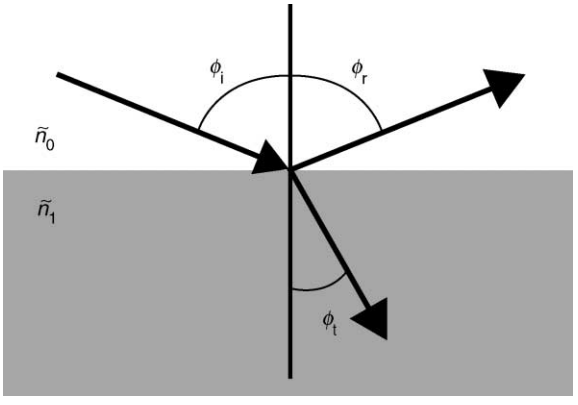

Figure 4 Light reflects and refracts according to Snell's law.

(ϕ_i) will be equal to the reflected angle, (ϕ_r). Light entering the material is refracted to an angle (ϕ_t) given by:

$$n_0 \sin(\phi_i) = n_1 \sin(\phi_t) \quad [7]$$

The same occurs at every interface where a portion reflects and the remainder transmits at the refracted angle. This is illustrated in Figure 5. The boundary conditions provide different solutions for electric fields parallel and perpendicular to the sample surface. Therefore, light can be separated into orthogonal components with relation to the plane of incidence. Electric fields parallel and perpendicular to the plane of incidence are considered p- and s-polarized, respectively. These two components are independent for isotropic materials and can be calculated separately. Fresnel described the amount of light reflected and transmitted at an interface between materials:

$$r_s = \left(\frac{E_{0r}}{E_{0i}}\right)_s = \frac{n_i \cos\theta_i - n_t \cos\theta_t}{n_i \cos\theta_i + n_t \cos\theta_t} \quad [8a]$$

$$r_p = \left(\frac{E_{0r}}{E_{0i}}\right)_p = \frac{n_t \cos\theta_i - n_i \cos\theta_t}{n_i \cos\theta_t + n_t \cos\theta_i} \quad [8b]$$

$$t_s = \left(\frac{E_{0t}}{E_{0i}}\right)_s = \frac{2n_i \cos\theta_i}{n_i \cos\theta_i + n_t \cos\theta_t} \quad [8c]$$

$$t_p = \left(\frac{E_{0t}}{E_{0i}}\right)_p = \frac{2n_i \cos\theta_i}{n_i \cos\theta_t + n_t \cos\theta_i} \quad [8d]$$

Thin film and multilayer structures involve multiple interfaces, with Fresnel reflection and transmission coefficients applicable at each. It is important to track the relative phase of each light component to correctly determine the overall reflected or transmitted beam. For this purpose, we define the film phase thickness as:

$$\beta = 2\pi\left(\frac{t_1}{\lambda}\right) n_1 \cos\theta_1 \quad [9]$$

The superposition of multiple light waves introduces interference that is dependent on the relative phase of each light wave. Figure 5 illustrates the combination of light waves in the reflected beam and their corresponding Fresnel calculations.

Ellipsometry Measurements

For ellipsometry, primary interest is measurement of how p- and s-components change upon reflection or transmission relative to each other. In this manner, the reference beam is part of the experiment. A known polarization is reflected or transmitted from the sample and the output polarization is measured. The change in polarization is the ellipsometry measurement, commonly written as:

$$\rho = \tan(\Psi)\, e^{i\Delta} \quad [10]$$

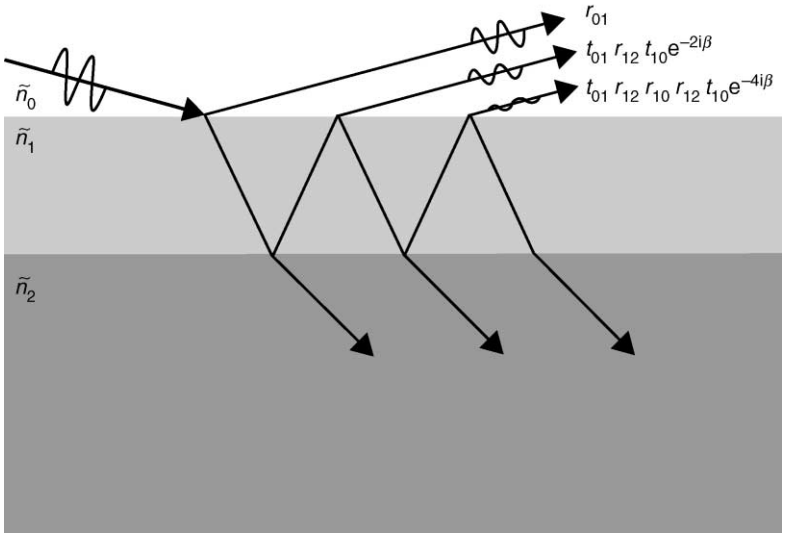

Figure 5 Light reflects and refracts at each interface, which leads to multiple beams in a thin film. Interference between beams depends on relative phase and amplitude of the electric fields. Fresnel reflection and transmission coefficients can be used to calculate the response from each contributing beam.

An example ellipsometry measurement is shown in Figure 6. The incident light is linear with both p- and s-components. The reflected light has undergone amplitude and phase changes for both p- and s-polarized light, and ellipsometry measures their changes.

The primary methods of measuring ellipsometry data all consist of the following components: light source, polarization generator, sample, polarization analyzer, and detector. The polarization generator and analyzer are constructed of optical components that manipulate the polarization: polarizers, compensators, and phase modulators. Common ellipsometer configurations include rotating analyzer (RAE), rotating polarizer (RPE), rotating compensator (RCE), and phase modulation (PME).

The RAE configuration is shown in Figure 7. A light source produces unpolarized light, which is sent through a polarizer. The polarizer passes light of a preferred electric field orientation. The polarizer axis is oriented between the p- and s-planes, such that both arrive at the sample surface. The linearly polarized light reflects from the sample surface, becoming elliptically polarized and travels through a continuously rotating polarizer (referred to as the analyzer). The amount of light allowed to pass will depend on the polarizer orientation relative to the electric field 'ellipse' coming from the sample. The detector converts light from photons to electronic signal to determine the reflected polarization. This information is used with the known input polarization to determine the polarization change caused by the sample reflection. This is the ellipsometry measurement of Ψ and Δ.

Single Wavelength Ellipsometry (SWE)

SWE uses a single frequency of light to probe the sample. This results in a pair of data, Ψ and Δ, used to determine up to two material properties. The optical design can be simple, low-cost, and accurate. Lasers are an ideal light source with well-known wavelength and significant intensity. The optical elements can be optimized to the single wavelength. However, there is relatively low information content (two measurement values). SWE is excellent for quick measurement of

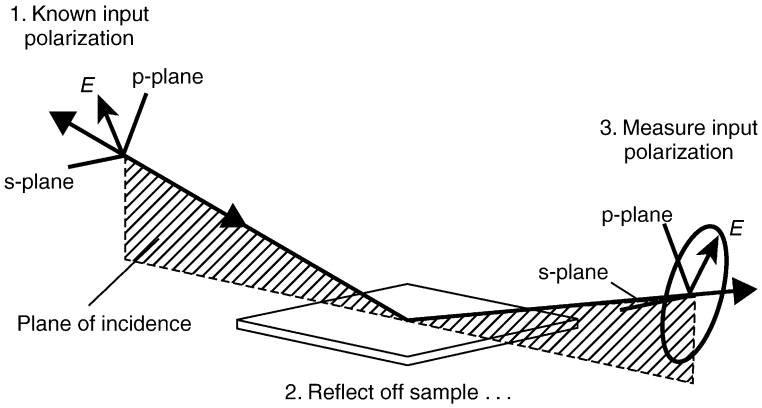

Figure 6 Typical ellipsometry configuration, where linearly polarized light is reflected from the sample surface and the polarization change is measured to determine the sample response.

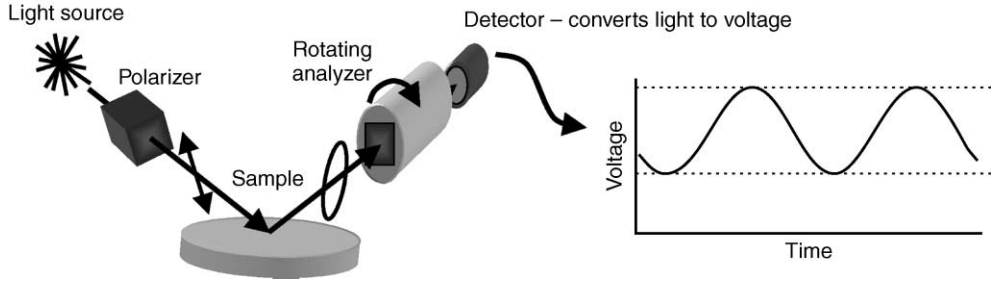

Figure 7 Rotating analyzer ellipsometer configuration uses a polarizer to define the incoming polarization and a rotating polarizer after the sample to analyze the outgoing light. The detector converts light to a voltage with the time-dependence leading to measurement of the reflected polarization.

nominally known films, like SiO_2 on Si. Care must be taken when interpreting unknown films, as multiple solutions occur for different film thickness. The data from a transparent film will cycle through the same values as the thickness increases. From Figure 5, it can be seen that this is related to interference between the multiple light beams. The refracted light may travel through different thicknesses to emerge in-phase with the first reflection, but is the returning light delayed by one wavelength or multiple wavelengths? Mathematically, the thickness cycle can be determined as:

$$D_\phi = \frac{\lambda}{2\sqrt{\tilde{n}_1^2 - \tilde{n}_0^2 \sin^2\phi}} \qquad [11]$$

This is demonstrated in Figure 8, where the complete thickness cycle is shown for SiO_2 on Si at 75° angle of incidence and 500 nm wavelength. A bare silicon substrate would produce data at the position of the star. As the film thickness increases, the data will move around this circle in the direction of the arrow. From eqn [11], the thickness cycle is calculated as 226 nm. Thus the cycle is completed and returns to the star when the film thickness reaches 226 nm. Any data point along the cycle represents a series of thicknesses which depend on how many times the cycle has been completely encircled. For example, the square represents a data point for 50 nm thickness. However, the same data point will represent 276 and 502 nm thicknesses. A second data point at a new wavelength or angle would help determine the correct thickness.

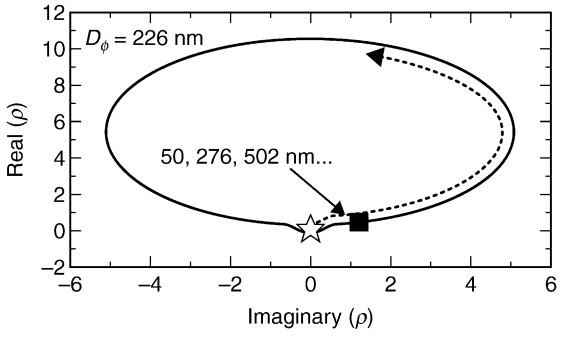

Figure 8 Data from a single wavelength will cycle through the same points as the film thickness increases. The star represents the starting point, with no SiO_2 film on Si. As the thickness increases, the data follow the cycle in the direction of the arrow. After the cycle is complete (thickness = D_ϕ), the data repeat the cycle. Thus, any point along the curve represents multiple possible thicknesses – example shown by a square at 50 nm thickness, which is also equal to 276 and 502 nm.

Spectroscopic Ellipsometry (SE)

Spectroscopic measurements solve the 'period' problem discussed for SWE. Data at surrounding wavelengths insure the correct thickness is determined, even as there remain multiple solutions at one wavelength in the spectrum. This is demonstrated in Figure 9, showing the spectroscopic data for the first three thickness results. The SE data oscillations clearly distinguish each thickness. Thus, a single thickness solution remains to match data at multiple wavelengths.

SE provides additional information content for each new wavelength. While the film thickness will remain constant regardless of wavelength, the optical constants will change across the spectrum. The optical constant shape contains information regarding the material microstructure, composition, and more. Different wavelength regions will provide the best information for each different material property. For this reason, SE systems have been developed to cover very wide spectral regions from the UV to the IR.

Spectroscopic measurements require an additional component, a method of wavelength selection. The most common methods include the use of monochromators, Fourier-transform spectrometers, and gratings or prisms with detection on a diode array. Monochromators are typically slow as they sequentially scan through wavelengths. Spectrometers and diode arrays allow simultaneous measurement at multiple wavelengths. This has become popular with the desire for high-speed SE measurements.

Variable Angle Ellipsometry

Ellipsometry measurements are typically performed at oblique angles, where the largest changes in polarization occur. The Brewster angle, defined as:

$$\tan(\phi_B) = \frac{n_1}{n_0} \qquad [12]$$

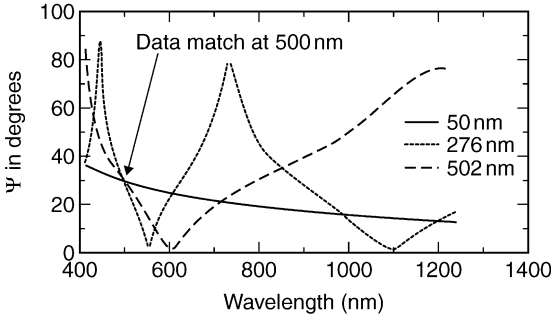

Figure 9 Three spectroscopic ellipsometry measurements that match at 500 nm wavelength, but are easily distinguishable as a function of wavelength.

gives the angle where reflection of p-polarized light goes through a minimum. Ellipsometry measurements are usually near this angle, which can vary from 55° for low-index dielectrics to 75° or 80° for semiconductors and metals.

It is also common to measure at multiple angles of incidence in ellipsometry. This allows additional data to be collected for the same material structure under different conditions. The most important change introduced by varying the angle is the change in path length through the film as the light refracts at a different angle. Multiple angles do not always add new information about a material structure, but the extra data builds confidence in the final answer.

In Situ

Within the last decade, it has become common to employ optical diagnostics during processing. *In situ* ellipsometry allows the optical response to be monitored in real-time. This has also led to feedback control for many processes. While *in situ* is generally restricted to a single angle of incidence, there is a distinct advantage to collecting data at different 'times' during processing to get unique 'glimpses' of the sample structure as it changes.

In situ SE is commonly applied to semiconductors. Conventional SE systems measure from the UV to NIR, which matches the spectral region where semiconductors absorb due to electronic transitions. The shape and position of the absorption can be very sensitive to temperature, composition, crystallinity, and surface quality, which allows SE to closely monitor these properties. *In situ* SE has also been used to monitor numerous material types, including metals and dielectrics. A promising *in situ* application is for multilayer optical coatings, where thickness and index can be determined in real-time to allow correction of future layers, to optimize optical performance.

Data Analysis

Ellipsometry measures changes in polarization. However, it is used to determine the material properties of interest, such as film thickness and optical constants. In the case of a bulk material, the equations derived for a single reflection can be directly inverted to provide the 'pseudo' optical constants from the ellipsometry measurement, ρ:

$$\langle\tilde{\varepsilon}\rangle = \sin^2(\phi)\left[1 + \tan^2(\phi)\left(\frac{1-\rho}{1+\rho}\right)\right] \qquad [13]$$

This equation assumes there are no surface layers of any type. However, there is typically a surface oxide or roughness for any bulk material and the direct inversion would incorporate these into the bulk optical constants. The more common procedure used to deduce material properties from ellipsometry measurements follows the flowchart in Figure 10. Regression analysis is required because an exact equation cannot be written. Often the answer is overdetermined with hundreds of experimental data points for a few unknowns. Regression analysis allows all of the measured data to be included when determining the solution.

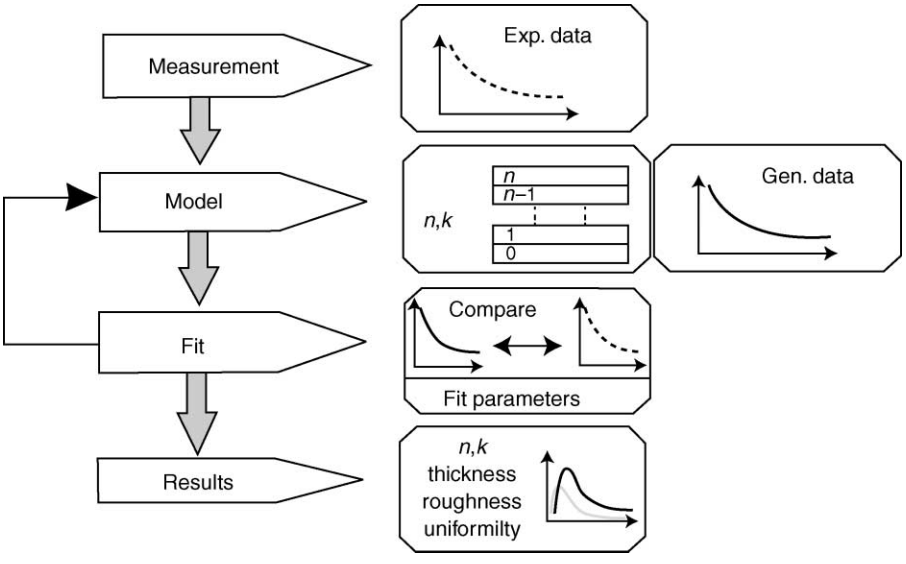

Figure 10 Flowchart for ellipsometry data analysis.

Data analysis proceeds as follows. After the sample is measured, a model is constructed to describe the sample. The model is used to calculate the predicted response from Fresnel's equations. Thus, each material must be described with a thickness and optical constants. If these values are not known, an estimate is given for the purpose of the preliminary calculation. The calculated values are compared to experimental data. Any unknown material properties can then be varied to improve the match between experiment and calculation. The number of unknown properties should not exceed the information content contained in the experimental data. For example, a single-wavelength ellipsometer produces two data points (Ψ,Δ) which allows a maximum of two material properties to be determined. Finding the best match between the model and experiment is typically done through regression. An estimator, like the mean squared error (MSE), is used to quantify the difference between curves. The unknown parameters are allowed to vary until the minimum MSE is reached.

Care must be taken to ensure the best answer is found, corresponding to the lowest MSE. For example, Figure 11a shows the MSE curve versus film thickness for a transparent film on silicon. There are multiple 'local' minima, but the lowest MSE value occurs at a thickness of 749 nm. This corresponds to the correct film thickness. It is possible that the regression algorithm will mistakenly fall into a 'local' minima, depending on the starting thickness and the MSE structural conditions. Comparing the results by eye for the lowest MSE and a local minima easily distinguish the true minima (see Figures 11b and c).

Ellipsometry Characterization

The two most common material properties studied by ellipsometry are film thickness and optical constants. In addition, ellipsometry can characterize material properties that affect the optical constants. Crystallinity, composition, resistivity, temperature, and molecular orientation can all affect the optical constants and in turn be measured by ellipsometry. This section details many of the primary applications important to ellipsometry.

Film Thickness

The film thickness is determined by interference between light reflecting from the surface and light traveling through the film. Depending on the relative phase of the rejoining light to the surface reflection, there can be constructive or destructive interference.

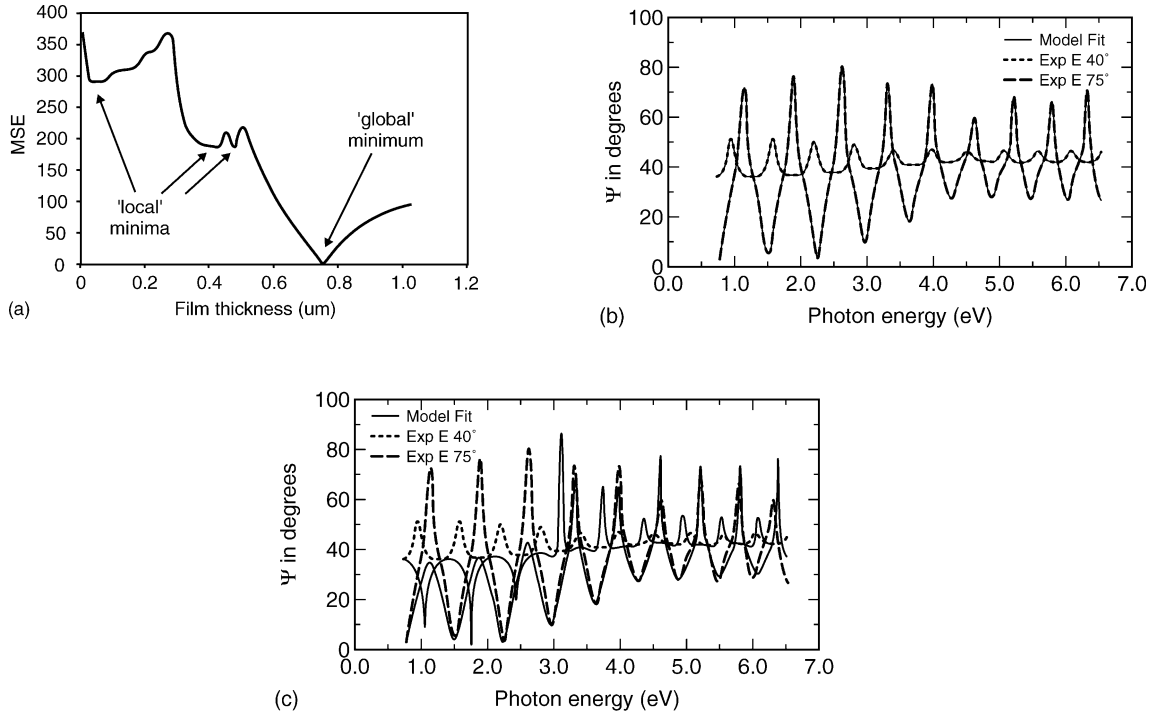

Figure 11 (a) MSE curve versus thickness shows the 'global' minimum where the best match between model and experiment occurs, and 'local' minima that may be found by the regression algorithm, but do not give the final result. (b) The experimental data and corresponding curves generated for the model at the 'global' minimum. (c) Similar curves at the 'local' minimum near 0.45 microns thickness is easily distinguishable as an incorrect result.

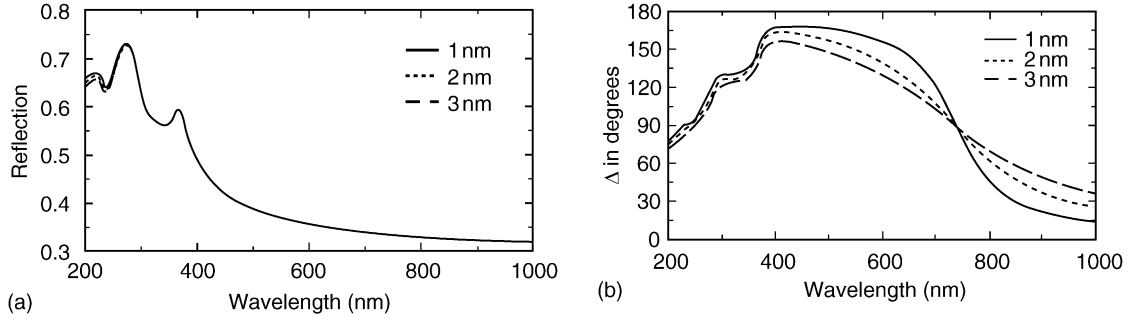

Figure 12 (a) Reflected intensity and (b) ellipsometric delta for three thin oxides on silicon show the high sensitivity of Δ to nanometer-scale films not available from the intensity measurement.

The interference involves both amplitude and phase information. The phase information from Δ is very sensitive to films down to submonolayer thickness. Figure 12 compares reflected intensity and ellipsometry for the same series of thin SiO_2 layers on Si. There are large variations in Δ, while the reflectance for each film is nearly the same.

Ellipsometry is typically used for films with thickness ranging from sub-nanometers to a few microns. As films become greater than several tens of microns thick, it becomes increasingly difficult to resolve the interference oscillations, except with longer infrared wavelengths, and other characterization techniques become preferred.

Thickness measurements also require a portion of the light to travel through the entire film and return to the surface. If the material is absorbing, thickness measurements by optical instruments will be limited to thin, semi-opaque layers. This limitation can be circumvented by measuring in a spectral region where there is lower absorption. For example, an organic film may strongly absorb UV and IR light, but remain transparent at mid-visible wavelengths. For metals, which strongly absorb at all wavelengths, the maximum layer for thickness determination is typically ~100 nm.

Optical Constants

Thickness measurements are not independent of the optical constants. The film thickness affects the path length of light traveling through the film, but the index determines the phase velocity and refracted angle. Thus, both contribute to the delay between surface reflection and light traveling through the film. Both n and k must be known or determined along with the thickness to get the correct results from an optical measurement.

The optical constants for a material will vary for different wavelengths and must be described at all wavelengths probed with the ellipsometer. A table of optical constants can be used to predict the response at each wavelength. However, it is less convenient to adjust unknown optical constants on a wavelength-by-wavelength basis. It is more advantageous to use all wavelengths simultaneously. A dispersion relationship often solves this problem, by describing the optical constant shape versus wavelength. The adjustable parameters of the dispersion relationship allow the overall optical constant shape to match the experimental results. This greatly reduces the number of unknown 'free' parameters compared to fitting individual n, k values at every wavelength.

For transparent materials, the index is often described using the Cauchy or Sellmeier relationship. The Cauchy relationship is typically given as:

$$n(\lambda) = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} \qquad [14]$$

where the three terms are adjusted to match the refractive index for the material. The Sellmeier relationship enforces Kramers–Krönig (KK) consistency, which ensures the optical dispersion retains a realistic shape. The Cauchy is not constrained by KK consistency and can produce unphysical dispersion. The Sellmeier relationship can be written as:

$$\varepsilon_1 = \frac{A\lambda^2\lambda_0^2}{(\lambda^2 - \lambda_0^2)} \qquad [15]$$

Absorbing materials will often have a transparent wavelength region that can be modeled with the Cauchy or Sellmeier relationships. However, the absorbing region must account for both real and imaginary optical constants. Many dispersion relationships use oscillator theory to describe the absorption for materials, which include the Lorentz, Harmonic, and Gaussian oscillators. They all share similar attributes, where the absorption features are described with an amplitude, broadening, and center energy (related to frequency of light).

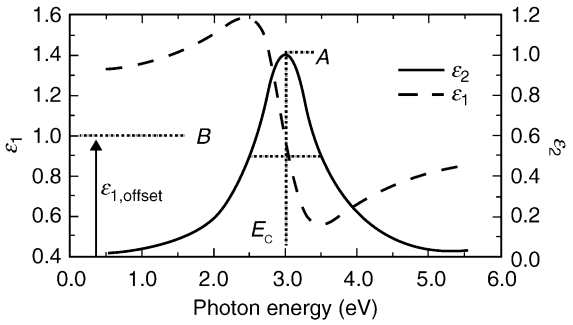

Figure 13 Lorentz oscillator illustrating the primary oscillator parameters: amplitude (A), broadening (B), and center energy (E_c) to describe the imaginary dielectric function shape and an offset ($\varepsilon_{1,\text{offset}}$) to help match the real component after KK transformation has defined its shape.

Kramers–Krönig consistency is used to calculate the shape of the real component after the imaginary behavior is described by the oscillator. An offset to the real component is added to account for extra absorption outside the measured spectral region. The Lorentz oscillator can be written as:

$$\tilde{\varepsilon} = \varepsilon_{1,\text{offset}} + \frac{AE_c}{E_c^2 - E^2 - iBE} \qquad [16]$$

where the parameters for amplitude (A), broadening (B), center energy (E_c), and offset ($\varepsilon_{1,\text{offset}}$) are also shown in Figure 13 for a typical Lorentz oscillator. The energy, E, is related to the frequency of a wave, ν:

$$E = h\nu \cong \frac{1240}{\lambda_{\text{nm}}} \qquad [17]$$

where h is Planck's constant and the wavelength, λ, is given in nanometers. More advanced dispersion models, like the Tauc–Lorentz and Cody–Lorentz, will include terms to describe the bandgap energy.

Mixing Materials

When two or more materials are mixed on a microscopic level, an effective medium approximation (EMA) may be used to determine the resulting optical constants. In the case of the Bruggemann EMA, which is commonly used, the mixture optical constants ($\tilde{\varepsilon}_{\text{eff}}$) relate to those of the individual materials, as:

$$f_a \frac{\varepsilon_a - \varepsilon_{\text{eff}}}{\varepsilon_a + 2\varepsilon_{\text{eff}}} + f_b \frac{\varepsilon_b - \varepsilon_{\text{eff}}}{\varepsilon_b + 2\varepsilon_{\text{eff}}} = 0 \qquad [18]$$

This can be interpreted as small particles of material A suspended in host material B. The length-scale for mixed particles must satisfy certain electromagnetic equations: typically smaller than one tenth the wavelength of light. In practice, EMA theory is useful for studying very thin surface roughness or interfacial intermixing of materials. These cases are both generally approximated by mixing the two surrounding materials in equal portions. In the case of surface roughness, the second material is void ($n = 1$). EMA theory has also been extended for application to porous materials where the directional dependence of the inclusions is handled mathematically.

Crystallinity

Semiconductors such as Si, are widely used materials, but their properties depend strongly on crystallinity. The UV absorption features in crystalline silicon are broadened and shifted as the material becomes more amorphous. This change in optical properties related to the degree of crystallinity has been used to advantage with ellipsometry measurements to monitor semiconductors and other films. Polysilicon films are used in both the display and semiconductor industry. The degree of crystallinity varies for different process conditions and can be monitored optically to ensure consistent material properties.

Composition

The composition of many alloys will affect the optical constants. The strongest changes often occur in the absorbing region, with shifts in position and amplitude of absorption features. For example, the electronic transitions in $Hg_{1-x}Cd_xTe$ move to higher energy with Cd concentration increase (Figure 14). This material is used for IR detectors that require precise control of composition. Spectroscopic ellipsometry performs this task in real-time with instant feedback to correct the composition during processing. Other applications include AlGaN and InGaN for optoelectronics.

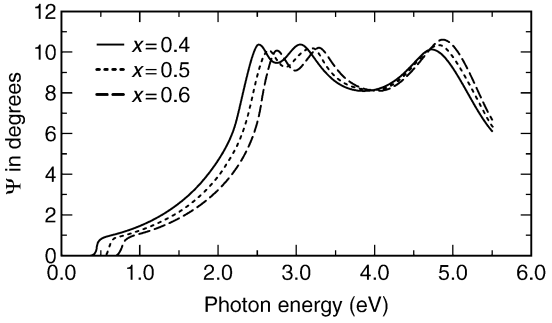

Figure 14 Optical properties for $Hg_{1-x}Cd_xTe$ vary with changes in composition.

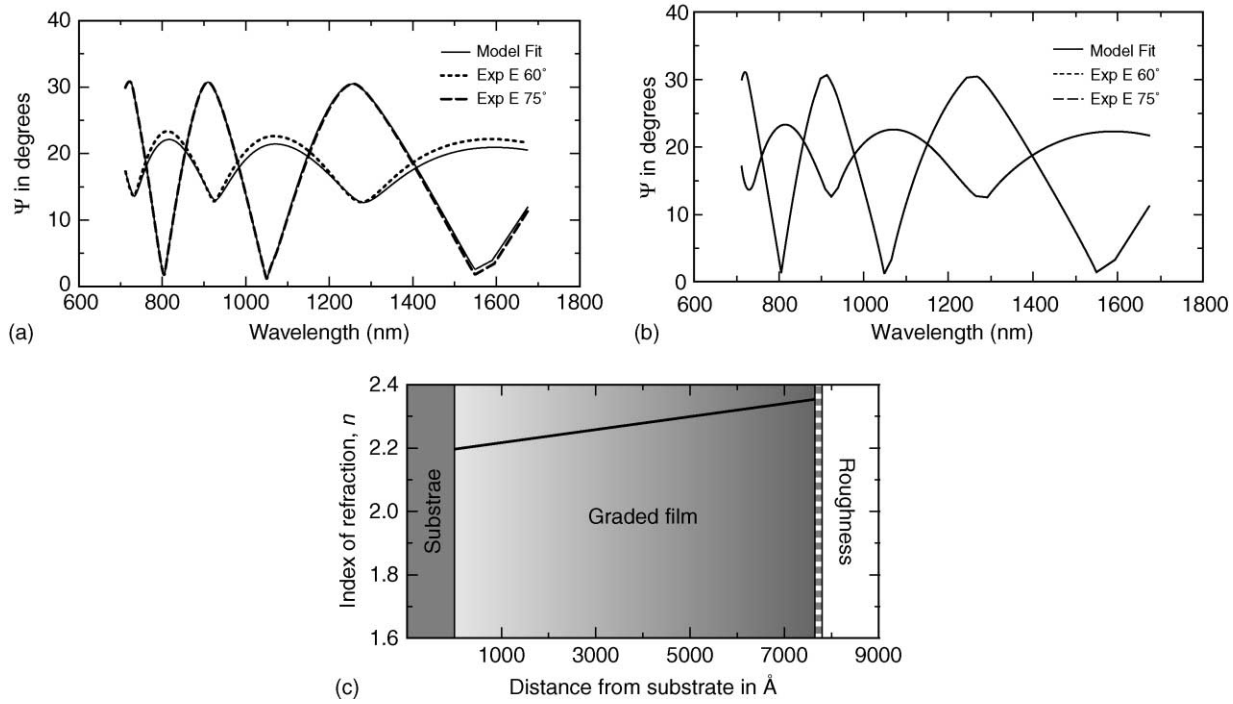

Figure 15 Experimental ellipsometry data and corresponding fit when the model is described as (a) a homogeneous single-layer and (b) a graded film with index variation through the film. (c) The best model to match subtleties in experimental data allows the index to increase toward the surface of the film, with a thin roughness layer on the surface.

Doping Concentration

Dopants in a material will introduce absorption in the infrared due to free-carriers. Spectroscopic ellipsometry measurements at long wavelengths can characterize this optical absorption, thus characterizing the doping concentration. This is common for highly doped semiconductors and transparent conductors such as indium tin oxide (ITO).

Optical Variation (Grading)

Many thin film properties change vertically throughout the film (along the direction perpendicular to the surface). This is most often induced by processing conditions, whether intentional or unintentional. Figure 15a shows the fit to experimental spectroscopic ellipsometry data taken from a single-layer film when it is modeled as a homogeneous layer. To improve the agreement between experimental and model-generated curves, the index was allowed to vary in a linear manner throughout the film. The best fit is shown in Figure 15b, where the model includes the index variation and a thin surface roughness layer. The sample structure is demonstrated in Figure 15c.

Optical Anisotropy

Many materials are optically anisotropic; i.e., their optical properties vary in different film directions. Typical ellipsometry measurements assume no cross-coupling between p- and s-polarizations. This cannot be assumed with anisotropic materials, which has led to 'generalized' ellipsometry measurements. Generalized ellipsometry measures additional information regarding the p- to s- and s- to p- conversion upon reflection. This allows characterization of anisotropic materials, which contain directionally dependent optical constants.

Conclusions

Ellipsometry is a common optical technique for measuring thin films and bulk materials. It relies on the polarization changes due to reflection or transmission from a material structure to deduce material properties, like film thickness and optical constants. This technique continues to develop as the requirement for thin film characterization increases.

Photometry

Introduction

Fundamentals of Photometry

Photometry is defined by the International Commission on Illumination (internationally known as CIE from the abbreviation of its French name: Commission Internationale de l'Eclairage) as 'measurement of quantities referring to radiation as evaluated according to a given spectral efficiency function, e.g., $V(\lambda)$ or $V'(\lambda)$.' A note to the above definition states that in many languages it is used in a broader sense, covering the science of optical radiation measurement. We will restrict our treatise to the above fundamental meaning of photometry.

Under spectral efficiency function we understand the spectral luminous efficiency function of the human visual system. The internationally agreed symbols are $V(\lambda)$, for photopic vision (daylight conditions) and $V'(\lambda)$ for scotopic vision (nighttime conditions). CIE standardized the $V(\lambda)$ function in 1924 and the $V'(\lambda)$ function in 1951; their spectral distribution is shown in Figure 1. The $V(\lambda)$ function was determined using mainly the so-called flicker photometric technique, where the light of a reference stimulus and of a test stimulus of varying wavelengths are alternatively shown to the human observer at a frequency at which the observer is already unable to perceive the difference in color (due to the different wavelength of the two radiations), but still perceives a

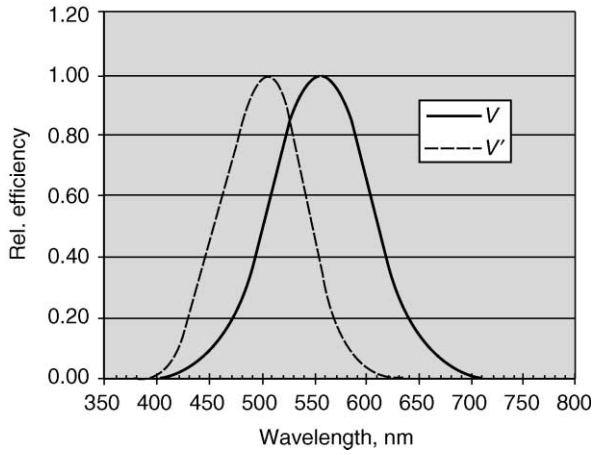

Figure 1 Spectral efficiency functions of the human eye under photopic $V(\lambda)$ and scotopic $V'(\lambda)$ conditions (see CIE The basis of physical photometry. CIE 18.2:1983).

flicker sensation if the luminances of the two stimuli are different. Adjusting the radiance of the test stimulus, we can reach the situation of minimum flicker sensation. In this case we state that we set the two stimuli to equal luminance. Luminance is the quantity that the human observer perceives as brightness (in the case of near white stimuli, see below); radiance is the physical counterpart measured in $\mathrm{W\,m^{-2}\,sr^{-1}}$. For the $V'(\lambda)$ function one can just project the two stimuli side by side, as under scotopic adaptation we cannot distinguish colors, only brightness differences are perceived, thus one can set equal scotopic luminance for the two stimuli by adjusting the brightness of the test stimulus until it agrees with that of the reference stimulus.

Illuminating engineering was mainly interested in describing the effect of near white light, and therefore a psychophysical correlation was selected that described the perceived brightness sensation reasonably well. For near white stimuli, additivity holds, i.e., if A, B, C, and D are four stimuli, and the A stimulus matches the B stimulus and the C stimulus matches the D stimulus, then the superposition of the A and C stimuli matches the superposition of the B and D stimuli. The 'match' word is used here to describe stimuli that produce the same perception. It could be shown that for these stimuli, if the radiance is weighted with the $V(\lambda)$ function, the constructed luminances will be equal, i.e:

$$\text{if} \qquad L_A = L_B \text{ and } L_C = L_D$$

$$\text{then} \quad L_A + L_C = L_B + L_D, \text{ or } L_A + L_D = L_B + L_C$$

where

$$L_x = K_m \int_{380\ \mathrm{nm}}^{780\ \mathrm{nm}} S_{\lambda x} V(\lambda) \mathrm{d}\lambda \qquad [1]$$

and x refers to A, or B, or C, or D, and $S_{\lambda x}$ is the spectral radiance distribution that produces the stimulus

$$S_\lambda = \frac{\mathrm{d}S(\lambda)}{\mathrm{d}\lambda}$$

where $S(\lambda)$ is the spectral radiance. K_m is the maximum value of the luminous efficacy of radiation, its value is $683\ \mathrm{lm\,W^{-1}}$ (see the discussion of luminous flux in the sub-section on photometric quantities). To be precise the integration should go from 0 nm to infinity, but it is usual to define the lower and upper wavelength limits of the visible spectrum as 380 nm and 780 nm. $V(\lambda)$ is defined between 360 nm and 830 nm, and $V'(\lambda)$ between 380 nm and 780 nm, see Figure 1.

We have to stress that the concept of luminance – and the entire system of the present-day photometry – is not to quantify brightness perception; it is only a reasonable approximation for near white stimuli. For colored lights a brightness–luminance discrepancy exists (called the Helmhotz–Kohlrausch effect: saturated colors look brighter than predicted by luminance). Luminance is, however, a good description for the visibility of fine details, thus it is a good concept for lighting calculations.

Photometry has a unique situation in the SI system of units: the candela (cd) is a base unit of the SI system, the only one that is connected to psychophysical phenomena. By 1979, in the definition of the 16th General Conference of Weights and Measures, the candela was traced back to radiation quantities; nevertheless it was kept as the base unit of photometry:

> The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and that has a radiant intensity in that direction of $1/683\ \mathrm{W\,sr^{-1}}$. ($540 \times 10^{12}$ Hz corresponds approximately to 555 nm.)

To be able to calculate a photometric quantity of radiation of other wavelengths, one of the psychophysical functions $V(\lambda)$ or $V'(\lambda)$ has to be used and eqn [1] applied. We will see later that besides $V(\lambda)$ and $V'(\lambda)$ in modern applications, a number of further spectral luminous efficiency functions might be used.

Photometric Quantities

As discussed in the previous section, from the point of view of vision, the most important quantity is

luminance. Looking, however, at the definition of the base unit, it is obvious that from the physical point of view the definition of a quantity corresponding to radiant power, measured in watts, can help to bridge the gap between photometry and radiometry: luminous flux, measured in lumens (lm), with the symbol Φ, is defined by eqn [1], with $S_\lambda(\lambda)$ inserted in W m^{-1}.

Based on this more practical quantity of luminous flux and its unit, lm, the different quantities used in photometry can be built up as follows:

$$\textit{Luminous flux}: \quad \Phi = K_m \int_0^\infty \frac{\mathrm{d}\Phi_e(\lambda)}{\mathrm{d}\lambda} V(\lambda)\mathrm{d}\lambda \qquad [2]$$

where $\Phi_e(\lambda)$ is the radiant flux measured in W,

$$\Phi_{e,\lambda} = \frac{\mathrm{d}\Phi_e(\lambda)}{\mathrm{d}\lambda}$$

is the spectral distribution (or spectral concentration) of the radiant flux (W m^{-1}). $K_m = 683$ lm W^{-1}, is the maximum value of the luminous efficacy of radiation for $\lambda_m \approx 555$ nm.

Similar equations can be written for scotopic luminous flux, with $V(\lambda)$ exchanged with $V'(\lambda)$, where $K'_m = 1700$ lm W^{-1} for $\lambda_m \approx 507$ nm. All further quantities can be defined both for photopic and scotopic conditions. Here we write them only as photopic quantities.

$$\textit{Luminous intensity}: \quad I = \frac{\mathrm{d}\Phi}{\mathrm{d}\Omega} \qquad [3]$$

where $\mathrm{d}\Phi$ is the luminous flux traveling in an elementary solid angle $\mathrm{d}\Omega$, assuming a point source (see Figure 2). The unit of luminous intensity is the candela (cd = lm sr^{-1}).

$$\textit{Luminance}: \quad L = \frac{\partial^2\Phi}{\partial A \cos\Theta\, \partial\Omega} \qquad [4]$$

where $\mathrm{d}\Phi$ is the luminous flux traveling in an elementary solid angle $\mathrm{d}\Omega$, $\mathrm{d}A$ is the elementary surface area emitting the radiation, and Θ is the angle between the normal of $\mathrm{d}A$ and the direction of luminance measurement (see Figure 3). The unit of luminance is cd m^{-2} (in some older literature called nit).

$$\textit{Illuminance}: \quad E = \frac{\mathrm{d}\Phi}{\mathrm{d}A} \qquad [5]$$

where $\mathrm{d}\Phi$ is the luminous flux incident on the $\mathrm{d}A$ element of a surface (see Figure 4). The unit of illuminance is the lux (lx = lm m^{-2}).

A remark on the use of SI units and related quantities
No prefixes can be added to the SI units, thus irrespective whether one measures luminance based

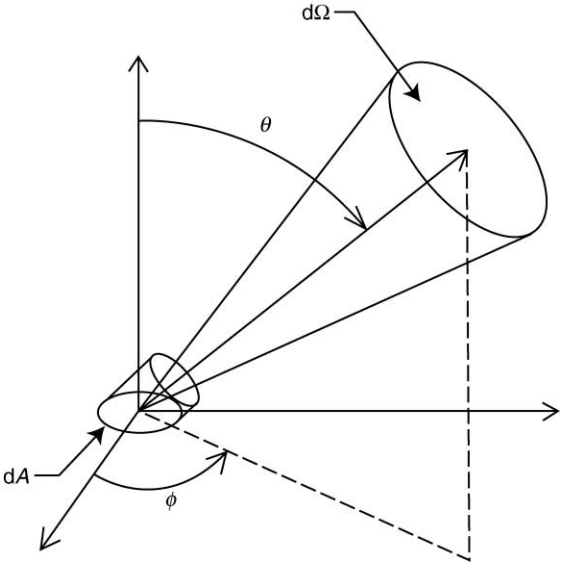

Figure 3 Geometry for the definition of luminance.

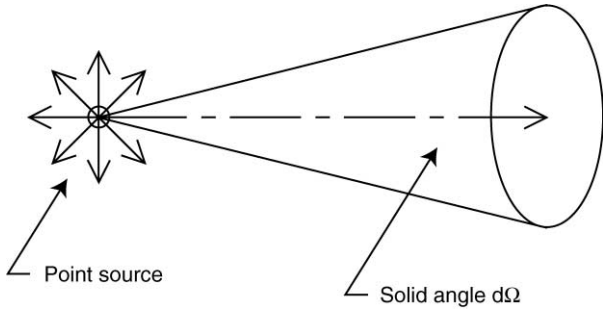

Figure 2 Concept of point source, solid angle, and luminous intensity.

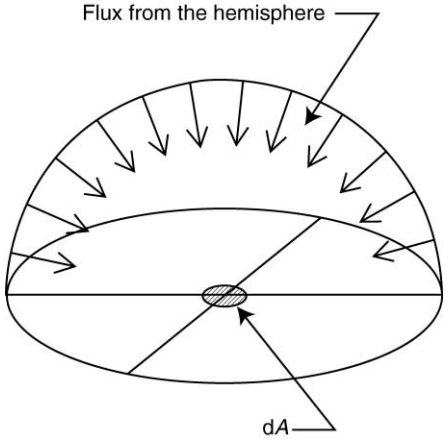

Figure 4 Illuminance is the total luminous flux per unit area incident at a point coming from a hemispherical solid angle.

on the photopic $V(\lambda)$ function, or the scotopic $V'(\lambda)$ function, the so-determined photopic luminance or scotopic luminance is measured in cd m^{-2} (no photopic or scotopic lumen, candela, etc., exist!). This often creates confusion, because only for a 555 nm monochromatic radiation will a 1 cd m^{-2} photopic or scotopic luminance produce equal visual sensation, for every other wavelength the two are not commensurable. One can only relate photopic measurement results to photopic ones, and scotopic measurement results to scotopic ones.

Concepts of Advanced Photometry

The quantities and units, as described in the previous section, are the quantities and units internationally agreed by the Meter Convention and the International Standards Organization (ISO). Modern photometric applications need, however, some further quantities and weighting functions. Thus CIE, the international organization for the development of standards in the field of optical radiation measurements, has defined a series of further weighting functions and quantities. The most important ones are the following:

$V_M(\lambda)$ function

In the blue part of the spectrum (below 460 nm) the values of the $V(\lambda)$ function turned out to be too low. For decades this was only of concern for the vision research community, but with the introduction of blue LEDs and other short wavelength emitting sources (e.g., blue channel of displays) this shortcoming of the $V(\lambda)$ function became of practical importance. The 'CIE 1988 2° spectral luminous efficiency function for photopic vision' corrects this anomaly (see Figure 5).

$V_{10}(\lambda)$ function

The official $V(\lambda)$ function is valid only for foveal vision (i.e., for targets that are smaller than 4° of visual angle). The foveal area of the retina is covered with a yellow pigmented layer (macula lutea) that absorbs in the blue part of the spectrum, at larger visual angles this screening is not effective anymore. The $V_{10}(\lambda)$ function was determined for a visual angle of 10° (see Figure 5). Its international recommendation is still under consideration at the time of writing this article and if accepted, it will be recommended for targets seen at approximately 10° off-axis, e.g., for measuring the photometric properties of traffic signs and signals, where the driver has to observe the information in the periphery of his or her eye.

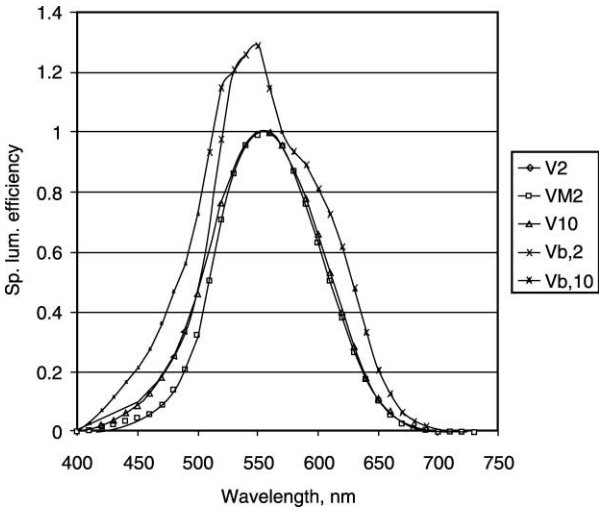

Figure 5 Spectral luminous efficiency (SPL) functions defined or under consideration for international adoption: V2: standard $V(\lambda)$ function; VM2: CIE 1988 $V_M(\lambda)$ function, this is equivalent to the brightness SPL for a point source; V10: 10° visual field SPL, Vb,2: 2° visual field brightness SPL, $V_{b,2}(\lambda)$; Vb,10: 10° visual field brightness SPL, $V_{b,10}(\lambda)$.

Brightness matching functions

As already mentioned in the Introduction, luminance is not a good correlate of brightness, which is a human perception. To find a better correlation of brightness the problem to be addressed is that brightness is a nonadditive phenomenon, i.e., in eqn [1] one cannot add (integrate) the monochromatic radiations to get a brightness correlation for a nonmonochromatic radiation. Brightness evaluating spectral luminous efficiency functions can be used only to compare monochromatic radiations. The CIE has compiled such functions for point sources, 2° and 10° visual field sizes. Figure 5 also shows these functions.

Due to the fact that the brightness perception is nonadditive in respect of the stimuli that produce it, no brightness photometry can be built that uses equations, as shown in eqn [1]. For brightness description we have to rely on the concept of equivalent luminance, a term the definition of which has recently been updated.

Equivalent luminance

Of a field of given size and shape, for a radiation of arbitrary relative spectral distribution L_{eq} : Luminance of a comparison field in which monochromatic radiation of frequency 540×10^{12} Hz has the same brightness as the field considered under the specified photometric conditions of measurement; the comparison field must have a specified size and shape

which may be different from that of the field considered.

To build an instrument that measures this quantity is a real challenge for the future.

Advanced Use of Photometry

Based on above newly defined quantities, several attempts are under way to extend the usefulness of photometry in designing the human visual environment. The eye is an optical system and as in every such system, the depth of focus and the different aberrations of the system will decrease with decreasing pupil size. Pupil size will decrease with increasing illumination, and in the case of constant luminance with higher content of short wavelength radiation. Thus, there exists a school of researchers who advocate that increased blue content in the light has beneficial effects on vision, and one should extend the classical photopic-based photometry with a scotopic-based one to properly describe the visual effect of lighting.

Other investigations are concerned about the visibility at low light levels, the range used in street lighting (from about a few thousands of a candela per square meter to about a few candelas per square meter, according to one definitions: 10^{-3}cd m^{-2}–3 cd m^{-2}). In this mesopic range both rods and cones are contributing to vision, and this changes with lighting level and direction of view (for foveal vision, i.e., looking straight ahead, photopic photometry seems to hold even at low light levels). For peripheral visual angles brightness perception and the perception of an object (a signal, sign or obstacle in a nighttime driving situation) seem to have different spectral responsivity. In driving situations the necessary reaction time of the driver is an important parameter, thus experiments are going on to define a photometric system based on reaction time investigations.

In indoor situations apart from the necessary level of illumination, the observed glare is a contributor whether an environment will be accepted as pleasing or annoying. Illuminating engineering distinguishes between two types of glare: disability glare reduces visibility, discomfort glare is just an annoying experience without influencing the short-term task performance. An interesting question is the spectral sensitivity to discomfort glare, as it can influence not only indoor but also outdoor activity. Preliminary experiments seem to show that luminance sensitivity and discomfort glare sensitivity have different spectral distribution; glare sensitivity seems to peak at shorter wavelengths.

The above might be related to a further question, lying already at the boundaries of photometry, but that has to be considered in photometric design and measurement: the human daily and yearly rhythm (circadian and seasonal rhythm) of human activity coupled to hormone levels. They are influenced by light, as, for example, the hormone melatonin production is influenced by light exposure. Physiological investigations showed that melatonin production suppression has a maximum around 460 nm and might be coupled to a radiation sensitive ganglion cell in the retina. Whether discomfort sensation is mediated via the same neural pathway or via a visual one has not yet been decided. But photometry has to take these also into consideration and in the future, measurement methods and instruments to determine them, will have to be developed.

Advances in Photometric Measurements

Primary Standards

The main concern in photometry is that the uncertainty of photometric measurements is still much higher than that in other branches of physics. This is partly due to the higher uncertainty in radiometry and partly to the increase in uncertainty within the chain of uncertainty propagation from the National Laboratory to the workshop floor measurement.

In National Standards Laboratories, very sophisticated systems are used to determine the power of the incoming radiation and then elaborated spectroradiometric techniques are used to evaluate the radiation in the form of light, i.e., perform photometric measurements (e.g., NIST CIRCUS equipment, where multiple laser sources are used as power sources, and highly sophisticated methods to produce a homogeneous nonpolarized radiation field for the calibration of secondary photometric detectors).

There is, however, also a method to supply end users with absolute detectors for the visible part of the spectrum. Modern high-end Si photovoltaic cells have internal quantum efficiencies in the visible part of the spectrum of over 99.9%. Reflection losses at the silicon surface are minimized by using three or more detectors arranged in a trap configuration, where the light reflected from one detector is fed to the second one, from there to the third one, and eventually to some further ones. In a three detector configuration, as shown in Figure 6, the light from the third detector is reflected back to the second and from there to the first one. As every detector reflects only a small amount of radiation, by the fifth reflection practically

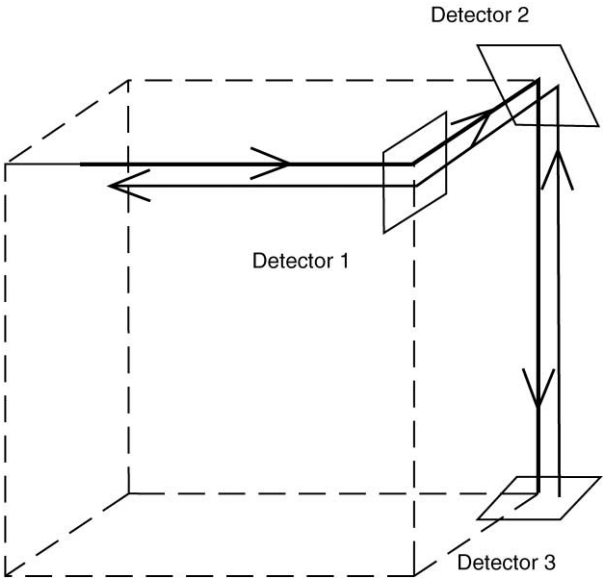

Figure 6 Schematic layout of a three Si-cell trap detector: light comes in from the left, is first partly absorbed, partly reflected on Detector 1, then on Detector 2, then on Detector 3, from where it is reflected back to Detector 2 and 1.

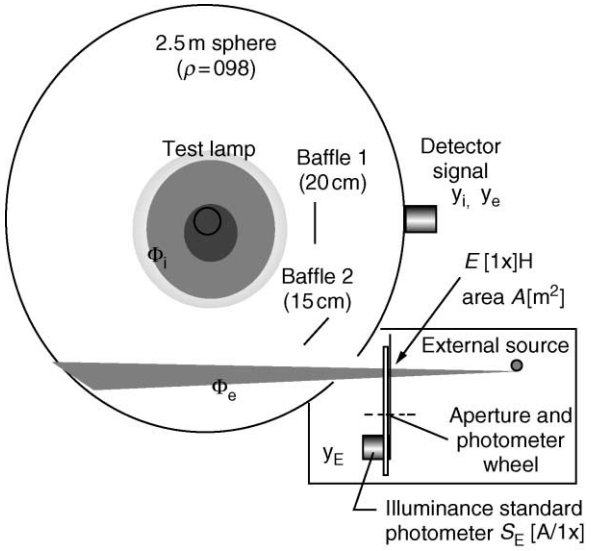

Figure 7 Arrangement of the absolute integrating sphere system developed at NIST for the detector-based total luminous flux calibration. By permission of IESNA from Ohno Y and Bergman R (2003) Detector-referenced integrating sphere photometry for industry. *J. IES Summer* 21–26.

all the radiation is absorbed and contributes to the electric signal. Such trap detectors have an almost 100% quantum efficiency in the visible part of the spectrum, and can be used as photometric detectors if a well designed color correcting filter is applied in front of the detector.

Secondary Type Measurements

In practical photometry the three most important quantities to be measured are the total luminous flux of different lamps, the illuminance in a plane and the luminance.

Light source measurement

Total luminous flux. The two methods to measure the total luminous flux is to use a goniophotometer or a photometer (Ulbicht) sphere. In goniophotometry, recent years have not brought major breakthroughs, the automation of the systems got better, but the principles are unchanged.

The integrating sphere photometer (a sphere with inner white diffuse coating, where the lamp is in the middle of the sphere) used to be a simple piece of equipment to compare total luminous flux lamps against flux standards. In recent years a new technique has been developed at NIST–USA. This enables the absolute measurement of luminous flux from illuminance measurement, the fundamentals of this new arrangement being shown in Figure 7: the test lamp is as usual in the middle of the sphere, but now light from an external source is introduced into the sphere. An illuminance meter measures the flux entering from this source. The sphere detector compares the two signals (y_i and y_e). Knowing the absolute characteristics of the sphere (a difficult measurement) one can determine the total luminous flux of the test lamp using the absolute illuminance value. As illuminance is easily determined from luminous intensity (from eqns [3] and [5] one gets with $d\Omega = dA/r^2$ that $E = I/r^2$, where r is the distance between the source and the illuminated surface, supposed to be perpendicular to the direction to the source), this technique permits us to derive the total luminous flux scale from illuminance or luminous intensity measurement using an integrating sphere.

Luminous intensity of LEDs. An other major break-through achieved during the past years was the unified measurement of LED intensity. Light-emitting diodes became, in recent years, important light sources for large scale signaling and signing, and it is foreseen that they will become important contributors in every field of light production (from car headlamps to general illumination). The most fundamental parameter of the light of an LED is its luminous intensity. The spatial power distribution of LEDs is usually collimated, but the LEDs often squint, as seen in Figure 8. In the past, some manufacturers measured the luminous intensity in

the direction of maximum emission, others used the direction of the optical axis for this quantity. The highly collimated character of the radiation made measurements in far field rather difficult. Therefore, CIE recommended a new term and measuring geometry: average LED intensity can be measured under two measuring conditions, as shown in Figure 9. The detector has to be set in the direction of the LED mechanical axis (discussions are still going on as to what the reference direction should be with modern surface mounted LEDs, as with those the mechanical axis is ill-defined, the normal to the base-plane could be a better reference direction). The detector has to have an exactly 1.00 cm^2 circular aperture, and the distance between this aperture and the tip of the LED is for condition A, $d = 0.316$ m, and for Condition B, $d = 0.100$ m (these two distances with the 1.00 cm^2 detector area provide 0.001 sr (steradians) and 0.01 sr opening angles). Recent international round-robins have shown that, based on the new recommendations, agreement between different laboratories decreased from the 10 to 20% level to 1 to 2%. The remaining difference is mainly due to the fact that the LEDs emit in narrow wavelength bands, and the transfer of the calibration value for the 100 mm^2 detector from a white (CIE Standard Illuminant A color temperature) incandescent lamp to the narrow band LED emission is still uncertain, mainly due to stray light effects in the spectral responsivity and emission measurement.

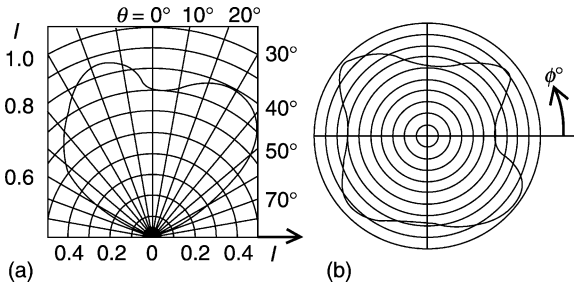

Figure 8 Spatial light distribution of an LED, Figure 8a shows the distribution of a 'squinting' LED in a plane including the optical axis, Figure 8b shows light distribution in a plane perpendicular to the optical axis. By permission of the Commission Internationale de l'Eclairage, from the Publication "Measurement of LEDs" CIE 127-1997; CIE Publications are obtainable from the CIE Central Bureau: Kegelgasse 27, A-1033 Wien, Austria.

Luminance distribution measurement

The human observer sees luminance (and color) differences. Thus for every illuminating engineering design task the luminance distribution in the environment is of utmost importance. Traditionally this was measured using a spot-luminance meter, aiming the device into a few critical directions. The recent development of charge coupled device (CCD) two-dimensionally sensitive arrays (and other, e.g., MOSFET, CMOS, Charge injection device (CID), charge imaging matrix (CIM) systems: as for the time being the CCD technology provides best performance, we will refer to two-dimensional electronic image capture devices as to CCD cameras) opened the possibility of using an image-capturing camera for luminance distribution measurements. Such measurements are badly needed in display calibration, near-field photometry (photometry in planes nearer than in which the inverse square law holds), testing of car headlamp light distribution, glare, and homogeneity studies indoors and outdoors, etc.

Solid-state cameras have the big advantage over older type vacuum-tube image capturing devices, that the geometric position and alignment of the single pixels is well-defined and stays constant. Nowadays, CCD image detector chips are mass produced, and one can get a variety of such devices and cameras starting with some small resolution

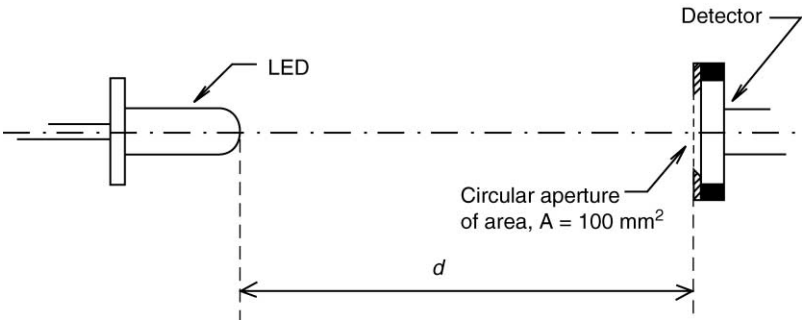

Figure 9 Schematic diagram of CIE Standard Conditions for the measurement of Average LED Intensity. Distance $d = 0.316$ m for Condition A and $d = 0.100$ m for Condition B. By permission of the Commission Internationale de l'Eclairage, from the Publication "Measurement of LEDs" CIE 127-1997; CIE Publications are obtainable from the CIE Central Bureau: Kegelgasse 27, A-1033 Wien, Austria.

(few thousand pixels) devices up to cameras with tens of mega pixel resolution. Detectors are now available with internal intensification enabling measurements down to a few photons per second intensity levels.

Main problems with these detectors are:

- spectral and absolute nonuniformities of the single pixels (see Figure 10), where a spatial homogeneity map of a CCD two-dimensional array detector is shown; the irregular 3% sensitivity change on the surface of the detector is negligible for imaging purposes, but has to be corrected in cases of photometric measurements. Even if the receptor chip would have an absolutely homogeneous sensitivity, there would be a drop in response from the middle of the imaging area to the boarders: Light reaching the edges of the detector reach the detector at an oblique angle and this produces a decrease of sensitivity with α^4, where α is the angle of incidence, measured from the middle of the lens to the given pixel of the detector and the surface normal of the detector.
- aliasing effects if the pixel resolution is not large enough to show straight lines as such when they are not in line with a pixel row or column.
- nonlinearity and cross-talk among the adjacent pixels. Figure 11 shows the so-called 'inverse gamma' characteristic of a CCD camera. The digital electronic output of the camera shows a $Y = E^{-\gamma}$ type function, where Y is the output DAC (digital-analog converter) values, E is the irradiance of the pixel, and γ is the exponent (this description comes from the film industry, where the film density depends exponentially on the irradiation; display devices have usually a nonlinear input (DAC value) – output (luminance) characteristic, and the camera inverse gamma value corrects for this output device characteristic. This is, however, not required if the camera is used for photometric measurements; this built-in nonlinearity has to be corrected in the evaluating software if the camera is intended for photometric measurements.
- to be able to perform photometric measurements the camera has to have a spectral responsivity corresponding to the CIE $V(\lambda)$-function. Many cameras have built-in filters to do this – eventually also red and blue filters to be able to capture color – but the color correction of cameras, where the correction is made by small adjacent filter chips, is usually very poor. Figure 12 shows the spectral

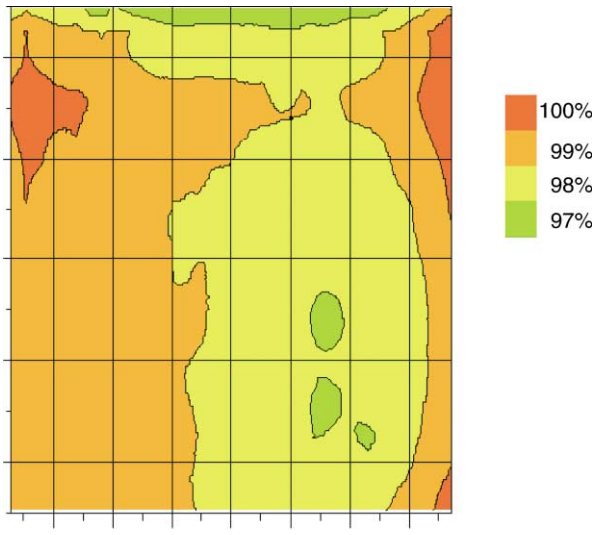

Figure 10 Spatial homogeneity of a two-dimensional CCD array.

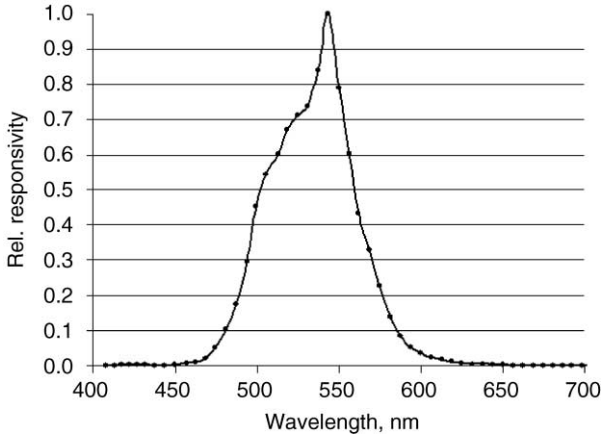

Figure 12 Spectral sensitivity of a commercial digital photographic camera.

sensitivity curve of a digital photographic camera; the output signal is produced by an internal matrix transformation of the signals produced by adjacent pixels equipped with different color filters. Figure 13 shows the spectral sensitivity of a CCD camera specially designed for photometric measurements. Naturally, meaningful photometric measurements can be made only with such a camera. Very often, however, an approximate luminance distribution is enough, and then a picture captured by a digital photographic camera, plus one luminance measurement of a representative object for absolute calibration, suffices.

Above nonspectral systematic errors can be corrected by appropriate soft-ware, so a CCD camera photometer, as shown schematically in Figure 14, is well suited to measure display characteristics, indoor and outdoor luminance distributions. The challenge for illuminating engineering is at present how the many millions of luminance values can be evaluated to get to meaningful light measurement data.

The real challenge will come if visual science provides better hints how the human visual system evaluates the illuminance distribution on the retina, and instrument manufacturers will be able to capture signals corresponding to those produced by the receptor cells and provide the necessary algorithms our brain uses to get to brightness, lightness, color, luminance contrast, and glare type of output information.

Concluding Remarks

Advances in optical instrumentation, both in the field of light sources and detectors – coupled with the possibilities modern digital computation (eventually in the future increasing the use of neural networks) – provide already many new measurement technical solutions and further ones are certainly underway.

The use of LEDs needs the rethinking of many classical illuminating engineering concepts, from visibility and glare evaluation, evenness of illumination to color rendering. All of them are coupled with problems in basic photometry. Thus, there is a need to re-evaluate concepts used in design techniques. The new area-sensitive detectors provide methods of determining classical photometric quantities of entire visual fields in one shot, but already foreshadow the development of new quantities that correlate better with visual perceptions.

List of Units and Nomenclature

Terms with an $*$ refer to definitions published by the CIE in the International Lighting Vocabulary, CIE 17.4:1986, where further terms and definitions related to light and lighting are to be found.

Candela*: SI unit of luminous intensity: The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt per steradian. (16th General Conference of Weights and Measures, 1979).

$$1\ \text{cd} = 1\ \text{lm sr}^{-1}$$

Equivalent luminance*: Luminance of a comparison field in which monochromatic radiation of frequency 540×10^{12} Hz has the same brightness as the field considered under the specified photometric conditions of measurement; the comparison field must have a specified size and shape which may be

different from that of the field considered.

$$\text{unit} : \text{cd m}^{-2}$$

Notes:

1. Radiation at a frequency of 540×10^{12} Hz has a wavelength in standard air of 555.016 nm.
2. A comparison field may also be used in which the radiation has any relative spectral distribution, if the equivalent luminance of this field is known under the same conditions of measurement.

Far field photometry: Photometry where the inverse square law is valid.

Flicker photometer*: Visual photometer in which the observer sees either an undivided field illuminated successively, or two adjacent fields illuminated alternately, by two sources to be compared, the frequency of alteration being conveniently chosen so that it is above the fusion frequency for colours but below the fusion frequency for brightnesses.

Fovea*: Central part of the retina, thin and depressed, which contains almost exclusively cones and forming the site of most distinct vision.

Note: The fovea subtends an angle of about 0.026 rad (1.5 degree) in the visual field.

Goniophotometer*: Photometer for measuring the directional light distribution characteristics of sources, luminaires, media or surfaces.

Illuminance*: Quotient of the luminous flux $d\Phi_v$ incident on an element of the surface containing the point, by the area dA of that element.

Equivalent definition. Integral, taken over the hemisphere visible from the given point, of the expression $L_v \cos\theta \, d\Omega$, where L_v is the luminance at the given point in the various directions of the incident elementary beams of solid angle $d\Omega$, and θ is the angle between any of these beams and the normal to the surface at the given point.

$$E_v = \frac{d\Phi_v}{dA} = \int_{2\pi sr} L_v \cos\theta \, d\Omega$$

$$\text{unit} : \text{lx} = \text{lm m}^{-2}$$

Inverse square law: The illumination at a point on a surface varies directly with the luminous intensity of the source, and inversely as the square of the distance between the source and the point if the source is seen as a point source.

Lumen*: SI unit of luminous flux: Luminous flux emitted in unit solid angle (steradian) by a uniform point source having a luminous intensity of 1 candela. (9th General Conference of Weights and Measures, 1948).

Equivalent definition. Luminous flux of a beam of monochromatic radiation whose frequency is 540×10^{12} hertz and whose radiant flux is 1/683 watt.

Luminance*: Quantity defined by the formula

$$L = \frac{\partial^2 \Phi}{\partial A \cos\theta \, \partial\Omega}$$

where $\partial\Phi$ is the luminous flux transmitted by an elementary beam passing through the given point and propagating in the solid angle $d\Omega$ containing the given direction; dA is the area of a section of that beam containing the given point, θ is the angle between the normal to that section and the direction of the beam.

$$\text{unit} : \text{cd m}^{-2}$$

Luminous intensity*: Quotient of the luminous flux $d\Phi_v$ leaving the source and propagated in the element of solid angle $d\Omega$ containing the given direction, by the element of solid angle:

$$I_v = \frac{d\Phi_v}{d\Omega}$$

$$\text{unit} : \text{cd} = \text{lm sr}^{-1}$$

Lux*: SI unit of illuminance: Illuminance produced on a surface of area 1 square meter by a luminous flux of 1 lumen uniformly distributed over that surface.

$$1 \text{ lx} = 1 \text{ lm m}^{-2}$$

Note: Non-metric unit: **lumen per square foot** (lm ft^{-2}) or **footcandle** (fc) (USA) = 10.764 lx.

Near-filed photometry: photometry made in the vicinity of an extended source, so that the inverse square law is not valid.

Photometer (or Ulbicht) sphere*: A hollow sphere, whitened inside. Owing to the internal reflexions in the sphere, the illumination on any part of the sphere's inside surface is proportional to the luminous flux entering the sphere, or produced inside the sphere by a lamp. The illuminance of the internal sphere wall is measured via a small window.

Pixel: The individual picture elements of an image or elements in a display that can be addressed individually.

Radiance*: Quantity defined by the formula

$$L = \frac{\partial^2 \Phi}{\partial A \cos\theta \, \partial\Omega}$$

where $\partial\Phi$ is the radiant flux transmitted by an elementary beam passing through the given point and propagating in the solid angle $d\Omega$ containing the given direction; dA is the area of a section of that beam containing the given point, θ is the angle between the normal to that section and the direction of the beam.

$$\text{unit} : \text{W m}^{-2} \text{ srad}$$

Retina*: Membrane situated inside the back of the eye that is sensitive to light stimuli; it contains photoreceptors, the cones and the rods, and nerve cells that interconnect and transmit to the optic nerve the signals resulting from stimulation of the photoreceptors.

Spectral*: An adjective that, when applied to a quantity X pertaining to electromagnetic radiation, indicates:

- either that X is a function of the wavelength λ, symbol: $X(\lambda)$,
- or that the quantity referred to is the spectral concentration of X, symbol: $X_\lambda \equiv dX/d\lambda$.

X_λ is also a function of λ and in order to stress this may be written $X_\lambda(\lambda)$ without any change of meaning.

Spectral luminous efficiency function: for photopic vision, $V(\lambda)$; for scotopic vision $V'(\lambda)$*: Ratio of the radiant flux at wavelength λ_m to that at wavelength λ such that both radiations produce equally intense luminous sensations under specified photometric conditions and λ_m is chosen so that the maximum value of this ratio is equal to 1.

Unless otherwise indicated, the values used for the spectral luminous efficiency in photopic vision are the values agreed internationally in 1924 by the CIE (*Compte Rendu* 6^e session, p.67), completed by interpolation and extrapolation (*Publications CIE* No.18 (1970), p.43 and No. 15 (1971), p.93), and recommended by the International Committee of Weights and Measures (CIPM) in 1972. For *scotopic vision*, the CIE in 1951 adopted, for young observers, the values published in *Compte Rendu* 12^e session, Vol. 3, p. 37, and ratified by the CIPM in 1976. These values define respectively the $V(\lambda)$ or $V'(\lambda)$ functions.

Total luminous flux: luminous flux of a source emitted into 4π steradians.

Trap detector: Detector array prepared from detectors of high internal quantum efficiency, where the reflected radiation of the first detector is directed to the second one, and so on so that practically all the radiation is absorbed by one of the detectors (the radiation is "trapped" in the detector system).

Scatterometry

Introduction

Scattered light is a limiting source of optical noise in many advanced optical systems, but it can also be a sensitive indicator of optical component quality. Consider the simple case of a telescope successfully used to image a dim star against a dark background; however, if light from a bright source (such as the moon located well out of the field of view) enters the telescope, it will scatter from the interior walls and the imaging optics themselves. Some of this light eventually reaches the detector and creates a dim background haze that washes out the image of the distant star. A good telescope design accounts for these effects by limiting potential scatter propagation paths and by requiring that critical elements in the optical system meet scatter specifications. This means doing a careful system analysis and a means to quantify the scattering properties of the telescope components. This article discusses modern techniques for quantifying, measuring, and analyzing scattered light, and reviews their development.

Like many scientific advances moving scatterometry from an art to a reliable metrology was done in a series of small hops (not always in the same direction), rather than a single leap. It started in 1961 when a paper by Hal Bennett and Jim Porteous reported measurements made by gathering most of the light scattered from front surface mirrors and normalizing this signal by the much larger specular reflection. They defined this ratio as the total integrated scatter (TIS), and using a scalar diffraction theory result drawn from the radar literature, related it to the surface root mean square (rms) roughness. By the mid-1970s, several angle-resolved scatterometers had been built as research tools in university, government, and industry labs. Unfortunately, instrument operation and data manipulation were generally poor, and meaningful comparison measurements were virtually impossible due to instrument differences, sample contamination, and confusion over what parameters should be compared. Analysis of scatter data, to characterize sample surface roughness, was the subject of many publications. A derivation of what is commonly called 'BRDF' (bidirectional reflectance distribution function) was published by Nicodemus and co-workers at the National Bureau of Standards (now the National Institute of Science and Technology or NIST) in 1970, but did not gain common acceptance as a way to quantify scatter measurements until the late 1980s when the advent of small computers, combined with inspection requirements for defense-related optics, dramatically stimulated the development of scatter metrology. Commercial laboratory instrumentation became available that could measure and analyze as many as 50 to 100 samples a day, and the number (and sophistication) of measurement facilities increased dramatically. The first ASTM Standards were published (TIS in 1987 and BRDF in 1991), but it was still several years before most publications correctly used these quantifying terms. Government defense funding decreased dramatically in the early 1990s, following the end of the Cold War, but the economic advantages of using scatter metrology and analysis for space applications and in the rapidly advancing semiconductor industry, continued state-of-the-art advancements.

The following sections detail how scatter is quantified when related to area (roughness) and local (pit/particle) generating sources. Instrumentation and the use of scattering models are also briefly reviewed.

Quantifying Scattered Light

Scatter signals can be easily quantified as scattered light power per unit solid angle (in watts per steradian); however, in order to make the results more meaningful, these signals are usually normalized, in some fashion, by the light incident on the scatter source. The three ways commonly employed to do this are defined below.

If the scattering feature in question is uniformly distributed across the illuminated spot on the sample (such as surface roughness), then it makes sense to normalize the collected scattered power in watts/steradian by the incident power. This simple ratio, which has units of inverse steradians, was commonly referred to as 'the scattering function.' Although this term is occasionally still found in the literature, it has been generally replaced by the closely related BRDF, which is defined by the differential ratio of the sample radiance normalized by its irradiance. After some simplifying assumptions are made, this reduces to the original scattering function with a cosine of the polar scattering angle in the denominator. The BRDF, defined in this manner, has become the standard way to report angle-resolved scatter from features that uniformly fill the illuminated spot. The cosine term results from the fact that NIST used radiometric terms to define BRDF:

$$\mathrm{BRDF} = \frac{\mathrm{Ps}/\Omega}{\mathrm{Pi}\cos\theta_s} \qquad [1]$$

The scatter function is often referred to as the 'cosine corrected BRDF' and is simply equal to the BRDF multiplied by the cosine of the polar scattering angle. Figure 1 gives the geometry for the situation, and defines the polar and azimuthal angles (θ_s and ϕ_s), as well as the solid collection angle (Ω). Other common abbreviations are BSDF, for the more generic bidirectional scatter distribution function, and BTDF for quantifying transmissive scatter.

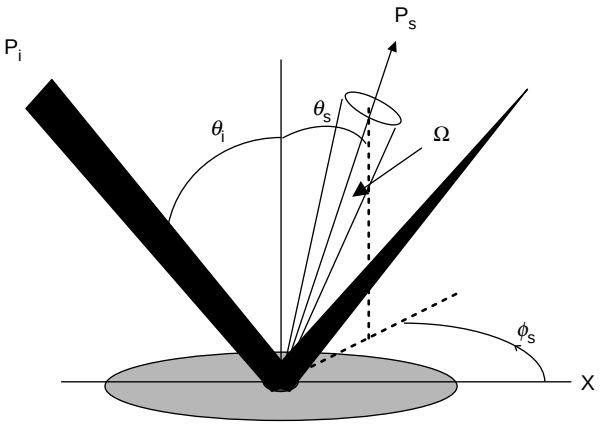

Figure 1 Scatter analysis uses standard spherical coordinates to define terms.

Integration of the scatter signal over much of the scattering hemisphere allows calculation of TIS, as the ratio of the scatter signal to the reflected specular power. This integration is usually carried out experimentally in such a way that both the incident beam and reflected specular beam are excluded. In the most common TIS situation, the beam is incident at a small angle near surface normal, and the integration is done from small values of θ_s to almost 90 degrees. If the fraction of light scattered from the specular reflection is small and if the scatter is caused by surface roughness, then it can be related to the rms surface roughness of the reflecting surface. As a ratio of powers, the TIS is a dimensionless quantity. The normalization is by Pr (instead of Pi) because reductions in scatter caused by low reflectance do not influence the roughness calculation. The pertinent relationships are given below, where σ is the rms roughness and λ is the light wavelength:

$$\mathrm{TIS} = \mathrm{Ps}/\mathrm{Pr} \cong (4\pi\sigma/\lambda)^2 \qquad [2]$$

Of course, all scatter measurements are integrations over a detector collection aperture, but the TIS designation is reserved for situations where the aim is to gather as much scattered light as possible, while 'angle resolved' designs are created to gain information from the distribution of the scattered light. Notice that TIS values become very large when measured from a diffuse surface, where the specular reflection is very small. Although TIS can be measured for any surface, the diffuse reflectance (equal to Ps/Pi) would often be more appropriate for diffuse surfaces. The various restrictions associated with relating TIS to rms roughness are detailed below.

Scatter from discrete features, such as particles and pits, which do not completely fill the illuminated spot, must be treated differently. This is because changes in spot size, with no corresponding change in total incident power, will change the incident intensity (watts/unit area) at the feature and thus also change the scatter signal (and BRDF) without any corresponding changes in the scattering feature. Clearly this is unacceptable if the object is to characterize the defect with scatter measurements. The solution is to define another quantification term, known as the differential scattering cross-section (DSC), where the normalization is the incident intensity at the feature (the units for DSC are area/steradian). Because this was not done in terms of radiometric units at the time it was defined, the cosine of the polar scattering angle is not in the definition. The same geometrical definitions, found in Figure 1, also apply for the DSC:

$$\mathrm{DSC} = \frac{\mathrm{Ps}/\Omega}{Ii} \qquad [3]$$

If the DSC is integrated over the solid angle associated with a collection aperture then the value has units of area. Because relatively small area focused laser beams are often used as a source, area is most commonly given in micrometers squared.

These three scatter parameters, the BRDF, the TIS, and the DSC, are obviously functions of system variables such as geometry, scatter direction (both in and out of the incident plane), incident wavelength and polarization, as well as feature characteristics. It is the dependence of the scatter signal on these system parameters that makes the scatter models useful for optimizing instrument designs. It is their dependence on feature characteristics that makes scatter measurement a useful metrology tool.

A key point needs to be stressed. When applied appropriately, TIS, BRDF, and DSC are absolute terms, not relative terms. The DSC of a 100 nm PSL in a given direction for a given source is a fixed value, which can be repeatedly measured and even accurately calculated from models. The same is true for TIS and BRDF values associated with surface roughness of known statistics. Scatter measuring instruments, such as particle scanners or lab scatterometers, can be calibrated in terms of these quantities. As has already been pointed out, the user of a scanner will almost always be more interested in characterizing defects than in the resulting scatter values, but the underlying instrument calibration can always be expressed in terms of these three quantities. This is true even though designers and users may find it convenient to use other metrics (such as polysterene latex (PSL) spheres) as a way to relate calibration.

Angle Resolved Scatterometers

The diagram in Figure 2 shows the most common scatterometer configuration. The source is fixed and the sample is rotated to the desired incident angle. The receiver is then rotated about the sample during scatter measurement. Most commonly, scatterometers operate just in the plane of incidence; however, instruments capable of measuring at virtually any location in either the reflective or transmissive hemispheres have been built. Although dozens of instruments have been built following this general design, other configurations are in use. For example, the source and receiver may be fixed and the sample rotated so that the scatter pattern moves past the receiver. This is easier mechanically than

moving the receiver at the end of an arm, but complicates analysis because the incident angle and the observation angle change simultaneously. Another combination is to fix the source and sample together, at constant incident angle, and rotate this unit (about the point of illumination on the sample) so that the scatter pattern moves past a fixed receiver. This has the advantage that a long receiver/sample distance can be used without motorizing a long (heavy) receiver arm. It has the disadvantage that heavy (or multiple) sources are difficult to deal with. Other configurations, with everything fixed, have been designed that employ several receivers to merely sample the BSDF and display a curve fit of the resulting data. This is an economical solution if the BSDF is relatively uniform without isolated diffraction peaks. The goniometer section of a real instrument, similar to that of Figure 2, is shown in Figure 3.

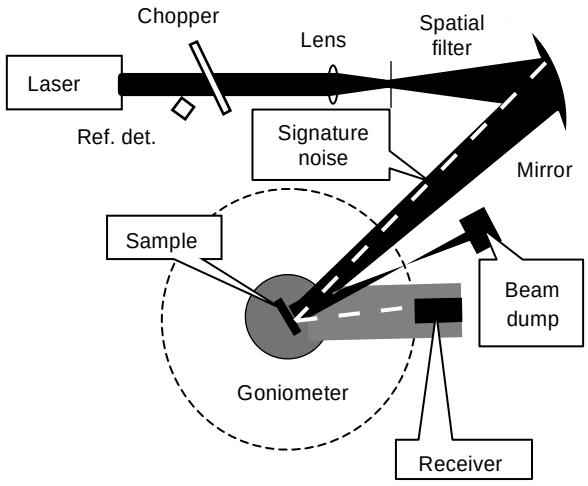

Figure 2 Basic elements of an incident plane scatterometer are shown.

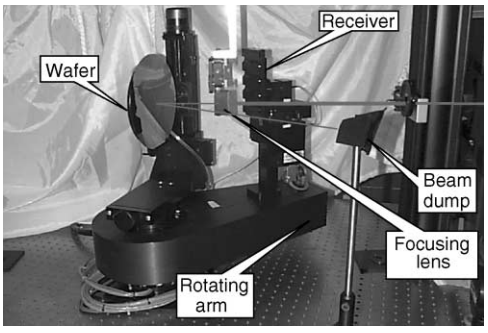

Figure 3 The author's scatterometer, which is similar to the diagram of Figure 2 is shown. In this case a final focusing lens is introduced to produce a very small illuminated spot on the silicon wafer sample. The white background was introduced to make the instrument easier to view.

Computer control of the measurement is essential to maximize versatility and minimize measurement time. The software required to control the measurement plus the display and analysis of the data can be expected to be a significant portion of total instrument development cost. The following reviews typical design features (and issues) associated with the source, sample mount and receiver components.

The source in Figure 2 is formed by a laser beam that is chopped, spatially filtered, expanded, and finally brought to a focus on the receiver path. The beam is chopped to reduce both optical and electronic noise. This is usually accomplished through the use of lock-in detection in the electronics package which suppresses all signals except those at the chopping frequency. Low noise, programmable gain electronics are essential to reducing system noise. The reference detector is used to allow the computer to ratio out laser power fluctuations and, in some cases, to provide the necessary timing signal to the lock-in electronics. Polarizers, wave plates, and neutral density filters are also commonly placed prior to the spatial filter. The spatial filter removes source scatter from the laser beam and presents a point source which is imaged by the final focusing element, in this case a mirror, to the detector zero position. Focusing the beam at this location allows near specular scatter to be more easily measured. Lasers are convenient sources, but are not necessary. Broadband sources are often required to meet a particular application or to simulate the environment where a sample will be used. Monochromators and filters can be used to provide scatterometer sources of arbitrary wavelength. The noise floors with these tunable incoherent sources increases as the spectral bandpass is narrowed, but they have the advantage that the scatter pattern does not contain laser speckle.

The sample mount can be very simple or very complex. In principal, six degrees of mechanical freedom are required to fully adjust the sample. The order in which these stages are mounted affects the ease of use (and cost) of the sample holder. In practice, it often proves convenient to either eliminate, or occasionally duplicate, some of these degrees of freedom. In addition, some of these axes may be motorized to allow the sample area to be raster-scanned to automate sample alignment or to measure reference samples. As a general rule, the scatter pattern is insensitive to small changes in incident angle but very sensitive to small angular deviations from specular. Instrumentation should be configured to allow location of the specular reflection (or transmission) very accurately. Receiver designs vary, but changeable entrance apertures, bandpass

filters, lenses, and field stops are generally positioned in front of the detector.

A serious measurement problem is getting light scattered by the instrument, called instrument signature, confused with light scattered by the sample. An example of instrument signature is shown by the dotted line in Figure 2, which represents scatter from the final mirror. The signature is often measured in the straight through (transmission) direction, multiplied by the measured specular reflectance and then compared to the measured sample BRDF. Another issue is the fact that the measured BRDF is really the convolution of the receiver aperture with the actual (incremental) BRDF. When the scatter signal varies slowly across the aperture the measurement is virtually identical to the true BRDF. Near the specular reflection, or at diffraction peaks, the differences between the measurement (or convolution) and the actual (incremental) BRDF can be huge. Measurements made using invisible sources and measurements of curved samples present additional problems. These problems and the issues of calibration and accuracy are covered in the Further Reading section at the end of this article.

TIS Instruments

The two common methods of making TIS measurements are shown in Figures 4 and 5. The first one is based on a hemispherical mirror (or Coblentz sphere) to gather scattered light from the sample and image it onto the scatter detector. The specular beam enters and leaves the hemisphere through a small circular hole. The diameter of that hole defines the near specular limit of the instrument. The reflected beam (not the incident beam) should be centered in the hole

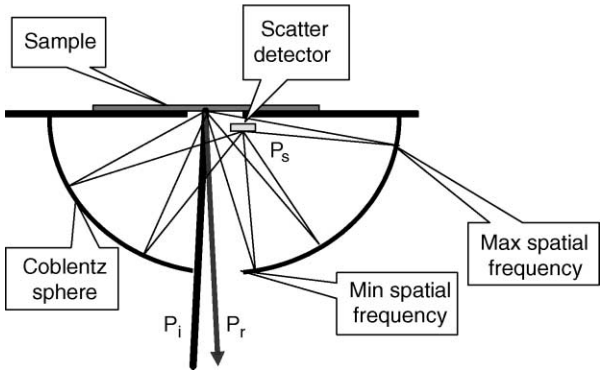

Figure 4 A diagram showing the Coblentz sphere approach to TIS measurements used in the early development of scatter instrumentation.

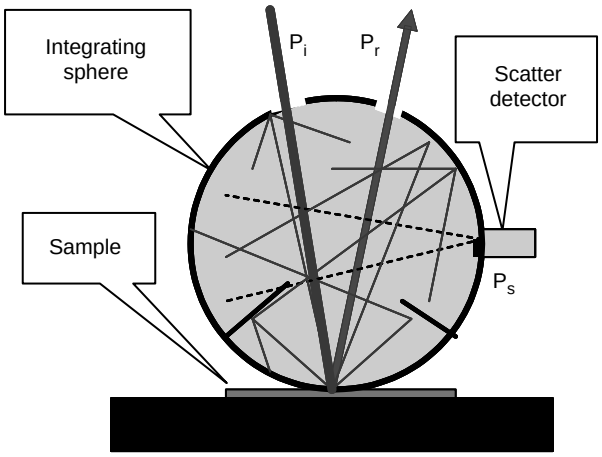

Figure 5 More modern TIS instruments make use of an integrating sphere approach which is easier to align and does not suffer from problems associated with measuring high-angle scatter from the sample.

because the BRDF will be symmetrical about it. Alignment of the hemispherical mirror is critical, and not trivial, in this approach. The second approach involves the use of an integrating sphere. A section of the sphere is viewed by a recessed detector. If the detector field of view (FOV) is limited to a section of the sphere that is not directly illuminated by scatter from the sample, then the signal will be proportional to total scatter from the sample. Again, the reflected beam should be centered on the exit hole. The Coblentz sphere method presents more signal to the detector; however, some of this signal is incident on the detector at very high angles. Thus, this approach tends to discriminate against high-angle scatter (which is not a problem for many samples). The integrating sphere is easier to align, but has a lower signal to noise ratio (less signal on the detector) and is more difficult to build in the IR where uniform diffuse surfaces are harder to obtain. A common mistake with TIS measurements is to assume that for near normal incidence, the orientation between source polarization and sample orientation is not an issue. TIS measurements made with a linearly polarized source on a grating at different orientations will quickly demonstrate this dependence.

TIS measurements can be made very near the specular reflection by utilizing a diffusely reflecting plate with a small hole in it. A converging beam is reflected off the sample and through the hole. Scatter is diffusely reflected from the diffuse plate to a receiver designed to uniformly view the plate. The reflected power is measured by moving the plate so the specular beam misses the hole and then taking that measurement. The ratio of the two scatter measurements gives the TIS. Measurements starting

closer than 0.1 degrees from specular can be made in this manner and it is an excellent way to check incoming optics or freshly coated optics for low scatter.

Analyzing Scatter from Surface Roughness

The preceding sections have concentrated on obtaining and quantifying accurate scatter data, but that leaves the question of what to do with it once you have it. In rare situations you may be given a scatter (BRDF) specification – such as, the BRDF from the mirror must be less than 10^{-4} sr^{-1} 10 degrees from specular when measured at a wavelength of 633 nm incident at 5 degrees with an S polarized source. Unfortunately this is very uncommon. If the issue is limiting scatter as a noise source, you will probably have to generate your own specification based on specific system requirements. More difficult, and often of more economic value, is the situation where scatter measurements are being used as a metrology to learn something about the sample characteristics – like roughness or defect size and/or type.

The relationship between the measured BRDF and reflector roughness statistics was a subject of intense interest from the mid-1970s through the early 1990s. Dozens of papers, and even some books, have been written on the subject, and it can only be outlined here. The relatively easy case of scatter from roughness on a clean, optically smooth, front surface reflector was first published in 1975; however it was several years later before confirming experiments were completed. The deceptively simple relationship, based on vector perturbation theory, is shown below.

$$\text{BRDF} = (16\pi^2/\lambda^4)\cos\theta_i \cos\theta_s \, QS(f_x, f_y) \qquad [4]$$

Q is the polarization factor and is determined by the material constants of the reflector, as well as the system geometry. In many cases, it is numerically about equal to the specular reflectance and this approximation is often justified. Exact expressions are available in the literature. $S(f_x, f_y)$ is the surface power spectral density function (or PSD). It may be thought of as roughness power (surface height variations squared) per unit spatial frequency (undulations per unit distance instead of per unit time). Integration of the PSD over spatial frequency space results in the mean square roughness over that band of frequencies. Taking the square root gives the root mean square roughness (or rms). Frequencies in both the x and y directions on the surface are involved and they are defined by the well-known grating equations as:

$$f_x = (\sin\theta_s \cos\phi_s - \sin\theta_i)/\lambda \qquad \text{and}$$

$$f_y = (\sin\theta_s \sin\phi_s)/\lambda \qquad [5]$$

Thus eqn [4] becomes a model for surface roughness that allows BRDF measurement to be used to find and/or verify surface roughness specifications. Of course, there are exceptions. If the 'clean, optically smooth, front surface reflector' limitations are violated, then the surface will have more than just roughness as a source of scatter and the PSD found from eqn [4] will be too large. Obtaining the same PSD from BRDF measurements made at different wavelengths, or different polarizations, is an indication that the surface is scattering 'topographically' and the PSD can be found using this technique. Because some scatter measurements can be made very rapidly, there are industry situations where scatter metrology offers a very fast means of monitoring surface quality.

A little study of eqns [4] and [5] makes it clear that ranges of spatial frequencies in the PSD correspond directly to angular ranges of the BRDF. Scatter from a single spatial frequency corresponds to a single scatter direction.

Following the above discussion, it becomes clear why the pioneering integrated (TIS) scatter measurements could be used to produce surface rms values as indicated by eqn [2]. Unfortunately, the result of eqn [4] was not available in 1961. Instead eqn [2] was derived for the special case of a smooth surface with Gaussian statistics. Nobody was thinking about spatial bandwidths and angular limits. When striking differences were found between roughness measurements made by TIS and profilometer, the Gaussian assumption became the 'whipping boy,' and TIS scatter measurements took an underserved hit. In fact, integration of eqn [4] results in the TIS result given in eqn [2] under the generally true small angle assumption that most of the scatter is close to the specular reflection. The differences make sense when the concept of spatial frequency bandwidths (or appropriate angular limits) is introduced. It becomes clear that different wavelengths, incident angles and scatter collection angles will also generate different rms values (for the same surface) and why so much confusion resulted following the definition of TIS in terms of rms roughness. There is no such thing as a unique rms roughness for a surface, anymore than there is a single spatial bandwidth for the PSD, or a single set of angles over which to integrate the BRDF. TIS measurements and rms measurements

should always be given with enough information to determine bandwidth limits.

Measuring and Analyzing Scatter from Isolated Surface Features

Understanding scatter from discrete surface features has led to big changes in the entertainment business (CDs, DVDs, digitized music, and films, etc.) as well as providing an important source of metrology for the semiconductor industry as they develop smaller faster chips for a variety of modern uses. Thus, just about everybody in the modern world utilizes our understanding of scatter from discrete surface features.

On the metrology side, the roughness signals described in the last section are a serious source of background noise that limits the size of the smallest defects that can be found. Discrete surface features come in a dazzling array of types, sizes, materials, and shapes – and they all scatter differently. A 100 nm silicon particle scatters a lot differently than a 100 nm silicon oxide particle (even if they have the same shape), and a 100 nm diameter surface pit will have a different scatter pattern. Models describing scatter from a variety of discrete surface features have been developed. Although many of these are kept confidential for competitive reasons, NIST offers some models publicly through a web site.

Confirming a model requires knowing exactly what is scattering the light. In order to accomplish this, depositions of PSLs of known size are made on the surface. Scatter is measured from one or more spheres. A second measurement of background scatter is then subtracted and the net BRDF is converted to DSC units using the known (measured) illuminated spot size. Measurements of this type have been used to confirm discrete feature scatter models. The model is then used to calculate scatter from different diameters and materials. Combined with the model for surface roughness to evaluate system noise, this capability allows signal to noise evaluation of different defect scanners designs.

Practical Industrial Instrumentation

Surface defects and particles, smaller than 100 nm are now routinely found on silicon wafers using scatter instruments known as particle scanners. Thousands of these instruments (with price tags approaching a million dollars each depending on type and use) are in daily use. These instruments are truly amazing; they inspect 200 mm wafers at a rate of one every thirty seconds reporting feature location, approximate size, and in some cases even type (pit or particle) by analyzing scatter signals that last only about 100 nanoseconds. Similar systems are now starting to be used in the computer disk industry and flat panel display inspection of surface features will follow.

Scanners are calibrated with PSLs of different sizes. Because it is impossible to identify all defect types and because diameter has little meaning for irregularly shaped objects, feature 'size' is reported in 'PSL equivalent diameters.' This leads to confusing situations for multiple detector systems, which (without some software help) would report different sizes for real defects that scatter much differently than PSLs. These difficulties have caused industry confusion similar to the 'Gaussian statistics/bandwidth limited' issues encountered before roughness scatter was understood. The publication of international standards relating to scanner calibration has reduced the level of confusion.

Scatter Related Standards

Early scatter related standards for BRDF, TIS, and PSD calculations were written for ASTM (the American Society for Testing Materials), but as the industrial need for these documents moved to the semiconductor industry, there was pressure to move the documents to SEMI (Semiconductor Equipment and Materials Inc.), which is an international organization. By 2004, the process of rewriting the ASTM documents in SEMI format was well underway in the Silicon Wafer Committee. Topics covered include: surface defect specification (M35), defect capture rate (M50), scanner specifications (M52), scanner calibration (M53), particle deposition testing (M58), BRDF measurement (ME1392), and PSD calculation (MF1811). This body of literature is probably the only place where all aspects of these related problems are brought together in one place.

Conclusion

The bottom line is that scatter measurement and analysis has moved from an art to a working metrology. Dozens of labs around the world can now take the same sample and get about the same measured BRDF from it. Thousands of industrial surface scanners employing scattered light signals are in use every day on every continent. In virtually every

house in the modern world there is at least one entertainment device that depends on scatter signals. In short – scatter works.

Introduction

Sp7ectrometers were developed after the discovery that glass prisms disperse light. Later, it was discovered that diffraction from multiple, equally spaced, wires or fibers also dispersed light. About 100 years ago, Huygens proposed his wave theory of light and Fraunhofer developed diffraction theory, which allowed scientific development of diffraction gratings.

These discoveries then led to the development of spectrometers. Light theory was sufficiently developed such that spectrometer designs, developed over 100 years ago, are still being used today. These theories and designs are briefly described along with comments on how current technology has improved upon these designs. This is followed by some examples of imaging spectrometers which have wide spectral coverage from 450 nm to 14 μm and produce images of more than 256 spectral bands.

The basic elements of a spectroscopic instrument are shown in Figure 1. The source, or more usually an image of the source, fills an entrance slit and the radiation is collimated by either a lens or mirror. The radiation is then dispersed, by either a prism or a grating, so that the direction of propagation of the radiation depends upon its wavelength. It is then brought to a focus by a second lens or mirror and the spectrum consists of a series of monochromatic images of the entrance slit. The focused radiation is detected, either by an image detector such as a photographic plate, or by a flux detector such as a photomultiplier, in which case the area over which the flux is detected is limited by an exit slit. In some cases the radiation is not detected at this stage, but passes through the exit slit to be used in some other optical system. As the exit slit behaves as a monochromatic source, the instrument can be regarded as a wavelength filter and is then referred to as a monochromator.

Prisms

The wavelength dependence of the index of refraction is used in prism spectrometers. Such an optical

element disperses parallel rays or collimated radiation into different angles from the prism according to wavelength. Distortion of the image of the entrance slit is minimized by the use of planewave illumination. Even with planewave illumination, the image of the slit is curved because not all of the rays from the entrance slit can traverse the prism in its principal plane. The prism is shown in the position of minimum angular deviation of the incoming rays in Figure 2. At minimum angular deviation, maximum power can pass through the prism. For a prism adjusted to the position of minimum deviation:

$$r_1 = r_2 = A_p/2 \qquad [1]$$

and

$$i_1 = i_2 = (D_p + A_p)/2 \qquad [2]$$

where

D_p = angle of deviation
A_p = angle of prism
r_1 and r_2 = internal angles of refraction
i_1 and i_2 = angles of entry and exit.

The angle of deviation, D_p, varies with wavelength. The resulting angular dispersion is defined as $dD_p/d\lambda$, while the linear dispersion is $dx/d\lambda = F\, dD_p/d\lambda$, where F is the focal length of the camera or imaging lens and x is the distance across the image plane.

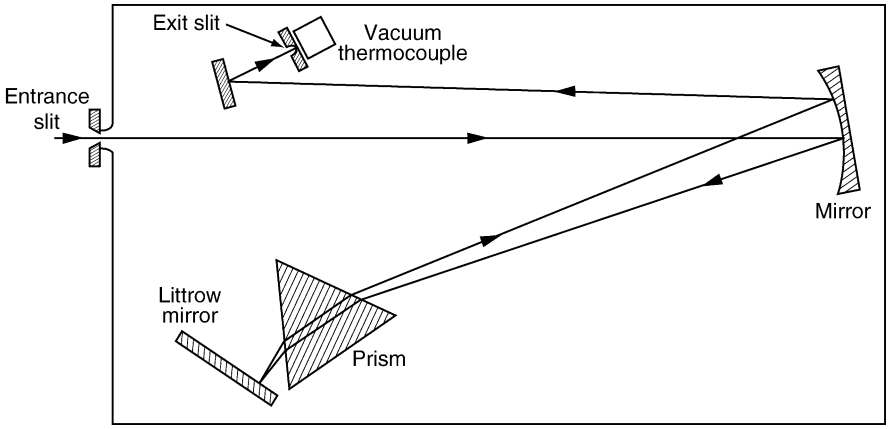

Figure 3 Infrared spectrograph of the Littrow-type mount with a rock salt prism. Reproduced with permission from *The Infrared Handbook* (1985) Ann Arbor, MI: Infrared Information Analysis Center.

It can be shown that:

$$dD_p/d\lambda = [B/W][dn/d\lambda] = [dD_p/dn][dn/d\lambda] \quad [3]$$

where

B = base length of the prism,
W = width of the illumination beam
n = index of refraction

while

$$dx/d\lambda = F[B/W][dn/d\lambda] \quad [4]$$

One may define the resolving power, RP, of an instrument as the smallest resolvable wavelength difference, according to the Rayleigh criterion, divided into the average wavelength in that spectral region. Thus:

$$RP = \lambda/\Delta\lambda = [\lambda/dD_p][dD_p/d\lambda]$$

$$= [\lambda/dD_p][B/W][dn/d\lambda] \quad [5]$$

The limiting resolution is set by diffraction due to the finite beamwidth, or effective aperture of the prism, which is rectangular. Thus:

$$RP = [\lambda/(\lambda/W)][B/W][dn/d\lambda] \quad [6]$$

so that:

$$RP = B[dn/d\lambda] \quad [7]$$

If the entire prism face is not illuminated, then only the illuminated base length must be used for B.

Littrow showed that aberrations would be minimized by making the angle of incidence equal to the angle of refraction β (also known as the Littrow Configuration). Littrow used a plane mirror behind the prism for a double pass through the prism, as shown in Figure 3.

Gratings

Rowland is credited with the development of a grating mount that reduced aberrations in the spectrogram. He found that a grating ruled on a concave surface of radius R and locating the entrance and exit slits on the same radius would give the least aberrations, as shown in Figure 4. $r = R\cos\alpha$ is the distance to the entrance slit *(r)* and $r_1 = R\cos\beta$ is the distance to the focal point for the exit slit (r_1). Rowland showed that:

$$\cos\alpha/R - \cos^2\alpha/r + \cos\beta/R - \cos^2\beta/r_1 = 0 \quad [8]$$

One solution to this equation is for α and β to each be zero and

$$r = R\cos\alpha$$

and

$$r_1 = R\cos\beta$$

This condition is met if r and r_1 lie on the Rowland circle.

There are various ways in which the Rowland circle condition may be satisfied and some of them are shown in Figure 5. The simplest mounting of all is that due to Paschen and Runge (Figure 5a) in which the entrance slit is positioned on the Rowland circle and a photographic plate (or plates) is constrained to fit the Rowland circle. Alternatively, for photoelectric detection, a series of exit slits is arranged around the Rowland circle each having its own detector. In the latter case, the whole spectrum is not recorded, only a series of predetermined wavelengths, but when used in this 'polychromator' form, it is very rugged and

convenient for applications such as the routine analysis of samples of metals and alloys. In this case, slits and detectors are set up to measure the light in various spectral lines, each characteristic of a particular component or trace element.

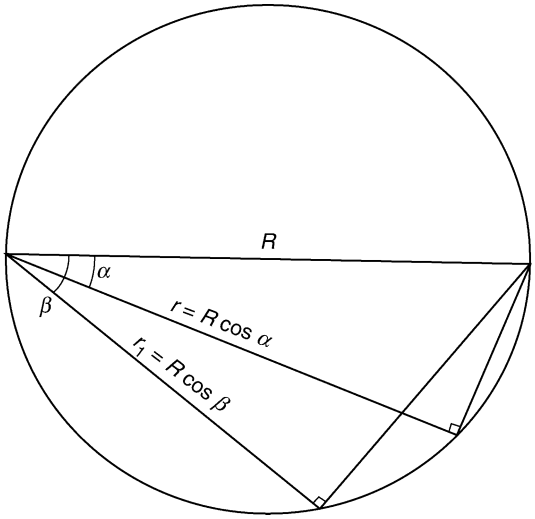

Figure 4 The construction of the Rowland Circle. With permission from Hutley MC (1982) *Diffraction Gratings*, pp. 57–232. London: Elsevier.

The oldest concave grating mount is that designed by Rowland himself and which bears his name (Figure 5b). In this case, the grating and photographic plates are fixed at opposite ends of the diameter of the Rowland circle by a moveable rigid beam. The entrance slit remains fixed above the intersection of two rails at right angles to each other and along which the grating plate holder (or the exit slit) is free to move. In this way, this entrance slit, grating, and plate holder are constrained always to lie on the Rowland circle and it has the advantage that the dispersion is linear, which is useful in the accurate determination of wavelengths. Unfortunately, this mounting is rather sensitive to small errors in the position of the entrance slit and in the orthogonality of the rails, and is now very rarely used.

A variation on this mounting was devised by Abney, who again mounted the grating and the plate holder on a rigid bar at opposite ends of the diameter of the Rowland circle (Figure 5c). The entrance slit is mounted on a bar of length equal to the radius of the Rowland circle. In this way, the slit always lays on the Rowland circle, but it had to rotate about its axis in order that the jaws should remain perpendicular to the line from the grating to

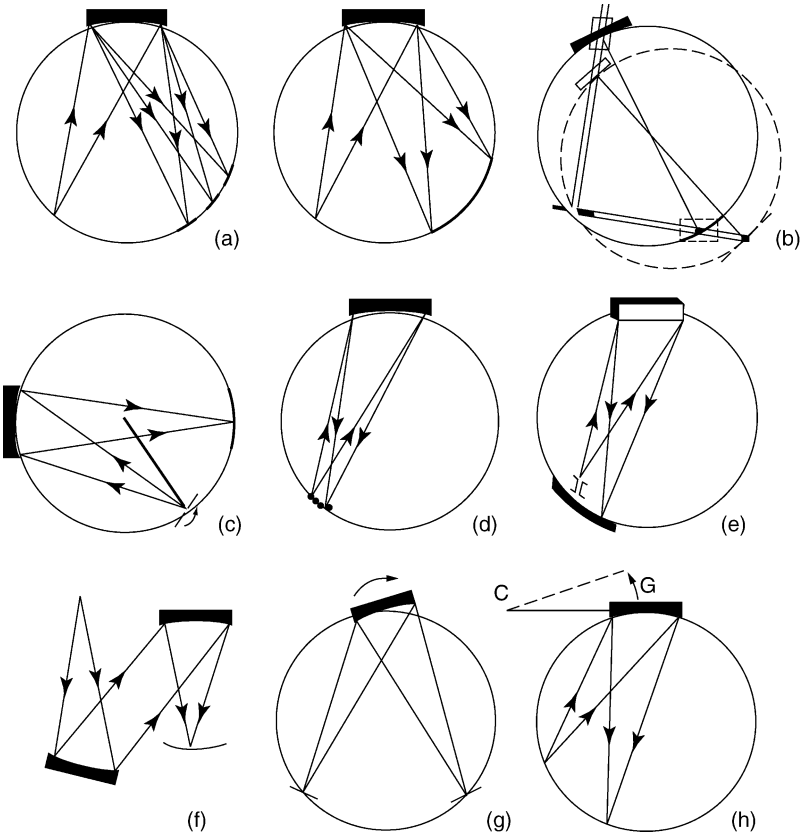

Figure 5 Mountings of the concave grating: (a) Paschen–Runge; (b) Rowland; (c) Abney; (d) and (e) Eagle; (f) Wadsworth; (g) Seya–Namioka; (h) Johnson–Onaka. With permission from Hutley MC (1982) *Diffraction Gratings*, pp. 57–232. London: Elsevier.

the slit. It also had the disadvantage that the source must move with the exit slit, which could be inconvenient.

In the Eagle mounting (Figures 5d and 5e), the angles of incidence and diffraction are made equal, or very nearly so, as with Littrow mounting for plane gratings. Optically, this system has the advantage that the astigmatism is generally less than that of the Paschen–Runge or Rowland mounting, but on the other hand, the dispersion is nonlinear. From a mechanical point of view, it has the disadvantage that it is necessary with great precision both to rotate the grating and to move it nearer to the slits in order to scan the spectrum. However, it does have the practical advantage that it is much more compact than other mountings, and this is of particular importance when we bear in mind the need to enclose the instrument in a vacuum tank. Ideally, the entrance slit and exit slit or photographic plate should be superimposed if we are to set $\alpha = \beta$. In practice, of course, the two are displaced either sideways, in the plane of incidence as shown in Figure 5, or out of the plane of incidence, in which case the entrance slit is positioned below the meridonal plane and the plate holder just above it, as shown in Figure 5. The out-of-plane configuration is generally used for spectrographs and the in-plane system for monochromators. The penalty incurred in going out of plane is that coma is introduced in the image, and slit curvature becomes more important. This limits the length of the ruling that can effectively be used.

The second well-known solution to the Rowland equation is the Wadsworth mounting (Figure 5f), in which the incident light is collimated, so r is set at infinity and the focal equation reduces to $r_1 = R\cos^2\beta/(\cos\alpha + \cos\beta)$. One feature of this mounting is that the astigmatism is zero when the image is formed at the center of the grating blank, i.e., when $\beta = 0$. It is a particularly useful mounting for applications in which the incident light is naturally collimated (for example, in rocket or satellite astronomy, spectroheliography and in work using synchrotron radiation). However, if the light is not naturally collimated, the Wadsworth mount requires a collimating mirror, so one has to pay the penalty of the extra losses of light at this mirror. The distance from the grating to the image is about half that for a Rowland circle mounting which makes the instrument more compact and, since the grating subtends approximately four times the solid angle, there is a corresponding increase in the brightness of the spectral image.

Not all concave grating mountings are solutions to the Rowland equation. In some cases, other advantages may compensate for a certain defect of focus. A particularly important example of this is the Seya–Namioka mounting (Figure 5g), in which the entrance slit and exit slit are kept fixed and the spectrum is scanned by a simple rotation of the grating (Figure 5g). In order to achieve the optimum conditions for this mounting, we set $\alpha = \varphi + \theta$ and $\beta = \theta - \varphi$, where 2φ is the angle subtended at the grating by the entrance and exit slit and θ is the angle through which the grating is turned. The amount of defocus is given by:

$$F(\theta, \varphi, r, r_1) = [\cos^2(\theta + \varphi)/r] + [\cos(\theta + \varphi)/R] + [\cos^2(\theta - \varphi)/r_1] + [\cos(\theta - \varphi)/R] \quad [9]$$

and the optimum conditions are those for which $F(\theta,\varphi,r,r_1)$ remains as small as possible as θ is varied over the required range. Seya set F and three derivatives of F with respect to θ equal to zero for $\theta = 0$ and obtained the result:

$$\varphi = \sin^{-1}(1/\sqrt{3}) = 35°15' \quad [10]$$

and

$$r = r_1 = R\cos\varphi \quad [11]$$

which corresponds to the Rowland circle either in zero order or for zero wavelength. In practice, it is usual to modify the angle slightly so that the best focus is achieved in the center of the range of interest rather than at zero wavelength.

The great advantage of the Seya–Namioka mounting is its simplicity. An instrument need consist only of a fixed entrance and exit slit, and a simple rotation of the grating is all that is required to scan the spectrum. It is, in fact, simpler than instruments using plane gratings. Despite the fact that at the ends of the useful wavelength range the resolution is limited by the defect of focus and the astigmatism is particularly bad, the Seya–Namioka mounting is very widely used, particularly for medium-resolution rather than high-resolution work.

A similar simplicity is a feature of the Johnson–Onaka mounting (Figure 5h). Here again, the entrance and exit slits remain fixed, but the grating is rotated about an axis which is displaced from its center; in this way, it is possible to reduce the change of focus that occurs in the Seya–Namioka mounting. The system is set up so that at the center of the desired wavelength range, the slits and grating lie on the Rowland circle, as shown in Figure 5h. The optimum radius of rotation, i.e., the distance GC, was found by

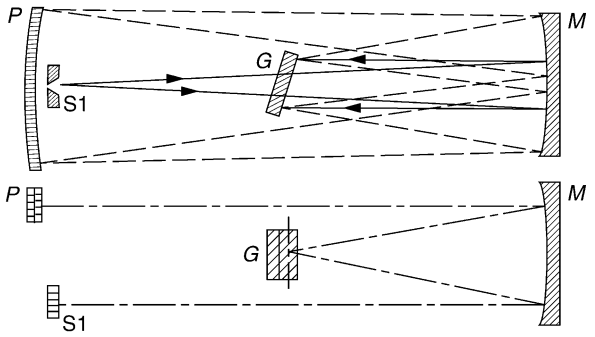

Figure 6 Ebert mounting of the plane grating designed by Fastie. 'SI' is the entrance slit; *G* is the grating; *M* is the concave mirror; and *P* is the photographic plate. Onaka to be:

$$GC_{opt} = [R \sin\tfrac{1}{2}(\alpha+\beta)]/[1 - \tfrac{1}{2}\tan(\alpha+\beta) \times (\tan\beta - \tan\alpha)] \quad [12]$$

Another non-Rowland spectrometer is the Ebert–Fastie mount, which mounts the slit, flat grating, and a detector array in the arrangement shown in Figure 6. Ebert first developed the design using two separate concave mirrors, one for collimating the incident beam and the second to focus the diffracted spectrum. Fastie used a single but larger concave mirror, which simplified the mounting structure and produced a rugged, compact spectrometer that has been used in rocket flights and space satellite observatories for astronomical and upper atmospheric applications. The Czerny–Turner mount is similar to the Ebert mount, except the flat grating is located in the same plane that contains the entrance and exit slits.

Advanced Spectrometers

While the above spectrometer designs are still used, major advances in implementation are now available. Ray tracing allows the designer to quantify the aberrations and determine solutions to remove them. Aspheric optic elements can now be fabricated to correct aberrations. Gratings can be ruled on aspherical surfaces to not only disperse the light beam, but also be an element in the optical design. Holography has been developed to etch gratings for use over a wide spectral range and to not only disperse the light, but also work as an optical element. Because holographic gratings are chemically etched, there are no machine burrs to scatter light and the hologram is free of periodic differences in groove widths that create ghosts in ruled gratings. Linear and array photodetectors have replaced film. An advantage of film was its ability to fit curved focal planes. Photodetectors are etched into flat wafers of the photodiode material. To adapt flat arrays to a curved focal plane, fiber optic face plate couplers have been ground on one side to match the focal plane curvature and the flat back side is either optically coupled to the detector or closely coupled for proximity focusing. The photodetector arrays are available in multiple materials to cover the spectral range, from soft X-rays to the thermal infrared. Often cooling is required to obtain low noise. They are now available with sensitivities never reached with film and the ease of coupling the output data to a computer for real-time analysis has taken much of the labor out of analyzing the spectrograph. Another advance is precision motor drives with precision motion sensors, some using laser interferometry, to provide feedback on automated movement of gratings, slits, and detectors as a spectrometer cycles through its wavelength range.

Imaging Spectrometers

Spectrometers that image the spectral characteristics in each pixel of the image to form a data cube, as shown in Figure 7, are named imaging spectrometers, and if the spectra have high resolution and blocks of consecutive neighbors, then the data are called hyperspectral. Imaging spectrometers have several applications that range from medical to remote sensing of land use and environment. This article will cover examples for remote sensing imaging spectrometers which require spectral coverage in all of the atmospheric windows from the UV to thermal IR.

Imaging spectrometers require a combination of spectrometers, light collecting optics, and scan mechanisms to scan the instantaneous field of view of the spectrometer over a scene. Remote sensing of the Earth applications requires an aerial platform. Either a helicopter, an aircraft, or orbital space satellites are used. The platform motion is used as part of the scanning process so that the optics image a single point on the ground so that a scanner (called a line scanner) scans a long line that is cross tracked to the platform motion. Or, the optics image a slit that is parallel to the platform track that covers many scan lines and a scanner moves the slit cross track to the platform motion. This scanner is called a whisk-broom scanner. Or, the optics image a large slit so no scan mechanism is needed other than the platform

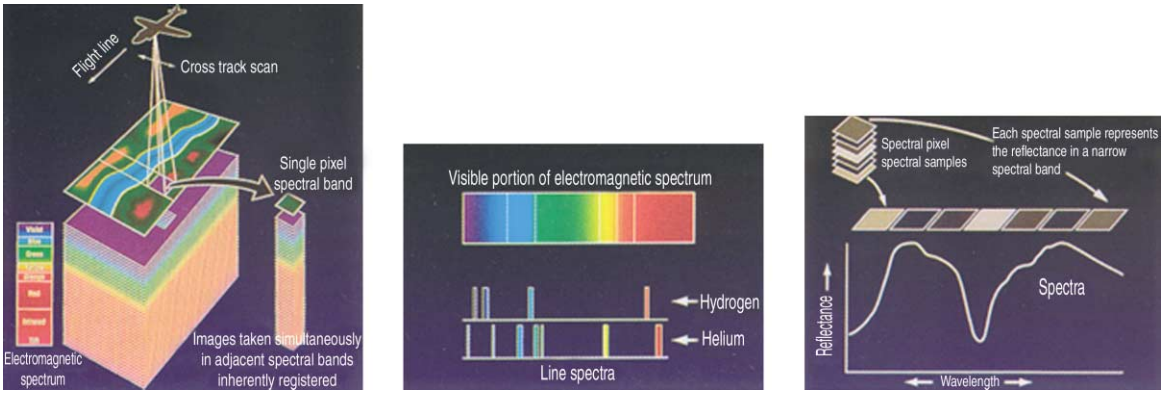

Figure 7 Hyperspectral Data Cube. Hyperspectral imagers divide the spectrum into many discrete narrow channels. This fine quantization ofn spectral information on a pixel by pixel basis enables researchers to discriminate the individual constituents in an area much more effectively. For example, the broad spectral bands of a multispectral sensor allow the user only to coarsely discriminate between areas of deciduous and coniferous forest, plowed fields, etc., whereas a hyperspectral imager provides characteristic signatures which can be correlated with specific spectral templates to help determine the individual constituents and possibly even reveal details of the natural processes which are affecting them.

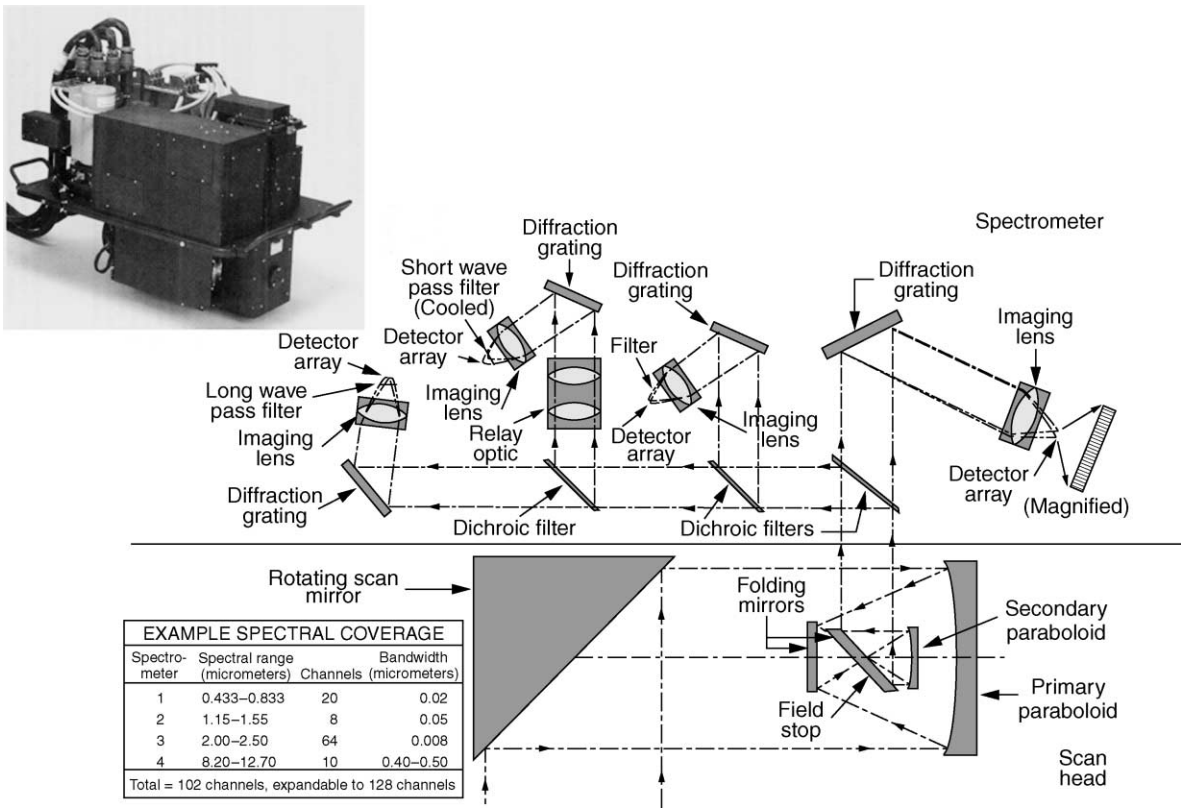

Figure 8 Multispectral infrared and visible imaging spectrometer optical schematic.

motion to form an image. This scanner is called a pushbroom scanner.

One important requirement is that all spectral measurements of a pixel be coregistered. Most airborne imaging spectrometers use a common aperture for a line scanner, or a slit for whisk and pushbroom scanners, so that platform instability from pitch roll and yaw and from inability to fly in a straight line do not compromise the coregistration of spectral data on each pixel. The image data may require geometric correction, but the spectral data are not compromised.

There is one other type of imaging spectrometer that uses a linear variable filter (also known as a wedge filter) over a 2D array of photodetectors. Each image contains a different spectral band over each row of pixels so that each frame images a scene with a different spectral band over each row of pixels. The array is oriented so the rows of spectral bands are perpendicular to the flight track. After the platform motion moves over one ground pixel, the whole array is read out and the frame is shifted one row of pixels so the second frame adds a second spectral band to each row imaged in the first frame. This frame stepping is carefully timed to the platform velocity and is repeated until each row of pixels is imaged in all spectral bands. This type of imaging spectrometer has been flown in aircraft and satellites. In aircraft, the platform motion corrupts the coregistration of the spectrum in each pixel. Extensive ground processing is required to geometrically correct each frame to improve spectral coregistration. This is a difficult task and this type of imaging spectrometer has lost favor for airborne use. Stabilized satellites have been a better platform and the wedge type of imaging spectrometer has been used successfully in space.

As examples of airborne and ground-based imaging spectrometers, a line scanner imaging

spectrometer and a ground-based scanned push broom scanner are described below.

MIVIS (multispectral infrared and visible imaging spectrometers) hyperspectral scanner developed by SenSyTech Imaging Group (formerly Daedalus Enterprises) for the CNR (Consiglio National Researche) of Italy is a line scanner imaging spectrometer. The optical schematic is shown in Figure 8. A rotating 45° mirror scans a line of pixels on the ground. Each pixel is collimated by a parabolic mirror in a Gregorian telescope mount. The collimated beam is reflected by a Pfund assembly to an optical bench that houses four spectrometers. An aperture pinhole in the Pfund assembly defines a common instantaneous field of view for each pixel. The collimated beam is then split off with either thin metallic coated or dielectric coated dichroics to four spectrometers. The thin metallic mirrors reflect long wavelengths and transmit short wavelengths. The multiple dielectric layers cause interference such that light is reflected at short wavelengths and transmitted at long wavelengths. After splitting off four wide bands (visible, near infrared, mid-wave infrared, and thermal infrared) each band is dispersed in its own spectrometers.

The wavelength coverage for each spectrometer is based on the wavelength sensitivity of different photodetector arrays. The visible spectrometer uses a silicon photodiode array; the near infrared spectrometer, an InGaAs array, the mid-infrared a InSb array and the thermal infrared, a MCT (mercury doped cadmium teluride) photo-conductor array. Note the beam expander in spectrometer 3 for the

Table 3 LAFS technical specifications

Spatial resolution	1.0 mrad IFOV vertical and horizontal (square pixels). Optical lens for 0.5 mrad IFOV
Spatial coverage	15° TFOV horizontal, nominal. A second, 7.5° TFOV, is an option
Focus range	5′ to infinity
Spectral resolution	5.0 nm per spectral channel, sampled at 2.5 nm interval
Spectral range	400–1100 nm
Dynamic range	8 bit (1 part in 256)
Illumination	Solar illumination ranging from 10:00 a.m. to 2:00 p.m. under overcast conditions to full noon sunshine
Acquisition time	1.5 sec for standard illuminations. Option for longer times for low light level conditions
Viewfinder	Near real time video view of the scene
Calibrations	Flat fielding to compensate for CCD variations in responsivity. Special calibration
Data displays	Single band imagery, selectable Waterfall Chart (one spatial line by spectral, as acquired by the CCD). Single pixel spectral display
Data format	Convertible to format compatible with image processors
Data storage	Replaceable hard disc, 14 data cubes/disk

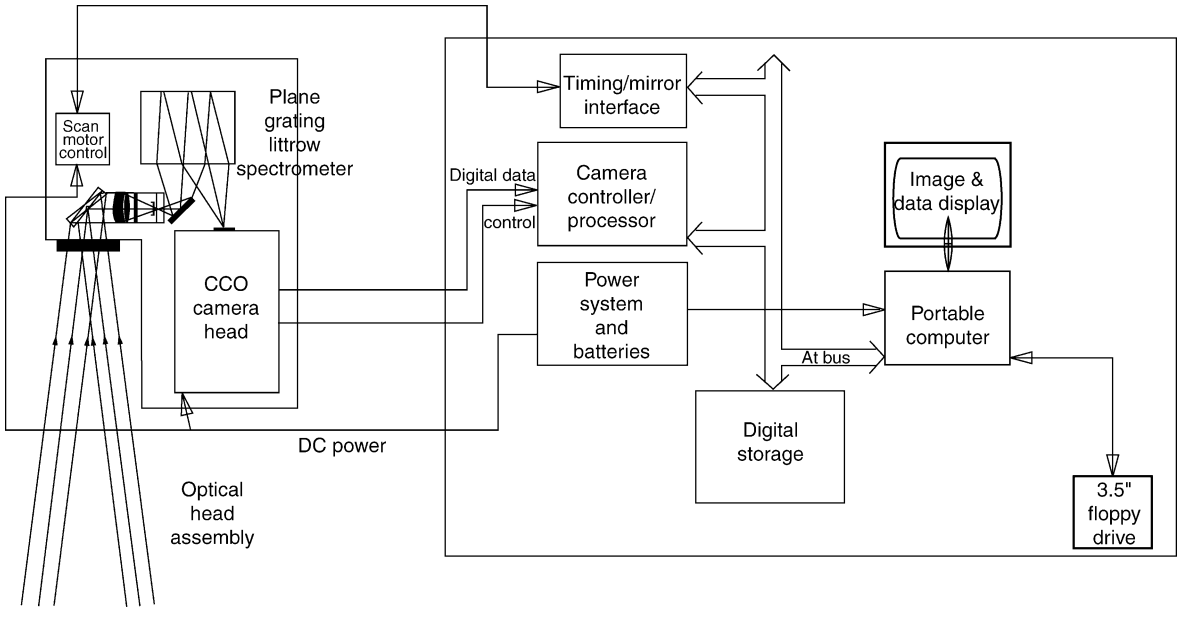

Figure 9 LAFS system block diagram.

mid-infrared (IR). Since wavelength resolution increases with the size of the illuminated area of a diffraction grating a beam expander was needed to meet the specified mid-IR resolution.

The physical characteristics of MIVIS are given in Table 1 and the spectral coverage in Table 2.

An example of a push broom imaging spectrometer is the large area fast spectrometer (LAFS), which is a field portable, tripod mounted, imaging spectrometer. LAFS uses a push broom spectrometer with a galvanometer driven mirror in front of the entrance slit. The mirror is stepped to acquire a 2D image $\times$ 256 spectral bands data cube.

LAFS was developed for the US Marine Corps under the direction of the US Navy Coastal Systems Station of the Dahlgren Division. The technical specifications are shown in Table 3. Various concepts for the imaging spectrometer were studied and the only concept that could meet the above specification was a Littrow configuration grating spectrometer that imaged one line in the scene and dispersed the spectra perpendicular to the line image onto a CCD array. A galvanometer mirror stepped the line image over the scene to generate a spectral image of the scene. A block diagram of LAFS is shown in Figure 9 and a photograph of the prototype in Figure 10. Figure 11 is a photograph of the optical head. Data from a single frame are stored in computer (RAM) memory then transferred to a replaceable hard disk for bulk storage. Data are collected in a series of 256 CCD frames and each CCD frame has a line of 256 pixels along one axis and 256 spectral samples along the second axis. The 256 CCD frames constitute a data cube as shown in Figure 12. This does not allow field viewing of an image in a single spectral band. Earth View™ software is used in the field portable computer

Power: Less than 150 W at 12 VDC; Battery time – 45 min/charge.

to reorder the data cube into 256 spatial images, one for each spectral band as shown in Figure 12.

The prototype is packaged in two chassis, a compact optical head and a portable electronic chassis. The size, weight, and power are shown in Table 4.

LAFS was designed to also work as an airborne imaging spectrometer. The framing mirror can be locked so it views a scene directly below the aircraft (push broom mode) or the mirror can be programmed to sweep a 256 lines cross track to the aircraft flight path (whisk broom mode). In the whisk broom mode, the scan mirror rotation arc can be increased for a wider field of view than in the push broom mode. LAFS illustrates the decrease in size, weight, and power of a push broom imaging spectrometer that results from a 256 × 256 pixel array rather than single pixel line arrays of a line scanner. The array increases integration time of a line by a factor of 256, which allows longer detector integration dwell time on each pixel and thus smaller light collecting optics.

List of Units and Nomenclature

Data cube	Multiple images of a scene in many spectral bands. The spectra of each pixel can be obtained by plotting the spectral value on the same pixel in each spectral band image.
Pixel	An image point (or small area) defined by the instantaneous-field-of-view of either the optics, entrance aperture or slit, and the detector area, or by some combination of these components. A pixel is the smallest element in a scene that is resolved by the imaging system.
Instantaneous-field-of-view (IFOV)	The IFOV is used in describing scanners to define the size of the smallest field-of-view (usually in milliradians or microradians) that be resolved by a scanner system.
Field-of-view	The total size in angular dimensions of a scanner or imager.
Hyperspectral	A data cube with many (>48) spectral bands.
Line scanners	An optical/mechanical system that scans one pixel at a time along a line of a scene.
Whisk broom	An optical/mechanical system that scans two or more lines at a time.
Push broom	An optical system that images a complete line at a time.

Introduction

In a broad sense, telescopes are optical instruments which provide an observer with an improved view of a distant object, where improved may be defined in terms of magnification, angular resolution, and light collecting power. Historically, the invention of the telescope was a breakthrough with an enormous impact on fundamental sciences (physics, astronomy), and, as a direct consequence, on philosophy; but also on other technological, economical, political, and military developments. It seems that the first refractive telescopes were built in the Netherlands near the end of the sixteenth century by Jan Lipperhey, Jakob Metius, and Zacharias Janssen. Based on reports of those first instruments, Galileo Galilei built his first telescope, which was later named after him, and made his famous astronomical observations of sunspots, the phases of Venus, Jupiter's moons, the rings of Saturn, and his discovery of the nature of the Milky Way as an assembly of very many stars. The so-called astronomical telescope was invented by Johannes Kepler, who in 1611 also published in *Dioptrice* the theory of this telescope. The disturbing effects of spherical and chromatic aberrations were soon realized by astronomers, opticians, and other users, but it was not before Moor Hall (1792) and John Dollond (1758) that at least the latter flaw was corrected for by introducing the achromat. Later, the achromat was significantly improved by Peter Dollond, Jesse Ramsden, and Josef Fraunhofer. The catadioptric telescope was probably introduced by Lenhard Digges (1571) or Nicolas Zucchius (1608). In 1671, Sir Isaac Newton was the first to use a reflector for astronomical observations. Wilhelm Herschel improved this technique and began in 1766 to build much larger telescopes with mirror diameters up to 1.22 m. When, in the nineteenth century, the conventional metal mirror was replaced by glass, it was Léon Foucauld (1819–1868) who applied a silver coating in order to improve the reflectivity of its surface.

Modern refractors can be built with superb apochromatic corrections, and astronomical reflectors have advanced to mirror diameters of up to 8.4 m (monolithic mirror), and 10 m (segmented mirror).

While the classical definition of a telescope involves an observer, i.e., the eye, in modern times often electronic detectors have replaced human vision. In the following, we will, therefore, use a more general definition of a telescope as an optical instrument, whose purpose is to image a distant object, either in a real focal plane, or in an afocal projection for the observation by eye.

Basic Imaging Theory

In the most simple case, a telescope may be constructed from a single lens or a single mirror,

creating a real focal plane. Let us, therefore, introduce some basic principles of imaging using optical elements with spherical surfaces.

Refraction at a Spherical Surface

Figure 1 shows an example of refraction at a spherical surface. A ray emerging from object O hits the surface between two media of refractive index n and n' at point P. After refraction, the ray continues at a deflected angle ε' towards the normal and intersects the optical axis at point O′. In the ideal case, all rays emerging from O at different angles σ are collected in O′, thus forming a real image of object point O in O′. In the paraxial approximation, we have $\sin\sigma = \tan\sigma = \sigma$, and $p \approx 0$. In triangle (O, O′, P): $\sigma' - \sigma = i - i'$. Using Snell's law $ni = n'i'$, we obtain:

$$\sigma' - \sigma = i' \frac{n' - n}{n} \qquad [1]$$

Since $\phi = \sigma' + i'$, and in the paraxial approximation:

$$\sigma' n' - \sigma n = \phi(n' - n) \qquad [2]$$

$$\frac{h}{s'} n' - \frac{h}{s} n = \frac{h}{r}(n' - n) \qquad [3]$$

we obtain finally:

$$\frac{n'}{s'} - \frac{n}{s} = \frac{n' - n}{r} \qquad [4]$$

For an object at infinity, where $s = \infty$, s' becomes the focal distance f':

$$f' = r\frac{n'}{n' - n} \quad \text{and} \quad \tilde{f} = -r\frac{n}{n' - n} \qquad [5]$$

Lenses

Combining two or more refractive surfaces, as in the preceding section, allows us to describe a single lens or more complex optical systems with several lenses in series. For a single lens in air, we just give the lens equation (without deriving it in detail):

$$s_2'(F') = \frac{1}{n-1}\frac{r_2[nr_1 - (n-1)d]}{(n-1)d + n(r_2 - r_1)} \qquad [6]$$

where d is the lens thickness, measured between the vertices of its surfaces, r_1, r_2 are the radii of the surfaces, n the index of refraction of the lens material, and $s_2'(F')$ the distance of the object image from the vertex of the last surface, facing the focal plane.

The back focal distance is given by:

$$f' = \frac{1}{n-1}\frac{nr_1r_2}{(n-1)d + n(r_2 - r_1)} \qquad [7]$$

An important special case is where the lens thickness is small compared to the radii of the lens surfaces, i.e., when $d \ll |r_2 - r_1|$. In this case we can neglect the term of $(n-1)d$ and write:

$$f' = \frac{1}{n-1}\frac{r_1r_2}{(r_2 - r_1)} \qquad [8]$$

Reflection at a Spherical Surface

Let us now consider the other simple case of imaging object O into O′ by reflection from the concave spherical surface, as depicted in Figure 2. In the paraxial case, we have:

$$\sigma = y/s, \quad i = \phi - \sigma, \quad \sigma' = y/s', \quad i' = \phi - \sigma', \quad \phi = y/r \qquad [9]$$

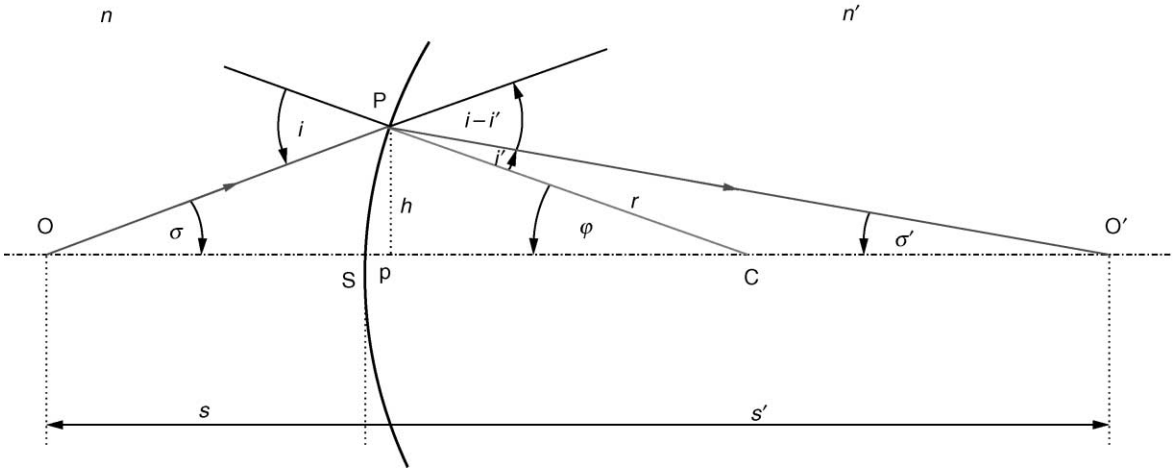

Figure 1 Refraction at a spherical surface between media with refractive indices n and n'.

With $i = -i'$, we obtain:

$$\frac{1}{s'} - \frac{1}{s} = -\frac{2}{r} \qquad [10]$$

Again, with $s = \infty$, the focal length becomes:

$$f' = -\frac{r}{2} \qquad [11]$$

In what follows, we will now assume that the distance of the object is always large (∞), which, in general, is the situation when a telescope is employed. The image is formed at a surface defined by O′, ideally a focal plane (paraxial case). We will consider deviations from the ideal case below.

Simple Telescopes

As we have observed above, a telescope is in principle nothing but an optical system, which images an object at infinity. In the most simple case, a lens with positive power or a concave mirror will satisfy this condition. The principle of a refractor and a reflecting telescope is shown in Figures 3 and 4. In both cases, parallel light coming from the distant object is entering through the entrance pupil, experiences refraction (reflection) at the lens (mirror), respectively, and is converging to form a real image in the focal plane.

Two point sources, for example two stars in the sky, separated by an angle δ, will be imaged in the focal plane as two spots with separation Δy. When f is the focal length of the telescope, we therefore have:

$$\tan \delta = \frac{\Delta y}{f} \qquad [12]$$

The so-called plate scale m of the telescope in units of arcsec/mm is given by:

$$m = 3600 \,\mathrm{atan}\frac{1}{f} \quad (f \text{ in mm}) \qquad [13]$$

In the case of the refractor, we have also shown an eyepiece, illustrating that historically the instrument was invented to enhance the human vision. The eye is located at the position of the exit pupil, thus receiving parallel light, i.e., observing an object at infinity, however (i) with a flux which is increased by a factor A, given by the ratio of the area of the telescope aperture with diameter D to the area of the eye's pupil d with $A = (D/d)^2$, and (ii) with a magnification M of the apparent angle between two separate objects at infinity, which is given by the ratio of the focal lengths of the objective and the eyepiece:

$$\Gamma = \frac{f_{\mathrm{obj}}}{f_{\mathrm{ocl}}} \qquad [14]$$

The magnification can also be expressed as the ratio of the diameters of the exit pupil and the entrance pupil:

$$\Gamma = \frac{D_{\mathrm{expup}}}{D_{\mathrm{enpup}}} \qquad [15]$$

The first astronomical telescopes with mirrors were equipped with an eyepiece for visual observation. The example in Figure 4 shows a configuration which is more common nowadays for professional astronomical observations, using a direct imaging detector in the focal plane (photographic plate, electronic camera).

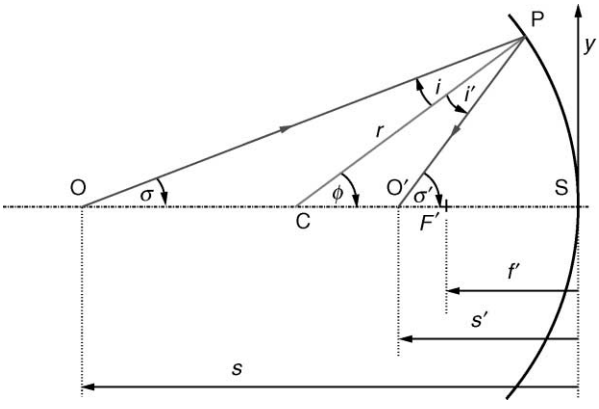

Figure 2 Reflection at a spherical surface with radius r.

Aberrations

Reflector Surfaces

We shall now study the behavior of a real telescope beyond the ideal in the case of a reflector. Figure 5 shows the situation of a mirror, imaging an on-axis

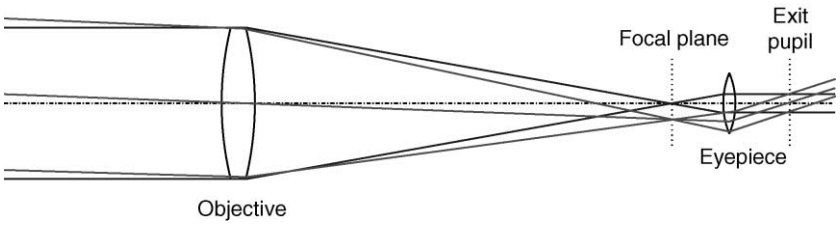

Figure 3 Refractor, astronomical telescope for visual observations with eyepiece (Kepler telescope).

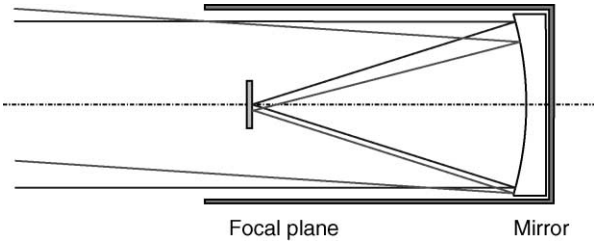

Figure 4 Reflector, astronomical telescope with prime focus imager.

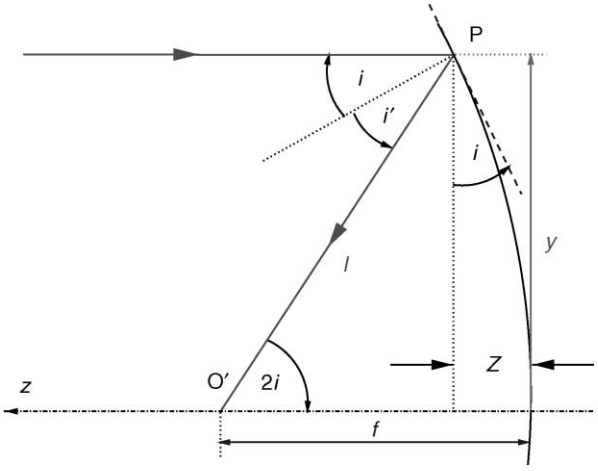

Figure 5 Imaging an object at infinity with reflector.

object at infinity into focus at point O′. With Fermat's principle, the optical paths of all rays forming the image must have identical length l. For all j, we must satisfy:

$$Z_j + f = l \qquad [16]$$

From the geometry in Figure 5, we find also:

$$y_i^2 + (f - Z_j)^2 = l^2 \qquad [17]$$

Combining eqns [16] and [17], we obtain the equation for a surface which satisfies the condition for perfect on-axis imaging:

$$y^2 = -4fz \qquad [18]$$

Obviously only a paraboloid is capable of fulfilling the condition for all rays parallel to the optical axis at whatever separation y. Also, we see that spherical mirrors are less than ideal imagers: rays at increasing distance y from the axis will suffer from increasing path length differences. The effect is called spherical aberration. We will investigate aberrations more quantitatively further below.

Elementary axisymmetrical surfaces can be expressed as follows, with parameter C being the conic constant:

$$y^2 - 2Rz + (1 + C)z^2 = 0 \qquad [19]$$

and the following characteristics:

$C > 0$	ellipsoidal, prolate
$C = 0$	spherical
$-1 < C < 0$	ellipsoidal, oblate
$C = -1$	paraboloidal
$C < -1$	hyperboloidal

Let us now leave the paraxial approximation and determine the focal length of rays which are parallel to, but further away at a distance y from the optical axis. Figure 5 shows the relevant geometrical relations. The intersection of the reflected ray with the optical axis at distance f from the vertex can be found from:

$$f = z + (f - z) \quad \text{where} \quad \frac{y}{f - z} = \tan(2i) \qquad [20]$$

We use the slope of the tangent in point P:

$$\frac{dz}{dy} = \tan i \qquad [21]$$

differentiate eqn [19] to get:

$$\frac{dz}{dy} = \frac{y}{R - (1 + C)z'} \qquad [22]$$

use the trigonometrical relation:

$$\tan 2\phi = \frac{2 \tan \phi}{1 - \tan^2 \phi} \qquad [23]$$

and substitute for $\tan(2i)$ in eqn [20] to obtain:

$$f = \frac{R}{2} + \frac{(1 - C)z}{2} - \frac{y^2}{2(R - (1 + C)z)} \qquad [24]$$

In order to express eqn [24] solely in terms of y, we rewrite eqn [19]:

$$z = \frac{R}{1 + C}\left(1 - \sqrt{1 - \frac{y^2}{R^2}(1 + C)}\right) \qquad [25]$$

Expanding z in a series and neglecting any orders higher than 6:

$$z = \frac{y^2}{2R} + (1 + C)\frac{y^4}{8R^3} + (1 - C)^3\frac{y^6}{16R^5} \qquad [26]$$

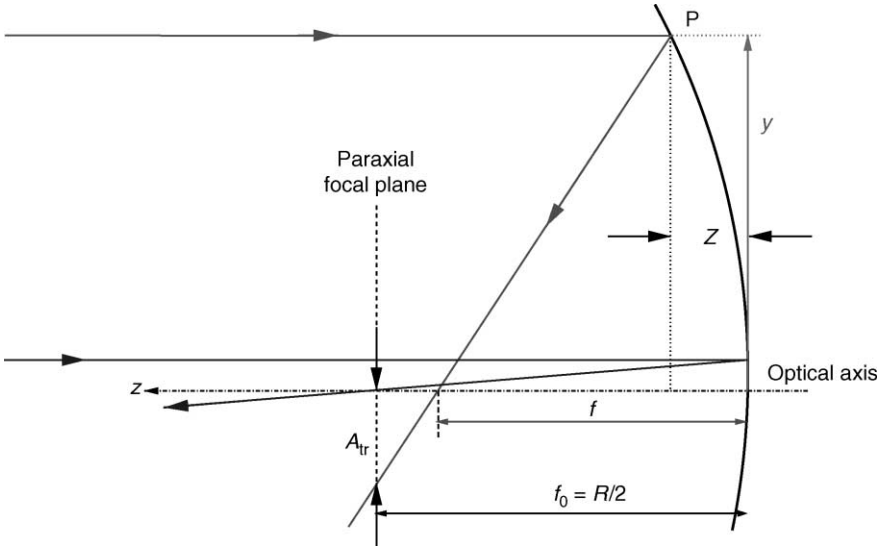

Figure 6 Transverse spherical aberration.

we obtain finally:

$$f = \frac{R}{2} - \frac{1+C}{4R}y^2 - \frac{(1+C)(3+C)}{16R^3}y^4 \qquad [27]$$

.

Transverse Spherical Aberration

Obviously, for any $C \neq -1$, rays of different distance y to the optical axis are focused at different focal lengths f (spherical aberration). The net effect for a distant point source is that the image is blurred, rather than forming a sharp spot. The lateral deviation of nonparaxial rays intersecting the nominal focal plane at $f_0 = R/2$ is described by the transverse spherical aberration A_{tr} (Figure 6):

$$A_{tr,sph} = \frac{y}{f-z}(f_0 - f) \qquad [28]$$

Using eqns [19] and [27], one obtains:

$$A_{tr,sph} = -\frac{1+C}{2R^2}y^3 + \frac{3(1+C)(3+C)}{8R^4}y^5 + \cdots \qquad [29]$$

Angular Spherical Aberration

It is sometimes more convenient to consider the angular spherical aberration, since a telescope is naturally measuring angles between objects at infinity. To this end, we compare an arbitrary reflector surface according to eqn [19] with a reference paraboloid, which is known to be free of on-axis spherical aberration (Figure 7). For any given ray, we observe how the reflected ray under study is tilted

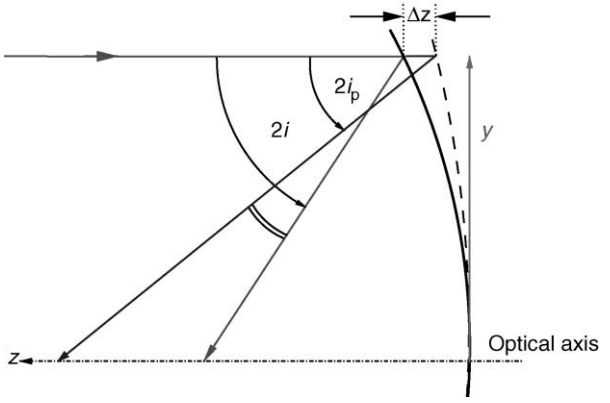

Figure 7 Angular aberration determined with reference to a paraboloid.

towards the reference ray, which would be reflected from the ideal surface of the paraboloid. While the former is measured under an exit angle of $2i$ towards the optical axis (see Figure 5), we designate the latter $2i_p$. The angular spherical aberration is defined as the difference of these two angles:

$$A_{ang,sph} = 2i - 2i_p = 2(i - i_p) \qquad [30]$$

Again, we can use the slope of the tangent to determine the change of angles $i \rightarrow i_p$:

$$A_{ang,sph} = 2\left(\frac{dz}{dy} - \frac{dz_p}{dy}\right) = 2\frac{d}{dy}\Delta z \qquad [31]$$

It is, therefore, sufficient to consider the difference in z between the surface under study and the

reference paraboloid. From eqn [26], we obtain as an approximation to third order:

$$A_{\text{ang,sph}} = -(1+C)\frac{y^3}{R^3} \qquad [32]$$

Aberrations in the Field

Since the use of a telescope exclusively on-axis would be somewhat limited, let us finally investigate the behavior under oblique illumination, i.e., when an object at infinity is observed under an angle Θ towards the optical axis of the system. This will allow us to assess aberrations in the field. For simplicity, we are considering a paraboloid, remembering that on-axis the system is free of spherical aberration. Again, we are employing an imaginary reference paraboloid which is pointing on-axis towards the object at angle Θ (Figure 8). Its coordinate system (O', z', y') is displaced and tilted with regard to the system under study (O, z, y). One can show that the offset Δz, which is used to derive the angular aberration in the same way as above, is given by:

$$2\Delta z = a_1\frac{y^3\Theta}{R^2} + a_2\frac{y^2\Theta^2}{R} + a_3 y\Theta^3 \qquad [33]$$

The angular aberration in the field is then:

$$A_{\text{ang,f}} = 3a_1\frac{y^2\Theta}{R^2} + 2a_2\frac{y\Theta^2}{R} + a_3\Theta^3 \qquad [34]$$

The coefficients are called:

a_1: coma

a_2: astigmatism

a_3: distortion

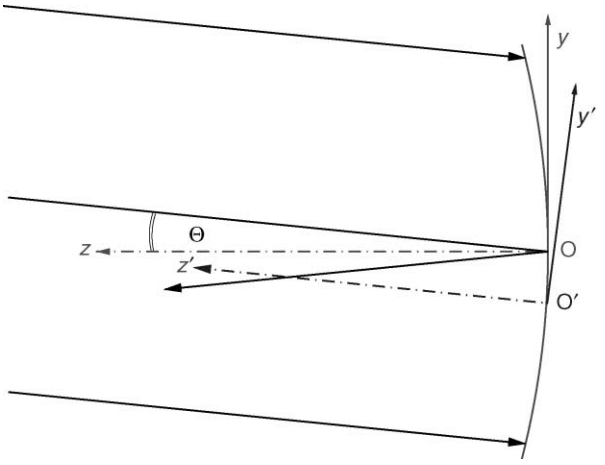

Figure 8 Aberration in the field, oblique rays.

Chromatic Aberration

So far we have only considered optical aberrations of reflecting telescopes. Spherical aberration in the case of a lens is treated in analogous ways and will not be discussed again. However, the wavelength dependence of the index of refraction in optical media (dispersion) is an important factor and gives rise to chromatic aberrations which are only encountered in refractive optical systems. We can distinguish two principal effects in the paraxial approximation: (i) longitudinal chromatic aberration, resulting in different axial image positions as a function of wavelength; and (ii) lateral chromatic aberration, which can be understood as an aberration of the principal ray as a function of wavelength, leading to a varying magnification as a function of wavelength (plate scale in the case of a telescope).

As an example, let us determine the wavelength dependence of the focal length of a single thin lens. Opticians are conventionally using discrete wavelengths of spectral line lamps of different chemical elements, e.g., the Mercury e line at 546.1 nm, Cadmium F' 480.0 nm, or Cadmium C' 643.8 nm, covering more or less the visual wavelength range of the human eye. Differentiation of eqn [8] yields for the wavelength of e:

$$\frac{f'}{\mathrm{d}n} = -\frac{1}{(n_e-1)^2}\frac{r_1 r_2}{r_2 - r_1} \qquad [35]$$

Substituting

$$\frac{r_1 r_2}{r_2 - r_1} = f'_e(n_e - 1) \qquad [36]$$

we get:

$$\mathrm{d}f' = -\frac{\mathrm{d}n}{n_e - 1}f'_e \qquad [37]$$

Replacing the differential by the differences $\Delta f' = f'_{F'} - f'_{C'}$ and $\Delta n = n_{F'} - n_{C'}$, then:

$$f'_{F'} - f'_{C'} = -\frac{n_{F'} - n_{C'}}{n_e - 1}f'_e = -\frac{f'_e}{\nu_e} \qquad [38]$$

ν_e is called Abbe's Number:

$$\nu_e = \frac{n_e - 1}{n_{F'} - n_{C'}} \qquad [39]$$

It is a tabulated characteristic value of dispersion for any kind of glass and allows one to quickly estimate the difference in focal length at the extreme wavelengths F' and C' when the nominal focal length of a lens is known as e.

Angular Resolution

In the previous sections, we have exclusively employed geometrical optics for the description of telescope properties. With geometrical optics and in the absence of aberrations, there is no limit to the angular resolution of a telescope, i.e., there is no limiting separation angle δ_{lim}, below which two distant point sources can no longer be resolved. However, real optical systems experience diffraction, leading to the finite width of the image of a point source (Airy disk), whose normalized intensity distribution in the focal plane as a function of radius r' from the centroid for the case of a circular aperture of diameter D can be conveniently described by a Bessell function (λ: wavelength, f': focal length of the objective):

$$\frac{I(r)}{I_0} = \left[\frac{2J_1(\nu)}{\nu}\right]^2 \quad \text{where} \quad \nu = \frac{\pi D r'}{\lambda f'} \qquad [40]$$

The intensity distribution is plotted in Figure 9. The first four minima of the diffraction ring pattern are listed in Table 1. Two point sources are defined to be at the resolution limit of the telescope when the maximum of one diffraction pattern happens to coincide with just the first diffraction minimum of the other one (Figure 9, right). As a rule of thumb, the angular resolution is of a telescope with diameter D is given by:

$$\delta_{\text{min}} = 1.22\frac{\lambda}{D} \rightarrow \frac{138}{D} \qquad [41]$$

the latter in units of arcsec for a wavelength of 550 nm and D in mm.

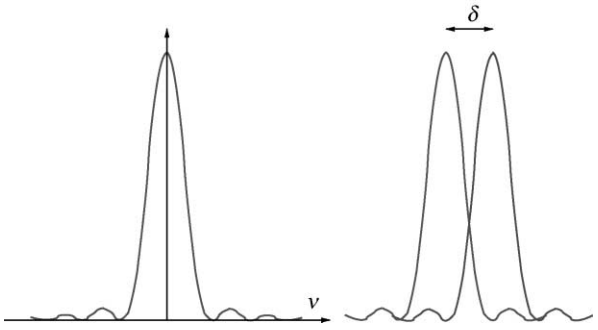

Figure 9 Left: radial intensity distribution of diffraction pattern (Airy disk). Right: two overlapping point source images with same intensity at limiting angular separation δ.

Table 1 Diffraction minima of airy disk

n	ν_n	$r'D/2f'\lambda$
1	3.83	0.61
2	7.02	1.12
3	10.2	1.62
4	13.3	2.12

Types of Telescopes

There are very many different types of telescopes which were developed for different purposes. In order to obtain an impression, we will only briefly introduce a nonexhaustive selection of refractors and reflectors, which by no means is representative of the whole. For a more complete overview, the reader is referred to the literature.

Refractor Objectives

Refractors are first of all characterized by their objectives. Figure 10 shows a sequence of lenses, indicating the progress of lens design developments from left to right. All lenses are groups 2 or 3, designed to compensate for chromatic aberration through optimized combinations of crown and flint glasses. The first lens is a classical C achromat, e.g., using BK7 and SF2 glass, which is essentially the design which was introduced by Hall and Dollond. It is still a useful objective for small telescopes, where a residual chromatic aberration is tolerable. The second lens is the Fraunhofer E type, which is characterized by an air gap between the two lenses (BK7, F2), which helps to optimize the image quality of the system, reducing spherical aberration and coma. As a disadvantage, the two additional glass–air interfaces lead to ghost images (reflected light) and Fresnell losses. The objective is critical with regard to the alignment of tip and tilt. The third example is an improved AS type achromat (KzF2, BK7), which is similar to the E type in

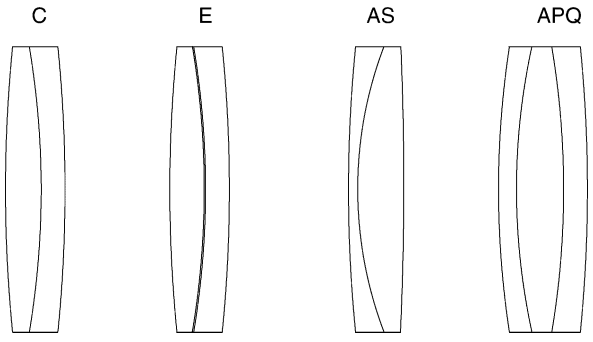

Figure 10 Different types of refractor objectives, from left to right: classical C achromat, Fraunhofer E achromat with air gap, AS achromat, APQ apochromat.

that it also possesses an air gap, however with an improved chromatic aberration correction in comparison to the Fraunhofer objective. The lenses show a more pronounced curvature and are more difficult to manufacture. The beneficial use of KzF2 glass is an example of the successful research for the development of new optical media, which was pursued near the end of the nineteenth century in a collaboration between Otto Schott and Ernst Abbé. The last example is a triplet, employing ZK2, CaF_2, and ZK2. This APQ type of objective is an apochromat, whose chromatic aberration vanishes at 3 wavelengths. It is peculiar for its use of a crystal (calcium fluoride, CaF_2) as the optical medium of the central lens. The manufacture of the CaF_2 lens is critical and expensive, but it provides for an excellent correction of chromatic and spherical aberration of this high quality objective. The triplet is also difficult to manufacture because of the coefficient of thermal expansion, which is roughly different by a factor of two between CaF_2 and the glass. In order to avoid disrupture of the cemented lens group, some manufacturers have used oil immersion to connect the triplet. Since CaF_2 not only has excellent dispersion properties to correct for chromatic aberration, but also exhibits an excellent transmission beyond the visual wavelength regime, this type of lens is particularly useful for applications in the blue and UV.

Finally, Figure 11 shows the complete layout of an astrograph, which is a telescope for use with photographic plates. The introduction of this type of instrument meant an important enhancement of astrophysical research by making available a significantly more efficient method, compared to the traditional visual observation of individual stars, one by one. Using photographic plates, it became possible to measure position and brightness of hundreds and thousands of stars, when previously one could investigate tens. Typical astrographs were built with apertures between 60 and 400 mm, and a field-of-view as large as 15 degrees. Despite the growing importance of space-based observatories for astrometry, some astrographs are still in use today.

Basic Oculars

While the general characteristics of a refractor are dominated by the objective, the eyepiece nevertheless plays an important role for the final appearance to the observer, with an effect on magnification, image quality, chromatism, field of view, and other properties of the entire system. From a large variety of different ocular types, let us briefly consider a few simple examples.

The first eyepiece in Figure 12 is the one of the Kepler telescope, which was already introduced in Figure 3. It has a quite simple layout with a single lens of positive power. The lens is located after the telescope focal plane at a distance which is equal to the ocular focal length f_oc. The telescope and the ocular focal planes are coinciding, and as a result, the outcoming beam is collimated, forming the system exit pupil after a distance f_oc. This is where ideally the observer's eye is located. The focal plane is creating a real image, which is a convenient location for a reticle. The Kepler telescope is, therefore, a good tool for measurement and alignment purposes. We note that the image is inverted, which is relatively unimportant for a measuring telescope and astronomy, but very annoying for terrestrial use.

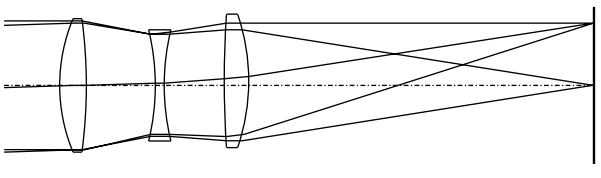

Figure 11 Astrograph.

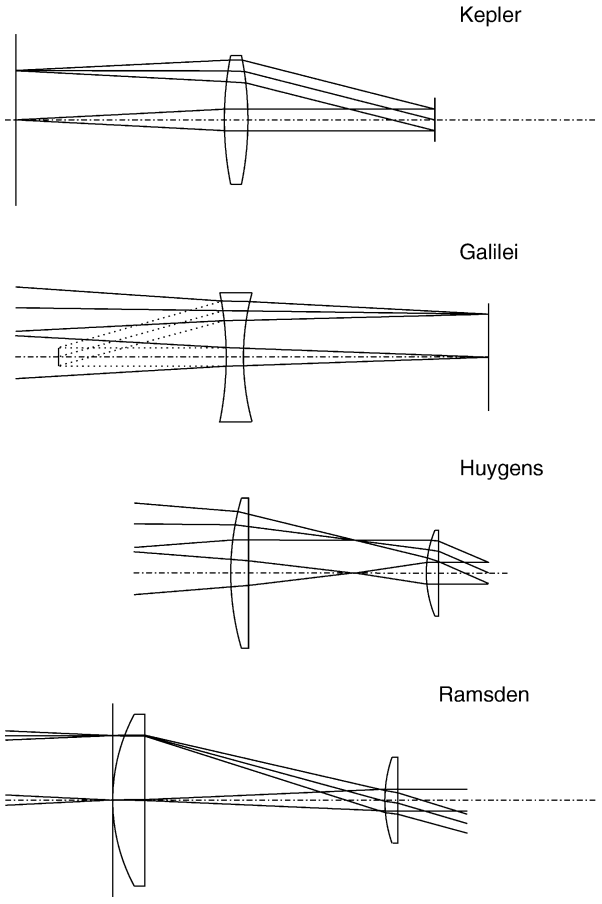

Figure 12 Elementary eyepieces after Kepler, Galilei, Huygens, and Ramdsen.

This latter property has been avoided in the next example, which is the ocular of the Galilean telescope, which was built by Galileo and used for his famous observations of planets and moons in the solar system. It uses a single lens, but contrary to the Kepler type with negative power. The lens is located in the telescope beam in front of the focal plane of the objective, which means that the exit pupil is virtual and not accessible to the observer (indicated by dotted lines in Figure 12). The overall length of the telescope is somewhat shorter than Kepler's, however at the expense of the lack of a real focal plane, so no reticle can be applied.

The third example is the 2-lens-ocular of Christian Huygens, who was able to prove with his design that it is possible to correct paraxially the lateral chromatic aberration. The eyepiece is still being built today.

Another elementary ocular is shown in Figure 12, which is the eyepiece after Ramsden. This system is also corrected for lateral chromatic aberration. The real image is formed on the front surface of the second lens, providing a location for a reticle or a scale for measuring purposes. The exit pupil is interior to the ocular. In addition to these selected basic types, there are many more advanced multilens oculars in use today, with excellent correction and large field of view (up to 60°).

Reflectors

Let us now describe several basic types of reflectors (see Figure 13). The first example is the Newton reflector, which uses a flat folding mirror to create an accessible exterior focus. It is conceptually simple and still in use today for amateur astronomy. When the main mirror is a paraboloid, the spherical aberration is corrected on the axis of the system.

The second example represents an important improvement over the simple 1-mirror design of Newton's telescope, in that the combination of a parabolic first mirror (main mirror, M1) with a hyperbolic secondary mirror (M2) eliminates spherical aberration, but not astigmatism and coma. The Cassegrain telescope has a curved focal surface which is located behind the primary mirror. Due to the onset of coma and astigmatism, the telescope has a modest useful field-of-view. Besides the correction properties, the system has significant advantages in terms of mechanical size and weight, playing an important role for the construction of large telescopes. The basic type of this design has practically dominated the construction of the classical large astronomical telescopes with M1 diameters of up to 5 m, and, more recently, the modern 8–10 m class telescopes. On the practical side, the external focus of the Cassegrain on the bottom of the mirror support cell is a convenient location for mounting focal plane instruments (e.g., CCD cameras, spectrographs, and others).

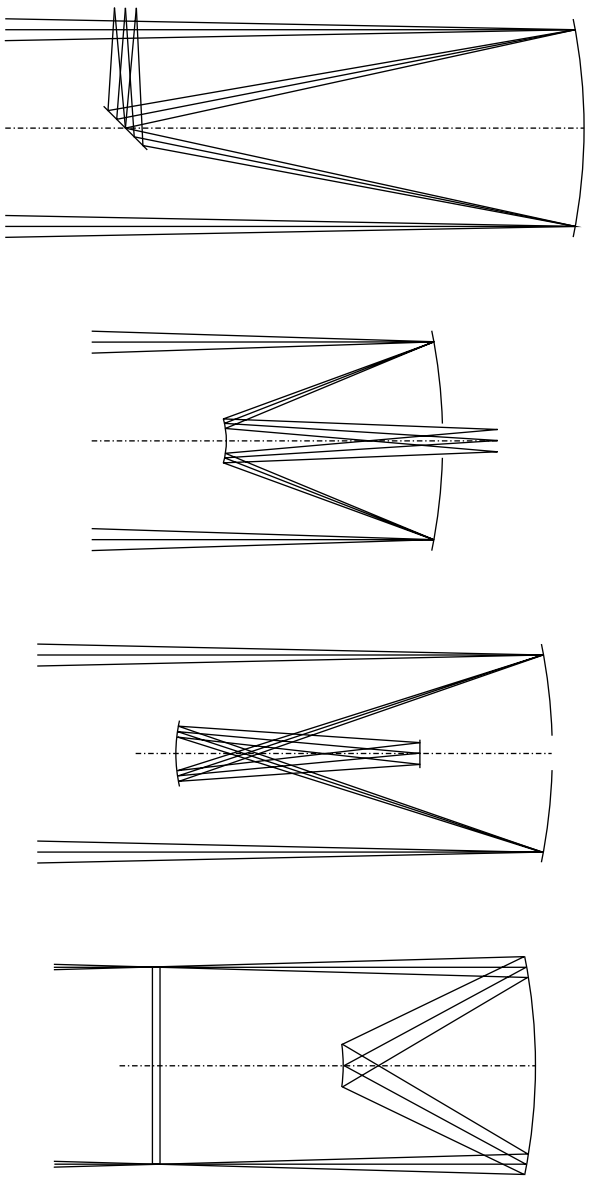

Figure 13 Reflectors, from top to bottom: Newton, Cassegrain, Gregory, Schmidt.

The more common variant of the Cassegrain type, which was actually used for the design of these telescopes, is the layout of Ritchey (1864–1945) and Cretien (1879–1956), which combines two hyperbolic mirrors for M1 and M2 (RCC), but otherwise has the same appearance as the Cassegrain. Besides spherical aberration, it also corrects for coma, giving a useful field-of-view of up to 1°. Like in the case of the Cassegrain telescope, the RCC exhibits some curvature of the focal plane.

Our third example is the Gregory reflector, which also is a 2-mirror system, however with a concave elliptical secondary mirror. The correction of this telescope is similar, but somewhat inferior to the one of the Cassegrain. The use of a concave M2 is advantageous for manufacture and testing. Nevertheless, the excessive length of the system has precluded the use of this layout for large astronomical telescopes, except for stationary beams, for example, in solar observatories.

The last example is the design put forward by Bernhard Schmidt (1879–1935) who wanted to create a telescope with an extremely wide field-of-view. The first telescope of his new type achieved a field-of-view of 16° – something which had not been feasible with previous techniques. The basic idea is to use a fast spherical mirror, and to correct for spherical aberration by means of an aspherical corrector plate in front of the mirror, which also forms the entrance pupil of the telescope. The focal surface is strongly curved, making it necessary to employ a detector with the same radius of curvature (bent photographic plates), or to compensate the curvature by means of a field lens immediately in front of the focus. The presence of the corrector plate and, if used, the field flattener, gives rise to significant chromatism. Nevertheless, the Schmidt telescope was a very successful design and dominated wide-angle survey work in astronomy for many decades.

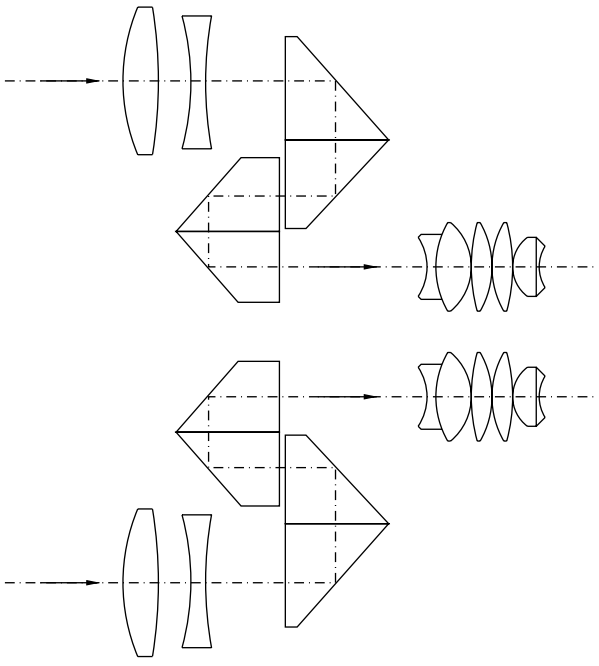

Figure 14 Principle of prism binoculars with folded beams.

Applications

General Purpose Telescopes

According to the original meaning of the Greek 'tele–skopein', the common conception of the telescope is the one of an optical instrument, which provides an enlarged view of distant objects. In addition, a large telescope aperture, compared to the eye, improves night vision and observations with poorly illuminated scenes. There are numerous applications in nautical, security, military, hunting, and other professional areas. For all of these applications, an intuitive vision is important, essentially ruling out the classical astronomical telescope (Kepler telescope, see Figure 3), which produces an inverted image.

Binoculars with Porro prisms are among the most popular instruments with upright vision, presenting a compact outline due to the folded beam geometry (Figure 14), but also single tube telescopes with re-imaging oculars are sometimes used.

Metrology

As we have realized in the introduction, telescopes are instruments which perform a transformation from angle of incidence in the aperture to distances from the origin in the focal plane. If the focal length of the objective is taken sufficiently long, and a high-quality eyepiece is used, very small angles down to the arcsec regime can be visually observed. Telescopes are, therefore, ideal tools to measure angles to very high precision.

In Figure 15 we see a pair of telescopes, facing each other, where one instrument is equipped with a light source, and the other one is used to observe the first one. The first telescope is also called a collimator. It possesses a lamp, a condensor system, a focal plane mask (usually a pinhole, a crosshair, or some other useful pattern imprinted on a transparent plate), and the telescope objective. The focal plane mask is projected to infinity. It can thus be observed with the

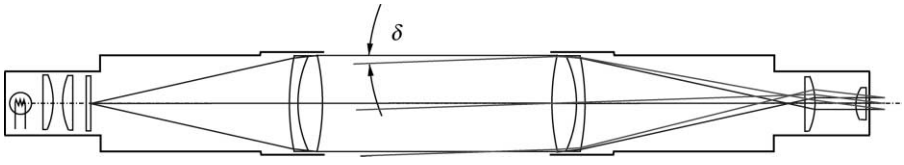

Figure 15 Collimator and telescope.

measuring telescope, such that an image of the collimator mask appears in the telescope focal plane. Also the telescope is equipped with a mask in its focal plane, usually with a precision scale or another pattern for convenient alignment with the collimator mask. If now the collimator is tilted by a small angle δ against the optical axis of the telescope, the angle of incidence in the measuring telescope changes by this same amount, giving rise to a shift of the image by $\Delta x = f \tan \delta$. Note that the measurement is completely insensitive to parallel shifts between the telescope and the collimator, since it is parallel light which is transmitted between the two instruments.

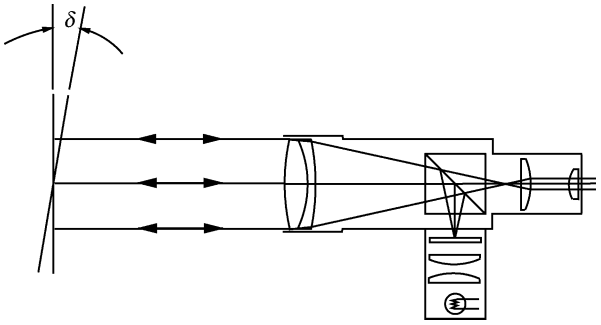

Figure 16 Autocollimator.

Another special device, which combines the former two instruments into one, is the Autocollimator. The optical principle is shown in Figure 16: in principle, the autocollimator is identical to a measuring telescope, except that a beamsplitter is inserted between the focal plane and the objective. The beamsplitter is used to inject light from the same kind of light source device as in the normal collimator. The axis of the folded light source beam and of the illuminated collimator mask are aligned to match the focal plane mask of the telescope section: the optical axis of the emerging beam is identical to the optical axis of the telescope. Under this condition, the reflected light from a test object will be exactly centered on the telescope focal plane mask, when it is perfectly aligned to normal incidence. Normally, a high-quality mirror is attached to the device under study, but sometimes also the test object itself possesses a plane surface of optical quality, which can be used for the measurement.

Figure 17 shows schematically an example for such a measurement, where a mirror is mounted on a linear stage carriage for the purpose of measuring the flexure of the stage to very high precision. With a typical length of ≈ 1 m, this task is not a trivial problem for a mechanical measurement.

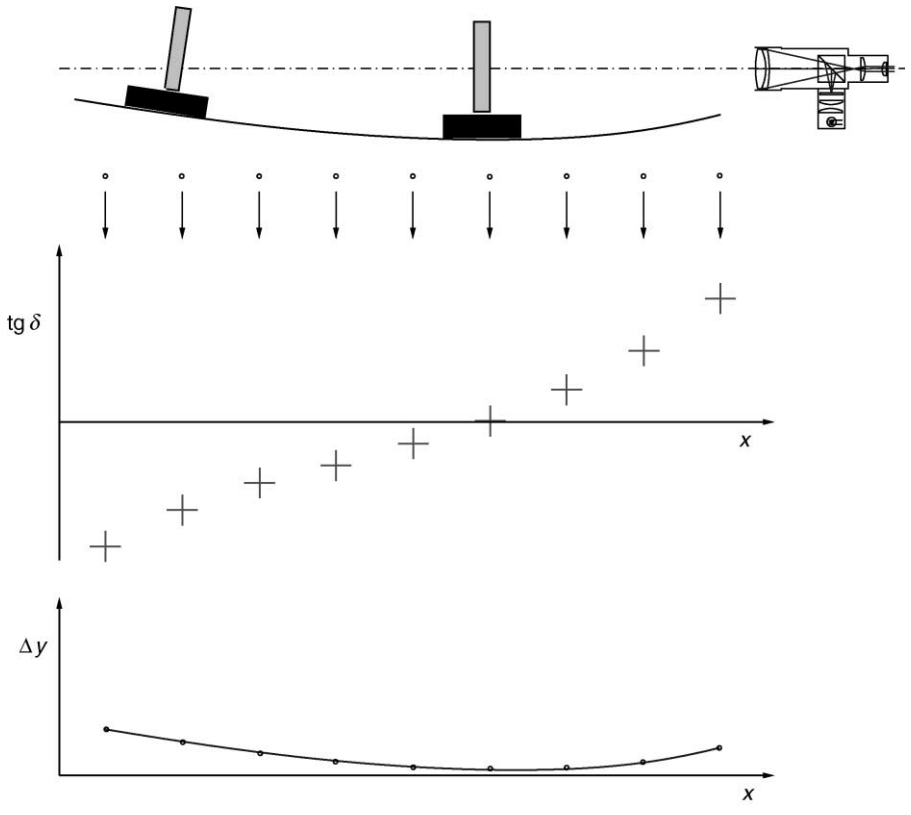

Figure 17 Using an autocollimator to measuring the flexure of a linear stage.

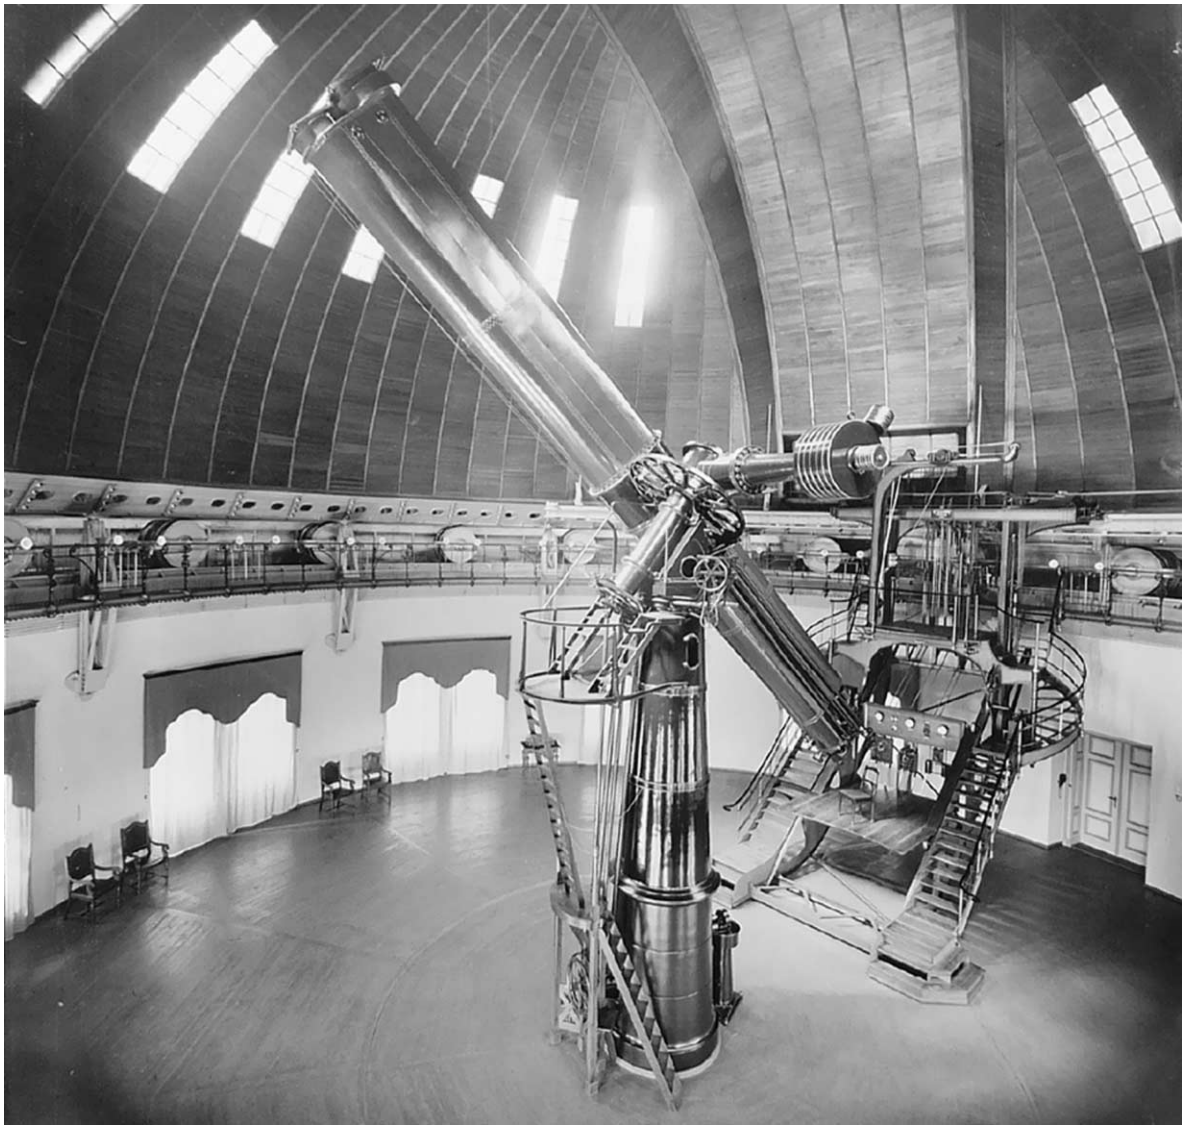

Figure 18 The 80 cm + 60 cm 'Great Refractor' at the Astrophysical Observatory Potsdam. The correction of the 80 cm objective of this telescope led Johannes Hartmann to the development of the 'Hartmann Test', which was the first quantitative method to measure aberrations. This method is still in use today, and has been further developed to become the 'Shack-Hartmann' technique of wavefront sensing. Courtesy of Astrophysikalisches Institut Potsdam.

By measurement with the autocollimator the tilt of the mirror consecutively for a sufficiently large number of points x_i along the rail, we can now plot the slope of the rail at each point x_i as tan d:

$$\frac{dy}{dx} = \tan \delta \qquad [42]$$

Integrating the series of slope values reproduces the shape of the rail $y = f(x)$.

Other applications include multiple autocollimation, wedge measurements, and right angle measurements.

Multiple autocollimation is achieved by inserting a fixed plane-parallel and semi-transparent mirror between the autocollimator and the mirror under study. Light coming from the test mirror will be partially transmitted through the additional mirror towards the autocollimator, and partially reflected back to the test mirror, and so forth. After k reflections, a deflection of $k\delta$ is measured, when δ is the tilt of the test mirror.

The wedge angle α of a plane-parallel plate with refractive index n_w is easily measured by observing the front and back surface reflections from the plate, keeping in mind that the beam bouncing back from the rear will also experience refraction in the plate. If δ is the measured angle difference between the two front and rear beams, then $\alpha = \delta/2n_w$.

Two surfaces of an object can be tested for orientation at right angles by attaching a mirror to surface 1 and observe the mirror with the fixed autocollimator. In a second step, an auxiliary pentaprism is inserted into the beam, deflecting the light towards surface 2, where the mirror is attached next. If a precision pentaprism is used, any deviation from right angles between the two surfaces is seen as an offset between step 1 and 2.

These are only a few examples of the very many applications for alignment and angle measurements in optics and precision mechanics.

Without going into much detail, we are just mentioning that also the theodolite and sextant make use of the same principle of angular measurements, however without the need of a collimator or autocollimation.

Astronomical Telescopes

Despite its importance as a measurement and testing device for optical technology and manufacture as described in the preceeding paragraph, it is the original invention and subsequent improvement of the telescope for *Astronomy* which is probably the most fascinating application of any optical system known to the general public. The historical development of the astronomical telescope spans from the 17th century Galileian refractor with an aperture of just a few centimeters in diameter, over the largest refractors built for the Lick and Yerkes observatories with objectives of up to ≈ 1 m in diameter (see also Figures 18–20), the 4 m-class reflectors of the second half of the 20th century like e.g. the Hale Observatory 5m, the Kitt Peak and Cerro Tololo 4 m, the La Silla 3.6 m, or the La Palma 4.2 m telescopes (to name only a few), to the current state-of-the-art of 8–10 m class telescopes, prominent examples being the two Keck Observatory 10 m telescopes on Mauna Kea (Hawaii), or the ESO Very Large Observatory (Paranal, Chile), consisting of four identical 8.2 m telescopes (Figures 21–24).

This development has always been driven by the discovery of fainter and fainter celestial objects, whose quantitative study is the subject of modern astrophysics, involving many specialized disciplines such as atom/quantum/nuclear physics, chemistry, general relativity, electrodynamics, hydrodynamics, magneto-hydrodynamics, and so forth. In fact, cosmic objects are often referred to as 'laboratories'

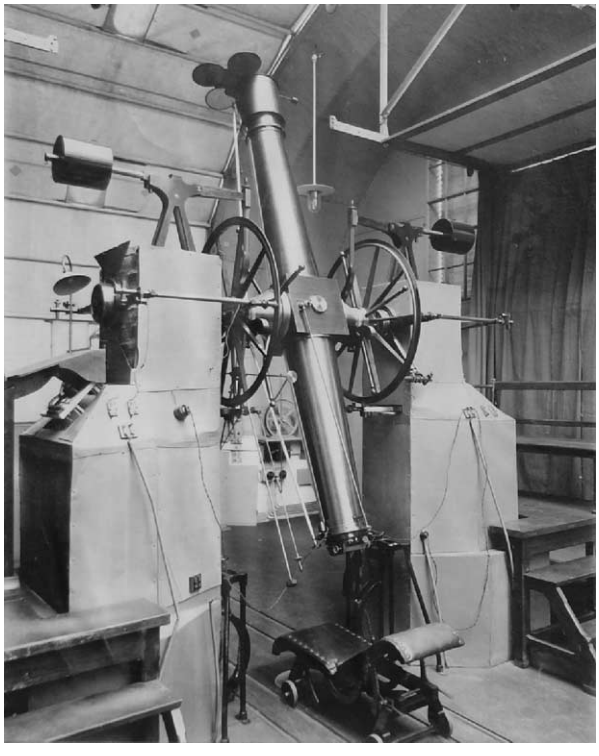

Figure 19 Pistor & Martin Meridian Circle at the former Berlin Observatory in Potsdam Babelsberg. The instrument was one of the finest art telescopes with ultra-high precision for astrometry, built in 1868. Courtesy of Astrophysikalisches Institut Potsdam.

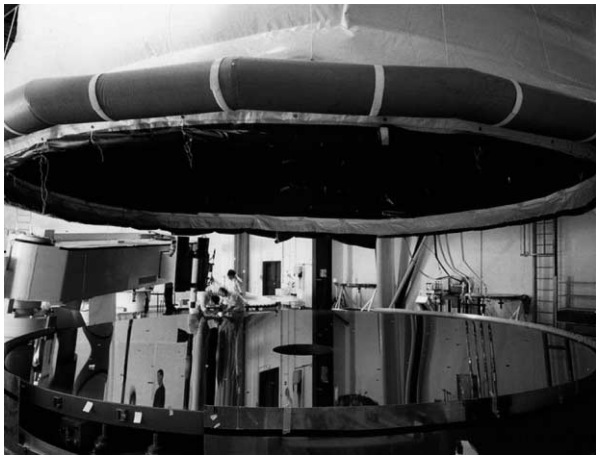

Figure 23 8.2 m thin primary mirror for the VLT. The VLT design is based on thin meniscus mirrors, made out of ZERODUR, which have low thermal inertia and which are always kept at ambient temperature, thus virtually removing the effect of thermal turbulence (mirror seeing). Seeing is the most limiting factor of ground-based optical astronomy. The optimized design of the VLT telescopes has introduced a significant leap forward to a largely improved image quality from the ground, and, consequently, improved sensitivity. The thin mirrors are constantly actively controlled in their mounting cells, using numerous piston actuators on the back surface of the mirror. Another key technology under development is 'adaptive optics', a method to compensate atmospheric wavefront deformations in real-time, thus obtaining diffraction limited images. Courtesy of European Southern Observatory.

with extreme conditions of density, temperature, magnetic field strength, etc., which would be impossible to achieve in any laboratory on Earth. Except for particles (neutrinos, cosmic rays), gravitational waves, and the physical investigation of meteorites and other solar system material collected by space probes, telescopes (for the entire wavelength range of the electromagnetic spectrum) are the *only* tool to accomplish quantitative measurements of these cosmic laboratories.

In an attempt to unravel the history of the birth and evolution of the universe, to discover and to measure the first generation of stars and galaxies, and to find evidence for traces of life outside of planet Earth, plans are currently underway to develop yet another new generation of giant optical telescopes with apertures of 30–100 m in diameter (ELT: extremely large telescope). The technological challenges in terms of precision and stability are outstanding.

Along with the impressive growth of light collecting area, we must stress the importance of angular resolution, which has also experienced a significant evolution over the history of astronomical telescopes: from ≈ 5 arcsec of the Galilei telescope, which already provided an order of magnitude improvement over the naked eye, over roughly 1 arcsec of conventional telescopes in the 20th century, a few hundredths of an arcsec for the orbiting Hubble Space

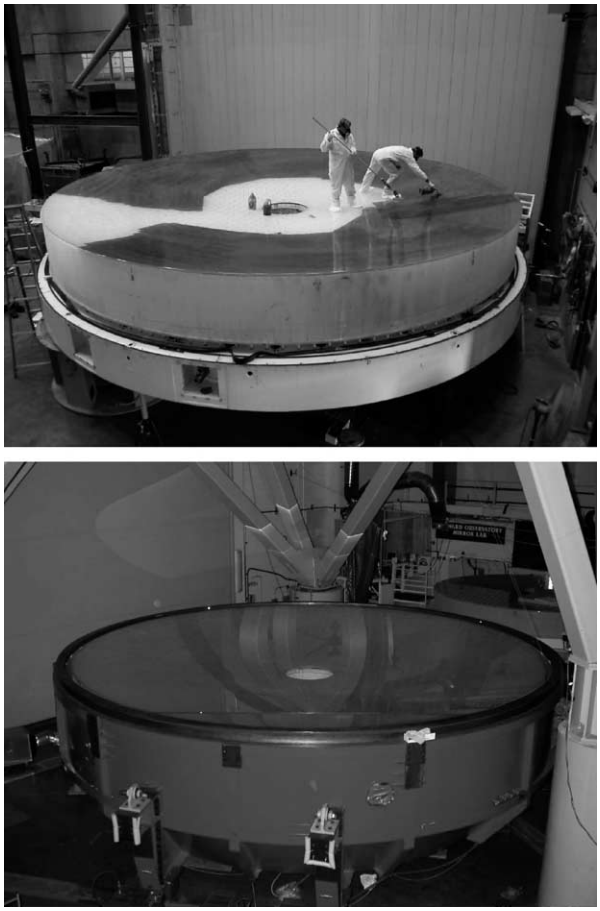

Figure 24 Top: spin-cast 8.4 m honeycomb mirror #1 for the Large Binocular Telescope, the largest monolithic mirror of optical quality in the world. Telescope (Figure 25), down to milli-arcsec resolution of the Keck and VLT Interferometers. The development of the aforementioned ELTs is thought to be only meaningful if operated in a diffraction-limited mode, using the emerging technique of *adaptive optics*, which is a method to correct for wavefront distortions caused by atmospheric turbulence (image blurr) in real-time.

The combination of large optical/infrared telescopes with powerful detectors and focal plane instruments (*see* **Instrumentation:** Astronomical Instrumentation) has been a prerequisite to make astrophysics one of the most fascinating disciplines of fundamental sciences.

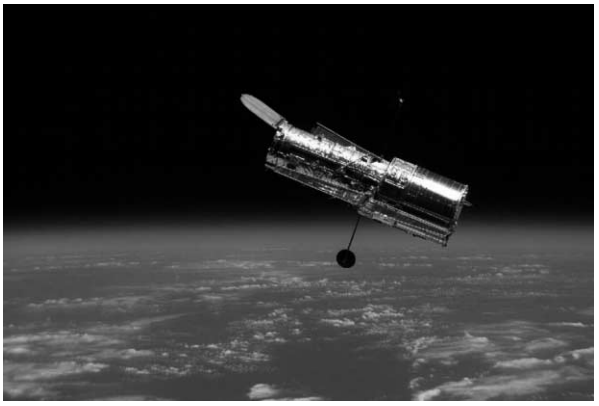

Figure 25 Hubble Space Telescope (HST) in orbit. This 2.4 m telescope is probably the most productive telescope which was ever built. Due to the absence of the atmosphere, the telescope delivers diffraction-limited, extremely sharp images, which have revealed unprecedented details of stars, star clusters, nebulae and other objects in the Milky Way and in other galaxies. Among the most spectacular results, HST has provided the deepest look into space ever, revealing light from faint galaxies that was emitted when the universe was only at 10% of its present age. Introduction

Interferometers are a powerful tool used in numerous industrial, research, and development applications, including measuring the quality of a large variety of manufactured items such as optical components and systems, hard disk drives and magnetic recording heads, lasers and optics used in CDs and DVD drives, cameras, laser printers, machined parts, components for fiber optics systems, and so forth. Interferometers can also be used to measure distance, spectra, and rotations, etc. The applications are almost endless.

There are many varieties of interferometers. Some interferometers form interference fringes using two beams and some use multiple beams. Some interferometers are common path; some use lateral shear; some use radial shear; and some use phase-shifting techniques. Examples of the various types are given below, but first we must give the basic equation for two-beam interference.

Two-Beam Interference

When two quasi-monochromatic waves interfere, the irradiance of the interference pattern is given by

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos[\phi] \qquad [1]$$

where the I's represent the irradiance of the individual beams and ϕ is the phase difference between the two interfering beams. The maximums of the interference occur when $\phi = 2m\pi$, where m is an integer. In most applications involving interferometers, ϕ is the quantity of interest since it is related to the quantity being measured. Figure 1 shows typical two-beam interference fringes.

There are many two-beam interferometers and we will now look at a few of them.

Fresnel Mirrors

Fresnel Mirrors are a very simple two beam interferometer. A beam of light reflecting off two mirrors, set at a slight angle to one another, will produce an interference pattern. The fringes are straight and equally spaced. The fringes become more finely spaced as the angle between the two mirrors increases, d increases, and D becomes smaller (Figure 2).

Plane Parallel Plate

When a monochromatic source illuminates a plane parallel plate, as shown in Figure 3, the interference

Figure 1 Typical two-beam interference fringes.

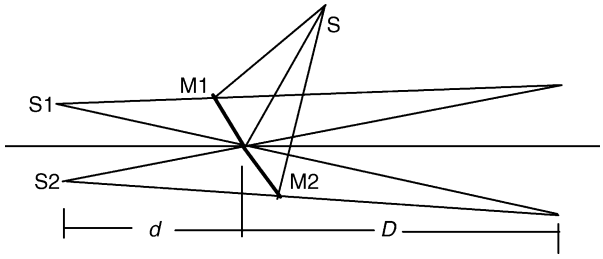

Figure 2 Fresnel mirrors.

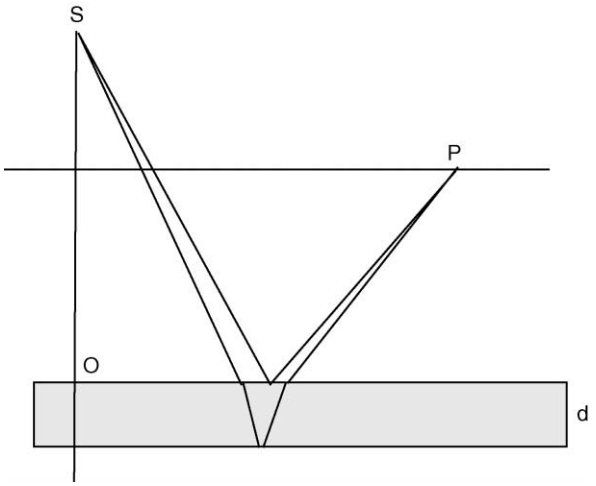

Figure 3 Plane parallel plate interferometer.

fringes are circles centered on the normal to plate. The fringes are called Haidinger fringes, or fringes of equal inclination since, for a given plate thickness, they depend on the angle of incidence. If the maximum or minimum occurs at the center, the radii of the fringes are proportional to the square root of integers. If the plate has a slight variation in thickness and it is illuminated with a collimated beam then the interference fringes are called Fizeau fringes of equal thickness and they give the thickness variations in the plate.

Michelson Interferometer

A Michelson interferometer is shown in Figure 4. Light from the extended source is split into two beams by the beamsplitter. The path difference can be viewed as the difference between the mirror M1 and the image of mirror M2, M2′. With the M1 and M2′ parallel, the fringes are circular and localized at infinity. With M1 and M2′ at a slight angle, the interference fringes are straight lines parallel to the equivalent intersection of the mirrors and localized approximately at the intersection. When the mirrors are only a few wavelengths apart, white light fringes

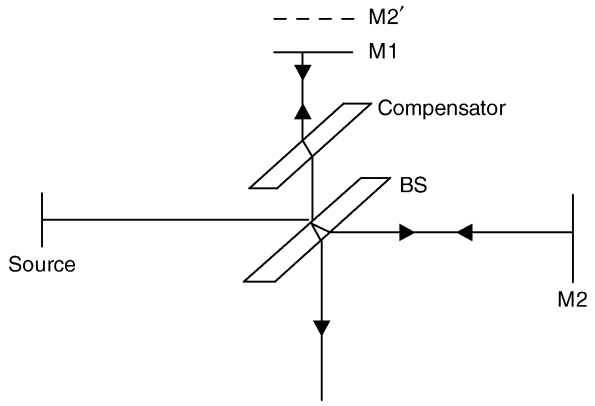

Figure 4 Michelson interferometer.

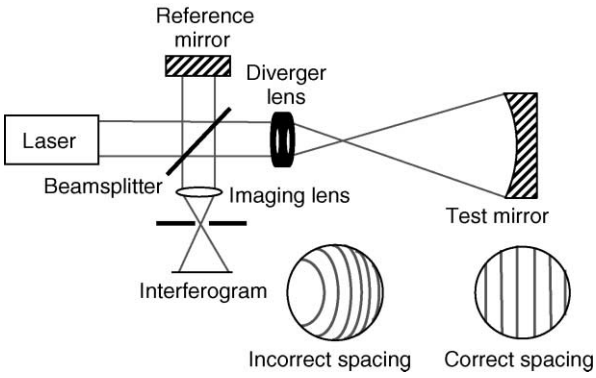

Figure 5 Twyman–Green interferometer for testing a concave spherical mirror.

appear, and can be used to determine their coincidence.

Twyman–Green Interferometer

If a point source is used in a Michelson interferometer it is generally called a Twyman–Green interferometer. Twyman–Green interferometers are often used to test optical components such as flat mirrors, curved mirrors, windows, lenses, and prisms. Figure 5 shows a Twyman–Green interferometer for the testing of a concave spherical mirror. The interferometer is aligned such that the focus of the diverger lens is at the center of curvature of the spherical mirror. If the mirror under test is perfect, straight equi-spaced fringes are obtained. Figure 6 shows two interference fringes and the relationship between surface height error for the mirror being tested and fringe deviation. λ is the wavelength of the light.

Fizeau Interferometer

The Fizeau interferometer is a simple device used for testing optical surfaces, especially flats and spheres

(Figure 7). The fringes are fringes of equal thickness. It is sometimes useful to tilt the reference surface a little to get several nearly straight interference fringes. The relationship between surface height error and fringe deviation from straightness is the same as for the Twyman–Green interferometer.

Mach–Zehnder Interferometer

A Mach–Zehnder interferometer is sometimes used to look at samples in transmission. Figure 8 shows a typical Mach–Zehnder interferometer for looking at a sample in transmission.

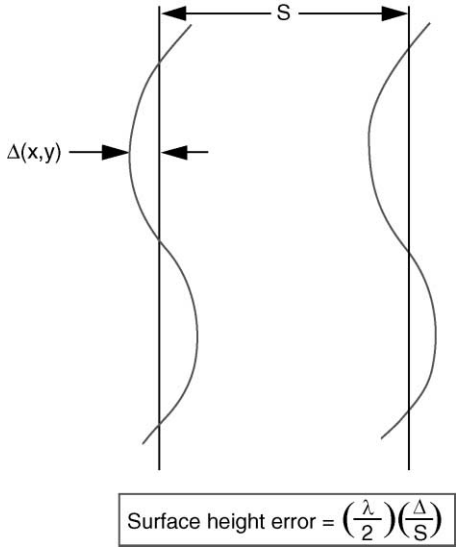

Figure 6 Relationship between surface height error and fringe deviation.

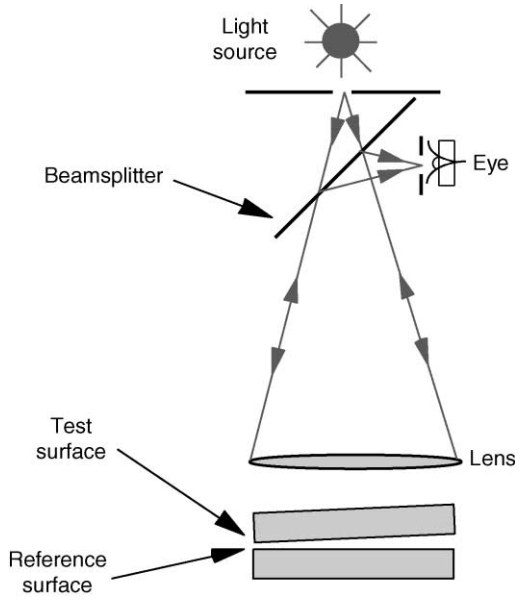

Figure 7 Fizeau interferometer.

Murty Lateral Shearing Interferometer

Lateral shearing interferometers compare a wavefront with a shifted version of itself. While there are many different lateral shear interferometers, one that works very well with a nearly collimated laser beam is a Murty shearing interferometer shown in Figure 9. The two laterally sheared beams are produced by reflecting a coherent laser beam off a plane parallel plate. The Murty interferometer can be used to measure the aberrations in the lens or it can be used to determine if the beam leaving the lens is collimated. If the beam incident upon the plane parallel plate is collimated a single fringe results, while if the beam is not perfectly collimated straight equi-spaced fringes result where the number of fringes gives the departure from collimation.

Radial Shear Interferometer

Radial shear interferometers compare a wavefront with a magnified or demagnified version of itself. While there are many different radial shear

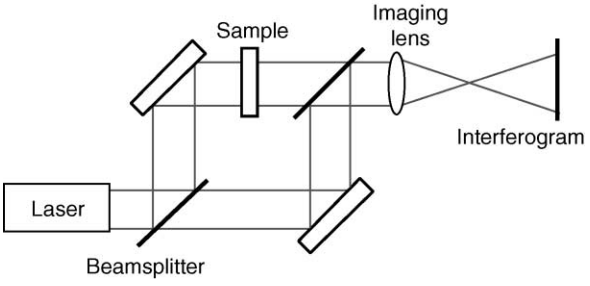

Figure 8 Mach–Zehnder interferometer.

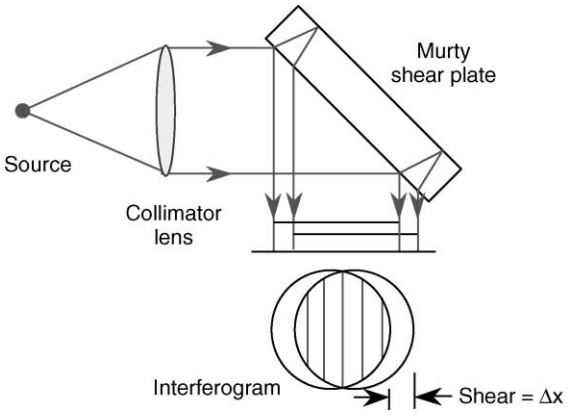

Figure 9 Murty lateral shear interferometer.

interferometers, one that works very well with a nearly collimated beam is shown in Figure 10. It is essentially a Mach–Zehnder interferometer where, in one arm, the beam is magnified and in the other arm the beam is demagnified. Interference fringes result in the region of overlap. The sensitivity of the interferometer depends upon the amount of radial shear. If the two interfering beams are approximately the same size there is little sensitivity, while if the two beams greatly differ in size there is large sensitivity. Sometimes radial shear interferometers are used test the quality of optical components.

Scatterplate Interferometer

A scatterplate interferometer, invented by Jim Burch in 1953, is one of the cleverest interferometers. Almost any light source can be used and no high-quality optics are required to do precision interferometry. The critical element in the interferometer is the scatterplate which looks like a piece of ground glass, but the important item is that the scattering points are arranged so the plate has inversion symmetry as shown in Figure 11. The light that is scattered the first time through the plate, and unscattered the second time through the plate, interferes with the light unscattered the first time and scattered the second time. The resulting interference fringes show errors in the mirror under test. This type of interferometer is insensitive to vibration because it is what is called a common path interferometer, in that the test beam (scattered–unscattered) and the reference beam (unscattered–scattered) travel along almost the same paths in the interferometer.

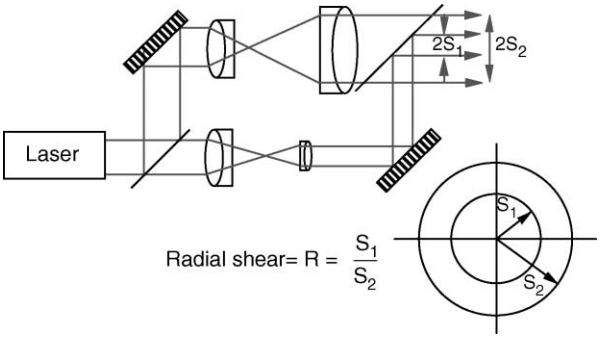

Figure 10 Radial shear interferometer.

Smartt Point Diffraction Interferometer

Another common path interferometer used for the testing of optics is the Smartt point diffraction interferometer (PDI) shown in Figure 12. In the PDI the beam of light being measured is focused onto a partially transmitting plate containing a pinhole. The pinhole removes the aberration from the light passing through it (reference beam), while the light passing through the plate (test beam) does not have the aberration removed. The interference of these two beams gives the aberration of the lens under test.

Sagnac Interferometer

The Sagnac interferometer has beams traveling in opposite directions, as shown in Figure 13. The interferometer is highly stable and easy to align. If the interferometer is rotated with an angular velocity there will be a delay between the transit times of the clockwise and the counterclockwise beams. For this reason, the Sagnac interferometer is used in laser gyros.

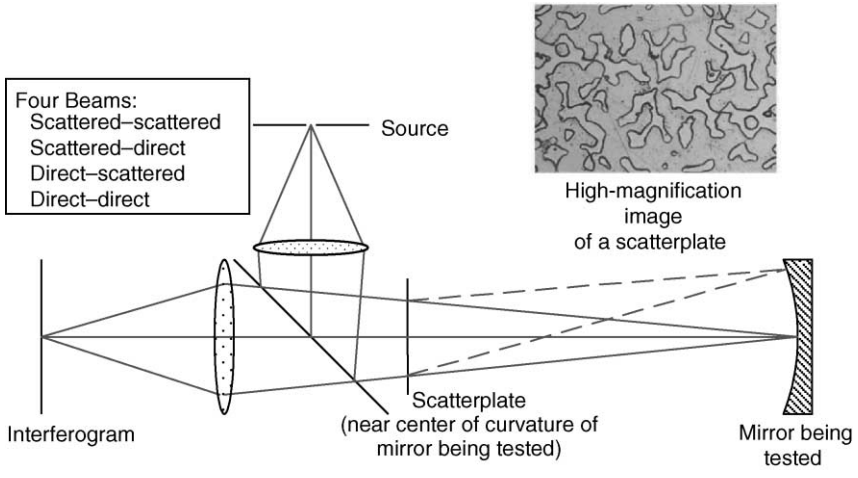

Figure 11 Scatterplate interferometer.

Fiber Interferometers

Fiber interferometers were first used for rotation sensing by replacing the ring cavity in the Sagnac interferometer with a multiloop made of a single-mode fiber. Fiber-interferometer rotation sensors are attractive as rotation sensors because they are small and low-cost.

Since the optical path in a fiber is affected by its temperature and it also changes when the fiber is stretched, fiber interferometers can be used as sensors for mechanical strains, temperature, and pressure. They can also be used for the measurement of magnetic fields by bonding the fiber to a magneto-restrictive element. Electric fields can be measured by bonding the fiber to a piezoelectric film.

Multiple Beam Interferometers

In general, multiple beam interferometers provide sharper interference fringes than a two beam interferometer. If light is reflected off a plane parallel plate there are multiple reflections. If the surfaces of the plane parallel plate have a low reflectivity, the higher-order reflections have a low intensity and the multiple reflections can be ignored and the resulting interference fringes have a sinusoidal intensity profile, but if the surfaces of the plane parallel plate have a high reflectivity, the fringes become sharper. Figure 14 shows the profile of the fringes for both the reflected and the transmitted light for different values of surface reflectivity. Multiple beam interference fringes are extremely useful for measuring the spectral content of a source. One such multiple beam interferometer, that is often used for measuring spectral distributions of a source, is a Fabry–Perot interferometer that consists of two plane-parallel plates separated by an air space, as shown in Figure 15.

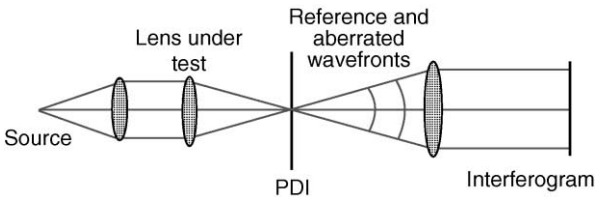

Figure 12 Smartt point diffraction interferometer.

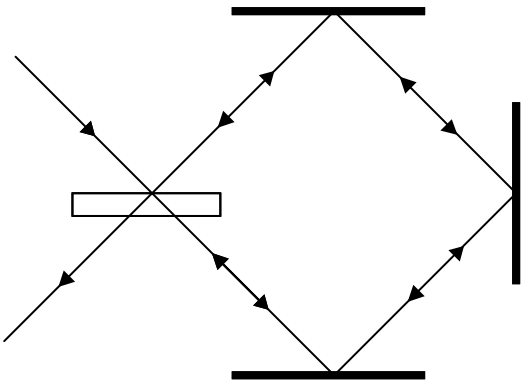

Figure 13 Sagnac interferometer.

Phase-Shifting Interferometry

The equation for the intensity resulting from two-beam interference, contains three unknowns, the two individual intensities and the phase difference between the two interfering beams. If three or more measurements are made of the intensity of the two-beam interference as the phase difference between the two beams is varied in a known manner, all three unknowns can be determined. This technique, called phase-shifting interferometry, is an extremely powerful tool for measuring phase distributions. Generally the phase difference is

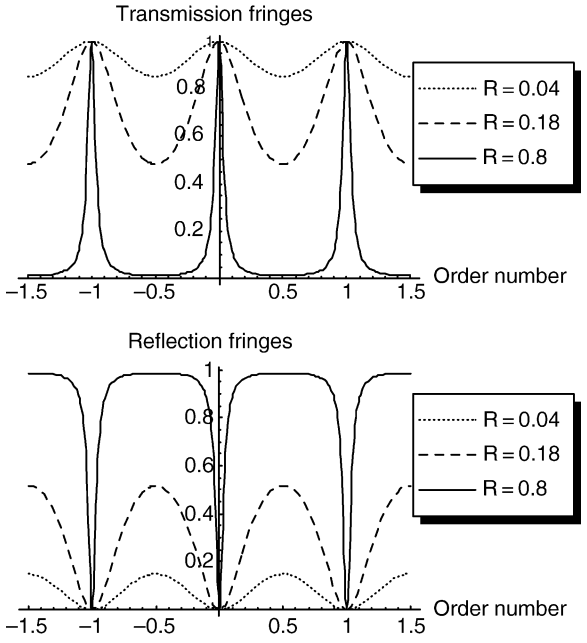

Figure 14 Multiple beam interference fringes for the transmitted and reflected light for a plane parallel plate.

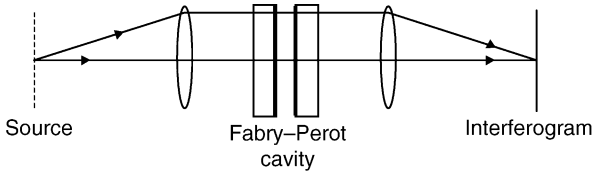

Figure 15 Fabry–Perot interferometer.

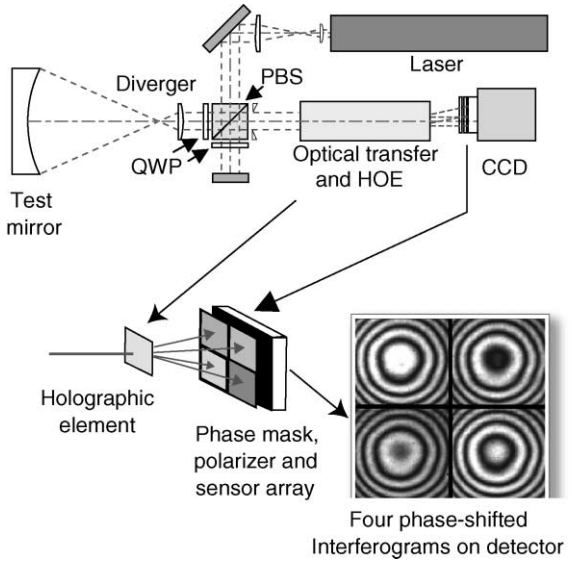

Figure 16 Vibration-insensitive phase-shifting interferometer.

changed by 90 degrees between consecutive measurements of the interference intensity in which case the three intensities can be written as

$$I_a(x,y) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos(\phi(x,y) - 90°)$$
$$I_b(x,y) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos(\phi(x,y))$$
$$I_c(x,y) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos(\phi(x,y) + 90°)$$

and the phase distribution is given by

$$\phi(x,y) = \mathrm{ArcTan}\left(\frac{I_a(x,y) - I_c(x,y)}{-I_a(x,y) + 2I_b(x,y) - I_c(x,y)}\right)$$

Phase-shifting interferometry has greatly enhanced the use of interferometry in metrology since it provides a fast low noise way of getting interferometric data into a computer.

Vibration-Insensitive Phase-Shifting Interferometer

While phase-shifting interferometry has greatly enhanced the use of interferometry in metrology, there are many applications where it cannot be used because of the environment, especially vibration. One recent phase-shifting interferometer that works well in the presence of vibration is shown in Figure 16. In this interferometer, four phase-shifted frames of data are captured simultaneously. The test and reference beams have orthogonal polarization. After the test and reference beams are combined they are passed through a holographic element to produce four identical beams. The four beams are then transmitted through wave retardation plates to cause 0, 90, 180, and 270 phase difference between the test and reference beams. After passing through a polarizer the four phase-shifted interferograms fall on the detector array. Not only can the effects of vibration be eliminated, but by making short exposures to freeze the vibration, the vibrational modes can be measured. Movies can be made showing the vibration. Likewise, flow fields can be measured.

Combining modern electronics, computers, and software with old interferometric techniques, provides for very powerful measurement capabilities.

Gravity Wave Detection

Introduction

In the later part of the nineteenth century Albert Michelson performed extraordinary experiments that shook the foundations of the physics world. Michelson's precise determination of the speed of light was an accomplishment that takes great skill to reproduce today. Edward Morley teamed up with Michelson to measure the velocity of the Earth with respect to the aether. The interferometer that they constructed was exquisite, and through amazing experimental techniques the existence of the aether was disproved. The results of Michelson and Morley led to a revolution in physics, and provided evidence that helped Albert Einstein to develop the general theory of relativity. Now the Michelson interferometer may soon provide dramatic confirmation of Einstein's theory through the direct detection of gravitational radiation.

An accelerating electric charge produces electromagnetic radiation – light. It should come as no surprise that an accelerating mass produces gravitational light, namely gravitational radiation. In 1888 Heinrich Hertz had the luxury to produce and detect electromagnetic radiation in his laboratory. There will be no such luck with gravitational radiation because gravity is an extremely weak force.

Albert Einstein postulated the existence of gravitational radiation in 1916, and in 1989 Joe Taylor and Joel Weisberg indirectly confirmed its existence through observations of the orbital decay of the binary pulsar 1913 + 16. Direct detection of gravity waves will be difficult. For humans to have any chance of detecting gravity waves there must be extremely massive objects accelerating up to relativistic velocities. The only practical sources are astrophysical: supernovae, pulsars, neutron star or black hole binary systems, black hole formation or even the Big Bang. The observation of these types of events would be extremely significant for contributing to knowledge in astrophysics and cosmology. Gravity waves from the Big Bang would provide information about the Universe at its earliest moments. Observations of supernovae will yield a gravitational snapshot of these extreme cataclysmic events. Pulsars are neutron stars that can spin on their axes at frequencies in the hundreds of hertz, and the signals from these objects will help to decipher their characteristics. Gravity waves from the final stages of coalescing binary neutron stars could help to accurately determine the size of these objects and the equation of state of nuclear matter. The observation of black hole formation from these binary systems would be the *coup de grace* for the debate on the existence of black holes, and the ultimate triumph for general relativity.

Electromagnetic radiation has an electric field transverse to the direction of propagation, and a charged particle interacting with the radiation will experience a force. Similarly, gravitational radiation will produce a transverse force on massive objects, a tidal force. Explained via general relativity it is more accurate to say that gravitational radiation will deform the fabric of space-time. Just like electromagnetic radiation there are two polarizations for gravity waves. Let us imagine a linearly polarized gravity wave propagating in the z-direction, $h(z,t) = h_{0+}e^{i(kz-\omega t)}$. The fabric of space is stretched due to the strain created by the gravity wave. Consider a length L_0 of space along the $\boldsymbol{x}$-axis. In the presence of the gravity wave the length oscillates like

$$L(t) = L_0 + \frac{h_{0+}L}{2}\cos\omega t$$

hence there is a change in its length of

$$\Delta L_x = \frac{h_{0+}L}{2}\cos\omega t$$

A similar length L_0 of the $\boldsymbol{y}$-axis oscillates, like

$$L(t) = L_0 - \frac{h_{0+}L}{2}\cos\omega t$$

or

$$\Delta L_y = \frac{-h_{0+}L}{2}\cos\omega t$$

One axis stretches while the perpendicular one contracts, and then vice versa, as the wave propagates through. The other polarization (h_{0x}) produces a strain on axes 45° from ($\boldsymbol{x}$,$\boldsymbol{y}$). Imagine some astrophysical event produces a gravity wave that has amplitude h_{0+} on Earth; in order to detect a small distance displacement ΔL one should have a detector that spans a large length L. A supernova within our own Galaxy might possibly produce a gravity wave of size $h \sim 10^{-18}$ with characteristic frequencies around

1 kHz, but the occurrence of an event such as this will be extremely rare. More events will come from novae in other galaxies, but due to the great distances and the fact that the magnitude of the gravity wave falls of as $1/r$, such events will be substantially diminished in magnitude.

A Michelson interferometer, with arms aligned along the x- and y- axes, can measure small phase differences between the light in the two arms. Therefore, this type of interferometer can turn the length variations of the arms produced by a gravity wave into changes in the interference pattern of the light exiting the system. This was the basis of the idea from which modern laser interferometric gravitational radiation detectors have evolved. Imagine a gravity wave of amplitude h is incident on an interferometer. The change in the arm length will be $h \sim \Delta L/L_0$, so in order to optimize the sensitivity it is advantageous to make the interferometer arm length L_0 as large as possible. Detectors coming on-line are attempting to measure distance displacements that are of order $\Delta L \sim 10^{-18}$ m or smaller, less that the size of an atomic nucleus! If the interferometers can detect such distance displacements, and directly detect gravitational radiation, it will be one of the most spectacular accomplishments in experimental physics. The first implementation of a laser interferometer to detect a gravity wave was by Forward who used earphones to listen to the motion of the interference signal. The engineering of signal extraction for modern interferometers is obviously far more complex.

Numerous collaborations are building and operating advanced interferometers in order to detect gravitational radiation. In the United States there is the Laser Interferometer Gravity Wave Observatory (LIGO), which consists of two 4-km interferometers located in Livingston, Louisiana and Hanford, Washington. In addition, there is an additional 2-km interferometer within the vacuum system at Hanford. An Italian–French collaboration (VIRGO) has a 3-km interferometer near Pisa, Italy. GEO, a German–British collaboration, is a 600-m detector near Hanover, Germany. TAMA is the Japanese 300-m interferometer in Tokyo. The Australians (AIGO) are constructing a 500-m interferometer in Western Australia. All of the detectors will be attempting to detect gravity waves with frequencies from about 50 Hz to 1 kHz.

As will be described below, there are a number of terrestrial noise sources that will inhibit the performance of the interferometric detectors. The sensitivity of detection increases linearly with interferometer arm length, which implies that there could be advantages to constructing a gravity wave detector in space. This is the goal of the Laser Interferometer Space Antenna (LISA) collaboration. The plan is to deploy three satellites in a heliocentric orbit with a separation of about 5×10^6 km. The launch for LISA is planned for around 2015, and the detector will be sensitive to gravity waves within the frequency range of 10^{-3} to 10^{-1} Hz. Due to the extremely long baseline, LISA is not strictly an interferometer, as most light will be lost as the laser beams expand while traveling such a great distance. Instead, the phase of the received light will be detected and used to lock the phase of the light that is re-emitted by another laser.

Joe Weber pioneered the field of gravitational radiation detection in the 1960s. He used a 1400-kg aluminum cylinder as an antenna. Gravitational waves would hopefully excite the lowest-order normal mode of the bar. Since the gravity wave is a strain on space-time, experimentalists win by making their detectors longer in length. This provides a long-term advantage for laser interferometers, which can scale in length relatively easily. However, as of 2002, interferometers and bars (now cooled to 4 K) have comparable sensitivities.

Interferometer Styles

The Michelson interferometer is the tool to be used to detect a gravitational wave. Figure 1 shows a basic system. The beamsplitter and the end mirrors would be suspended by wires, and effectively free to move in the plane of the interferometer. The arms have lengths L_1 and L_2 that are roughly equal on a kilometer scale. With a laser of power P and wavelength λ incident on the beamsplitter, the light

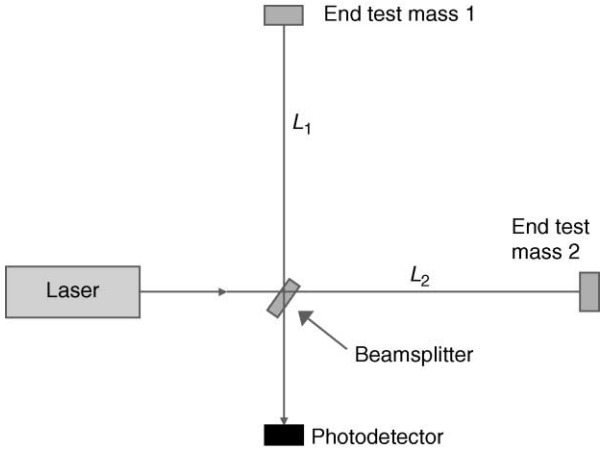

Figure 1 A basic Michelson interferometer. The photodetector receives light exiting the dark port of the interferometer and hence the signal.

exiting the dark port of the interferometer is

$$P_{\text{out}} = P \sin^2\left[\frac{2\pi}{\lambda}(L_1 - L_2)\right]$$

The interferometer operates with the condition that in the absence of excitation the light exiting the dark port is zero. This would be the case for a simple and basic interferometer. However, interferometers like those in LIGO will be more sophisticated, and will use a heterodyne detection strategy. If E_0 is the amplitude of the electric field from the laser, and assuming the use of a 50–50 beamsplitter, the electric field (neglecting unimportant common phase shifts) for the light incident on the photodetector would be

$$E_{\text{out}} = \frac{E_0}{2}\left(e^{i\delta\phi_1} - e^{i\delta\phi_2}\right) \approx i\frac{E_0}{2}(\phi_1 - \phi_2)$$

$$= iE_0\frac{2\pi}{L}(L_1 - L_2)$$

The laser light will be phase modulated at a frequency in the MHz regime. As such, the deconvolved current from the photodiode that detects light at the interferometer output will be proportional to the phase acquired by the light, namely $I \propto \frac{2\pi}{\lambda}(L_1 - L_2)$.

A gravity wave of optimal polarization normally incident upon the interferometer plane will cause one arm to decrease in length while the other increases. The Michelson interferometer acts as a gravity wave transducer; the change in arm lengths results in more light exiting the interferometer dark port. The mirrors in the interferometer are suspended via wires so that they are free to move under the influence of the gravity wave.

An interferometer's sensitivity increases with arm length, but geographical and financial constraints will limit the size of the arms. If there could be some way to bounce the light back and forth to increase the effective arm length it would increase the detector performance. Fabry–Perot cavities on resonance light have a storage time of $2L/[c(1 - \sqrt{R_1R_2})]$. Figure 2 shows the system of a Michelson interferometer with Fabry–Perot cavities. This gravity wave interferometer design was proposed and tested in the late 1970s by Ron Drever. The far mirror R_2 has a very high reflectivity ($R_2 \sim 1$) in order to ultimately direct the light back towards the beamsplitter. The front mirror reflectivity R_1 is such that LIGO's effective arm length increases to $L \sim 300$ km. The optical properties of the mirrors of the Fabry–Perot cavities must be exquisite in order to achieve success. LIGO's mirrors were tested, and the root mean squared surface uniformity is less than 1 nm, scattered light is less than 50 parts per million (ppm), absorption is less than 2 ppm, and the radii of curvature for the mirrors are matched to less than 3%. A LIGO test mass (and therefore a Fabry–Perot mirror) can be seen in Figure 3.

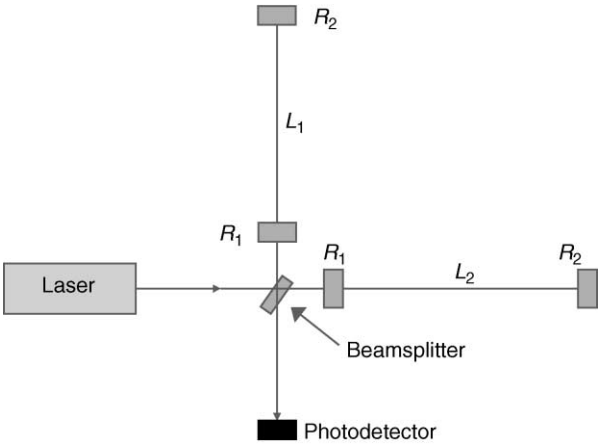

Figure 2 A Michelson interferometer with Fabry–Perot cavities in each arm. The front cavity mirrors have reflectivity R_1 while the end mirrors have $R_2 \sim 1$. By using Fabry–Perot cavities LIGO will increase the effective arm length by a factor of 75.

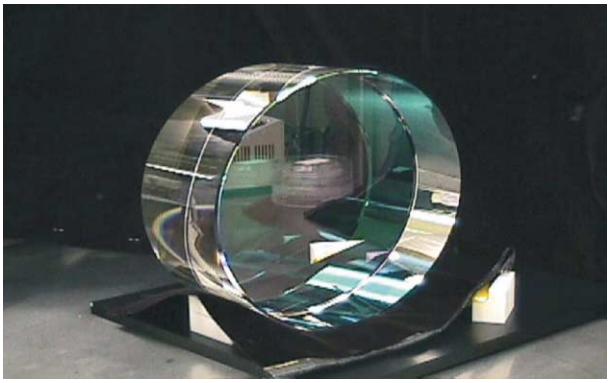

Figure 3 A picture of a mirror and test mass for LIGO. The fused silica component is 10.7 kg in mass and 25 cm in diameter. Photograph courtesy of Caltech/LIGO.

In 1888 Michelson and Morley, with their interferometer, had a sensitivity that allowed the measurement of 0.02 of a fringe, or about 0.126 radian. Prototype interferometers constructed by the LIGO science team have already demonstrated a phase noise spectral density of $\phi(f) = 10^{-10}$ radian/$\sqrt{\text{Hz}}$ for frequencies above 500 Hz. Assuming a 1 kHz signal with 1 kHz bandwidth this implies a phase sensitivity of $\Delta\phi = 3.2 \times 10^{-9}$ radian. This is about the phase sensitivity that LIGO hopes to accomplish in the 4-km Fabry–Perot system. There has been quite an evolution in interferometry since Michelson's time.

The noise sources that inhibit the interferometer performance are discussed below. However, let us

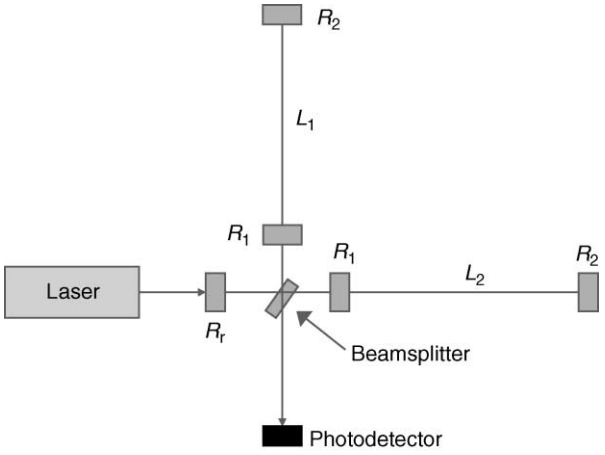

Figure 4 A power recycled Michelson interferometer with Fabry–Perot cavities in each arm. Normally light would exit the interferometer through the light port and head back to the laser. Installation of the recycling mirror with reflectivity R_r sends the light back into the system. A Fabry–Perot cavity is formed between the recycling mirror and the first mirror (R_1) of the arms. For LIGO this strategy will increase the power circulating in the interferometer by a factor of 50.

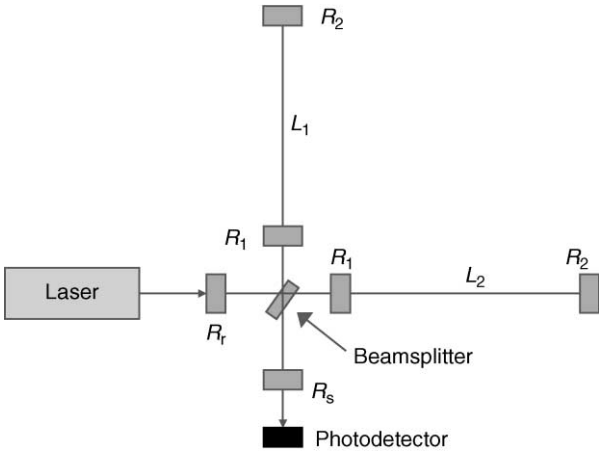

Figure 5 A signal recycled and power recycled Michelson interferometer with Fabry–Perot cavities in each arm. Normally light containing the gravity wave signal would exit the interferometer through the dark port and head to the photodetector. Installation of the signal recycling mirror with reflectivity R_s sends the light back into the system. The phase of the light acquired from the gravity wave will build up at a particular frequency determined by the reflectivity R_s.

consider one's ability to measure the relative phase between the light in the two arms. The Heisenberg uncertainty relation for light with phase ϕ and photon number N is $\Delta\phi\Delta N \sim 1$. For a measurement lasting time τ using laser power P and frequency f, the photon number is $N = P\lambda\tau/hc$, and with Poisson statistics describing the light $\Delta N = \sqrt{N} = \sqrt{P\lambda\tau/hc}$. Therefore

$$\Delta\phi\Delta N = \frac{2\pi}{\lambda}\Delta L\sqrt{P\lambda\tau/hc} = 1$$

implies that

$$\Delta L = \frac{1}{2\pi}\sqrt{\frac{hc\lambda}{P\tau}}$$

With more light power the interferometer can measure smaller distance displacements and achieve better sensitivity. LIGO will use about 10 W of laser power, and will eventually work towards 100 W. However, there is a nice trick one can use to produce more light circulating in the interferometer, namely power recycling. Figure 4 displays the power recycling interferometer design. The interferometer operates such that virtually none of the light exits the interferometer dark port, and the bulk of the light returns towards the laser. An additional mirror, R_r in Figure 4, recycles the light. For LIGO, recycling will increase the effective light power by another factor of 50. The higher circulating light power therefore improves the sensitivity.

There is one additional modification to the interferometer system that can further improve sensitivity, but only at a particular frequency. A further Fabry–Perot system can be made by installing what is called a signal recycling mirror; this would be mirror R_s in Figure 5. Imagine light in arm 1 on the interferometer that acquires phase as the arm expands due to the gravity wave. The traveling gravity wave's oscillation will subsequently cause arm 1 to contract while arm 2 expands. If the light that was in arm 1 could be sent to arm 2 while it is expanding, then the beam would acquire additional phase. This process could be repeated over and over. Mirror R_s serves this purpose, with its reflectivity defining the storage time for light in each interferometer arm. The storage time defined by the cavity formed by the signal recycling mirror, R_s, and the mirror at the front of the interferometer arm cavity, R_1, determines the resonance frequency. Signal recycling will give a substantial boost to interferometer sensitivity at a particular frequency, and will eventually be implemented in all the main ground-based interferometric detectors.

The LIGO interferometers are infinitely more complex than the relatively simple systems displayed in the figures of this paper. Figure 6 presents an aerial view of the LIGO site at Hanford, Washington. The magnitude of the 4-km system is apparent.

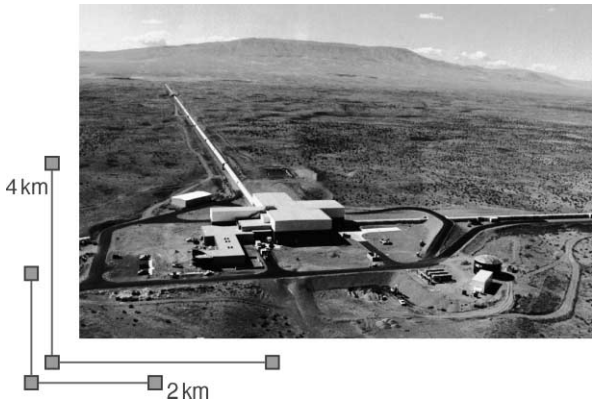

Figure 6 Arial view of the LIGO Hanford, Washington site. The vacuum enclosure at Hanford contains both 2-km and 4-km interferometers. Photograph courtesy of Caltech/ LIGO.

Noise Sources and Interferometer Sensitivity

If the interferometers are to detect distance displacements of order $\Delta L \sim 10^{-18}$ m then they must be isolated from a host of deleterious noise sources. Seismic disturbances should not shake the interferometers. Thermal excitation of components will affect the sensitivity of the detector and should be minimized. The entire interferometer must be in an adequate vacuum in order to avoid fluctuations in gas density that would cause changes in the index of refraction and hence modification of the optical path length. The laser intensity and frequency noise must be minimized. The counting statistics of photons influences accuracy. If ever there was a detector that must avoid Murphy's law this is it; little things going wrong cannot be permitted if such small distance displacements are to be detected. The expected noise sensitivity for the initial LIGO interferometers is displayed in Figure 7.

In the best of all worlds the interferometer sensitivity will be limited by the counting statistics of the photons. A proper functioning laser will have its photon number described by Poisson statistics, or shot noise; if the mean number of photons arriving per unit time is N then the uncertainty is $\Delta N = \sqrt{N}$, which as noted above implies an interferometer displacement sensitivity of

$$\Delta L = \frac{1}{2\pi}\sqrt{\frac{hc\lambda}{P\tau}}$$

or a noise spectral density of

$$\Delta L(f) = \frac{1}{2\pi}\sqrt{\frac{hc\lambda}{P}} \text{ (in units of m}/\sqrt{\text{Hz}})$$

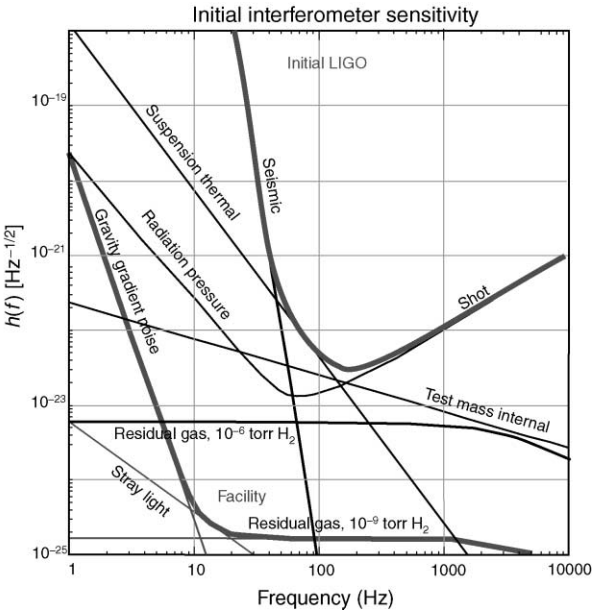

Figure 7 The target spectral density of the noise for the initial LIGO system. LIGO will be dominated by seismic noise at low frequencies (10–100 Hz), thermal noise (from the suspension system and internal modes within the mirrors) in the intermediate regime (100–300 Hz), and photon shot noise thereafter. Other sources of noise are also noted, specifically gravity gradients (gravitational excitation of masses from the seismic motion of the ground), radiation pressure of photons on the mirrors, stray (scattered) light, and index of refraction fluctuations from residual gas in the vacuum.

Note also that the sensitivity increases as the light power increases. The reason for this derives from the statistics of repeated measurements. The relative lengths of the interferometer arm lengths could be measured, once, by a photon. However, the relative positions are measured repeatedly with every photon from the laser, and the variance of the mean decreases as $\sqrt{N}$, where N is the number of measurements (or photons) involved. The uncertainty in the difference of the interferometer arm lengths is therefore inversely proportional to photon number, and hence the laser's power. In terms of strain sensitivity this would imply

$$h(f) = \frac{1}{2\pi L}\sqrt{\frac{hc\lambda}{P}} \text{ (in units of } 1/\sqrt{\text{Hz}})$$

This assumes the light just travels down the arm and back once. With Fabry–Perot cavities the light is stored, and the typical photon takes many trips back and forth before exiting the system. In order to maximize light power the end mirrors ($R_2 \sim 1$) and

the strain sensitivity is improved to

$$h(f) = \frac{1}{2\pi L'}\sqrt{\frac{hc\lambda}{P}}$$

where $L' = 4L/(1 - R_1)$.

As the frequency of gravity waves increases the detection sensitivity will decrease. If the gravity wave causes the interferometer arm length to increase, then decrease, while the photons are still in the arm cavity, then the phase acquired from the gravity wave will be washed away. This is the reason why interferometer sensitivity decreases as frequency increases, and explains the high-frequency behavior seen in Figure 7. Taking this into account, the strain sensitivity is

$$h(f) = \frac{1}{2\pi L'}\sqrt{\frac{hc\lambda}{P}}\left(1 + \left(\frac{2\pi L' f}{c}\right)^2\right)^{1/2}$$

where $L' = 4L/(1 - R_1)$ and f is the frequency of the gravity wave.

If the gravitational wave is to change the interferometer arm length then the mirrors that define the arm must be free to move. In systems like LIGO wires suspend the mirrors; each mirror is like a pendulum. While allowing the mirrors to move under the influence of the gravity wave is a necessary condition, the pendulum itself is the first component of an elaborate vibration isolation system. Seismic noise will be troublesome for the detector at low frequencies. The spectral density of the seismic noise is about $(10^{-7}/f^2)\mathrm{m}/\sqrt{\mathrm{Hz}}$ for frequencies above 1 Hz. A simple pendulum, by itself, acts as a motion filtering device. Above its resonance frequency the pendulum filters motion with a transfer function like $T(f) \propto (f_0/f)^2$. Detectors such as LIGO will have a pendulum with resonant frequencies of about $f_0 \approx 1$ Hz, thus providing an isolation of 10^4 when looking for signals at $f = 100$ Hz. The various gravity wave detector collaborations have different vibration isolation designs. The mirrors in these interferometers will be suspended in elaborate vibration isolation systems, which may include multiple pendulum and isolation stacks. Seismic noise will be the limiting factor for interferometers seeking to detect gravity waves in the tens of hertz range, as can be seen in the sensitivity curve presented in Figure 7.

Due to the extremely small distance displacements that these systems are trying to detect it should come as no surprise that thermal noise is a problem. This noise enters through a number of components in the system. The two most serious thermal noise sources are the wires suspending the mirrors in the pendulum, and the mirrors themselves. Consider the wires; there are a number of modes that can oscillate (i.e. violin modes). At temperature T each mode will have energy of k_BT, but distributed over a band of frequencies determined by the quality factor (or Q) of the material. Low-loss (or high-Q) materials work best; for the violin modes of the wires there will be much noise at particular frequencies (in the hundreds of hertz). The mirror is a cylindrical object, which will have normal modes of oscillation that can be thermally excited. The first generation of LIGO will have these masses composed of fused silica, which is typical for optical components. The Qs for the internal modes are greater than 2×10^6. A switch may eventually be made to sapphire mirrors, which have better thermal properties. The limitation to the interferometers' sensitivity due to the thermal noise internal to the mirrors can be seen in Figure 7, and will be a worrying noise source for the first-generation LIGO in the frequency band around 100–400 Hz.

The frequency noise of the laser can couple into the system to produce length displacement sensitivity noise in the interferometer. With arm lengths of 4 km, it will be impossible to hold the length of the two arms absolutely equal. The slightly differing arm spans will mean that the light sent back from each of the two Fabry–Perot cavities will have slightly differing phases. As a consequence, great effort is made to stabilize the frequency of the light entering the interferometer. The LIGO laser can be seen in Figure 8. The primary laser is a Lightwave Model 126 nonplanar ring oscillator. High power is generated from this stabilized laser through the use of optical amplifiers. The beam is sent through four optical amplifiers, and then retro-reflected back

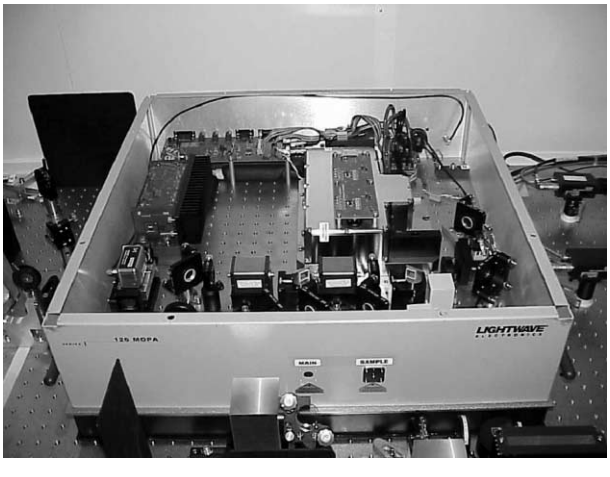

Figure 8 A picture of the Nd:YAG laser and amplifier system that produces 10 W of light for LIGO. Photograph courtesy of Caltech/LIGO.

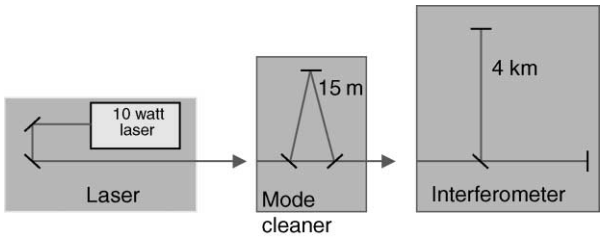

Figure 9 The optical system for the LIGO system. Light moves from the frequency-stabilized laser to a mode cleaner, and then to the interferometer. Presently 8 W of TEM_{00} laser power is delivered to the interferometer.

through the amplifiers again. For LIGO, the laser is locked and held to a specific frequency by use of signals from a reference cavity, a mode cleaner cavity, and the interferometer. For low-frequency stabilization the temperature of the ring oscillator is adjusted. At intermediate frequencies adjustment is made by signals to a piezo-electric transducer within the ring oscillator cavity. At high frequencies the noise is reduced with the use of an electro-optic crystal. The LIGO lasers currently have a frequency noise of $2 \times 10^{-2}\,\mathrm{Hz}/\sqrt{\mathrm{Hz}}$ at frequencies above 1 kHz.

It will prove important to worry about the stability of the laser power for the interferometric detectors. The hope is to be shot noise limited at frequencies above a few hundred hertz. The Nd:YAG power amplifiers used are pumped with an array of laser diodes, so the light power is controlled through feedback to the laser diodes. The LIGO requirements for the fluctuations on the power P are $\Delta P/P < 10^{-8}/\sqrt{\mathrm{Hz}}$. The spatial quality of the light is ensured through the use of a mode-cleaning cavity. LIGO uses a triangular array of mirrors separated by 15 m. LIGO's input optical system can be seen in Figure 9. The current LIGO optical system yields 8 W of 1.06 μm light in the TEM_{00} mode.

Conclusion

The attempt to measure gravitational radiation with laser interferometers could possibly be the most difficult optical experiment of our time. Over a hundred years ago Michelson succeeded in carrying off experiments of amazing difficulty as he measured the speed of light and disproved the existence of the aether. Gravity wave detection is an experiment worthy of Michelson, and there are hundreds of physicists striving to make it a reality.

Great success has already been achieved. The TAMA 300-m interferometer is operational and has achieved a sensitivity $h(f) = 5 \times 10^{-21}/\sqrt{\mathrm{Hz}}$ in the 700 Hz to 1.5 kHz frequency band. The LIGO interferometers are now operating, and scientists are presently de-bugging the system in order to achieve the target sensitivity. The first scientific data taking for LIGO commenced in 2002, and is continuing at the time of writing.

This will be a new telescope to peer into the heavens. With every new means of looking at the sky there has come unexpected discoveries. Physicists do know that there will be signals that they can predict. Binary systems of compact objects (neutron stars or black holes) will produce chirp signals that may be extracted by matched filtering techniques. A supernova will produce a burst that will hopefully rise above the noise. Pulsars, or neutron stars spinning about their axes at rates sometimes exceeding hundreds of revolutions per second, will produce continuous sinusoidal signals that can be seen by integrating for sufficient lengths of time. Gravity waves produced by the Big Bang will produce a background stochastic noise that can possibly be extracted by correlating the outputs from two or more detectors. These are exciting physics results that will come through tremendous experimental effort.

Introduction

Phase-measurement interferometry is a way to measure information encoded in interference patterns generated by an interferometer. Fringe patterns (fringes) created by interfering beams of light are analyzed to extract quantitative information about an object or phenomenon. These fringes are localized somewhere in space and require a certain degree of spatial and temporal coherence of the source to be visible. Before these techniques were developed in the late 1970s and early 1980s, fringe analysis was done either by estimating fringe deviation and irregularity by eye or by manually digitizing the centers of interference fringes using a graphics tablet. Digital cameras and desktop computers have made it possible to easily obtain quantitative information from fringe patterns. The techniques described in this article are independent of the type of interferometer used.

Interferometric techniques using fringe analysis can measure features as small as a micron wide or as large as a few meters. Measurable height ranges vary from a few nanometers up to 10s of mm, depending upon the interferometric technique employed. Measurement repeatability is very consistent, and typically repeatability of 1/100 rms of a fringe is easily obtainable while 1/1000 rms is possible. Actual measurement precision depends on what is being measured and how the technique is implemented, while accuracy depends upon comparison to a sanctified standard.

There are many different types of applications for fringe analysis. For example, optical surface quality can be determined using a Twyman–Green or Fizeau interferometer. In addition, wavefront quality measurements of a source or an optical system can be made in transmission, and the index of refraction and homogeneity of optical materials can be mapped out. Many nonoptical surfaces can also be measured. Typically, surface topography information at some specific spatial frequency scale is extracted. These measurements are limited by the resolution of the optical system and the field of view of the imaging system. Lateral and vertical dimensions can also be measured. Applications of nonoptical surfaces include disk and wafer flatness, roughness measurement, distance and range sensing. Phase measurement techniques used in holographic interferometry, TV holography, speckle interferometry, moiré, grating interferometry, and fringe projection are used for nondestructive testing to measure surface structure as well as displacements due to stress and vibration. This article outlines the basics of phase measurement interferometry (PMI) techniques as well as the types of algorithms used. The bibliography lists a number of references for further reading.

Background

Basic Parts of a Phase-Measuring Interferometer

A phase-measuring interferometer consists of a light source, an illumination system (providing uniform illumination across the test surface), a beamsplitter (usually a cube or pellicle so both beams have the same optical path), a reference surface (needs to be good because these techniques measure the difference between the reference and test surface), a sample

fixture, an imaging system (images a plane in space where the surface is located onto the camera), a camera (usually a monochrome CCD), an image digitizer/frame grabber, a computer system, software (to control the measurement process and calculate the surface map), and often a spatial or temporal phase shifter to generate multiple interferograms.

Steps of the Measurement Process

To generate a phase map, a sample is placed on a sample fixture and aligned, illumination levels are adjusted, the sample image is focused onto the camera, the fringes are adjusted for maximum contrast, the phase shifter or fringe spacing is adjusted or calibrated as necessary, a number of images is obtained and stored with the appropriate phase differences, the optical path difference (OPD) is calculated as the modulo 2π phase and then is unwrapped at each pixel to determine the phase map.

To make consistent measurements, some interferometers need to be on vibration isolation systems and away from heavy airflows or possible acoustical coupling. It helps to cover any air paths that are longer than a few millimeters. Consideration needs to be made for consistency of temperature and humidity.

The human operating the interferometer is also a factor in the measurement. Does this person always follow the same procedure? Are the measurements sampled consistently? Are the test surfaces clean? Is the sample aligned the same and correctly? Many different factors can affect a measurement. To obtain repeatable measurements it is important to have a consistent procedure and regularly verify measurement consistency.

Common Interferometer Types

One of the most common interferometers used in optical testing is the Twyman–Green interferometer (Figure 1). Typically, a computer controls a mirror pushed by a piezo-electric transducer (PZT). The test surface is imaged onto the camera and the computer has a frame grabber that takes frames of fringe data.

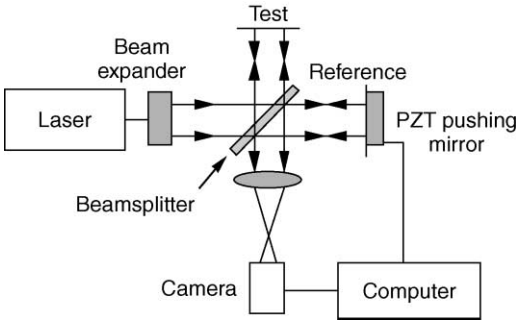

Figure 1 Twyman–Green interferometer.

The most common commercially available interferometer for optical testing is the Fizeau interferometer (Figure 2). This versatile instrument is very insensitive to vibrations due to the large common path for both interfering wavefronts. The reference surface (facing the test object) is moved by a PZT to provide the phase shift.

Interference microscopes (*see* **Microscopy:** Interference Microscopy. **Interferometry:** White Light Interferometry) are used for looking at surface roughness and small structures (see Figure 3). These instruments can employ Michelson, Mirau, and Linnik interference objectives with a laser or white light source, or Fizeau-type interference objectives that typically use a laser source because of the unequal paths in the arms of the interferometer. The phase shift is accomplished by moving the sample, the reference surface, or parts of the objective relative to the sample. Figure 3 shows a schematic of a Mirau-type interferometric microscope for phase measurement.

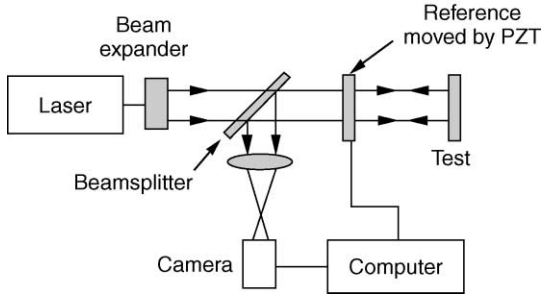

Figure 2 Fizeau interferometer.

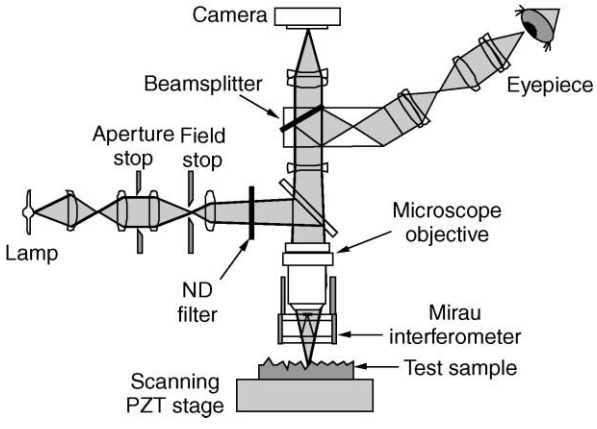

Figure 3 Mirau interference microscope.

Determination of Phase

The Interference Equation

Interference fringes from a coherent source (e.g., a laser) are theoretically sinusoidal (Figure 4a), while fringes from an incoherent source (e.g., white light) are localized in a wavepacket at a point in space (Figure 4b) where the optical paths of the arms of the interferometer are equal and marked on Figure 4 as scanner positions $z = 0$ (*see* **Interferometry:** White Light Interferometry). For generality, this analysis considers the determination of phase within the wave packet for fringes localized in space.

Interference fringes at any point in the wavepacket can be written in the following form:

$$I(x, y) = I_0\{1 + \gamma(x, y, z)\cos[\phi(x, y)]\} \qquad [1]$$

where I_0 is the dc irradiance, γ is the fringe visibility (or contrast), $2I_0\gamma$ is the modulation (irradiance amplitude or the ac part of the signal), and ϕ is the phase of the wavefront as shown in Figure 5. For simplicity, this drawing assumes that the interference fringe amplitude is constant.

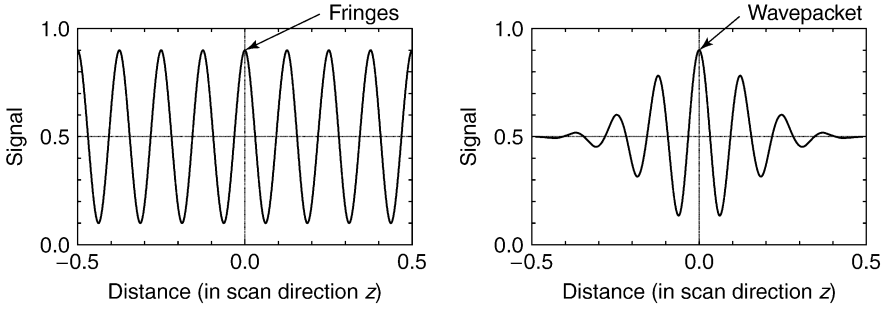
Fringe visibility can be determined by calculating

$$\gamma = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \qquad [2]$$

where $I_{\max}$ is the maximum value of the irradiance for all phase values and $I_{\min}$ is the minimum value. The fringe visibility has a real value between 0 and 1 and varies with the position along the wavepacket. The fringe visibility, as defined here, is the real part of the complex degree of coherence.

Types of Phase Measurement Techniques

Phase can be determined from either a number of interference fringe patterns or from a single interferogram with appropriate fringe spacing. Temporal techniques require an applied phase shift between the test and reference beams as a function of time while multiple frames of interference fringe data are obtained. Spatial techniques can obtain data from a single interferogram that requires a carrier pattern of almost straight fringes to either compare phases of adjacent pixels or to separate orders while performing operations in the Fourier domain. Spatial techniques may also simultaneously record multiple interferograms with appropriate relative phase shift differences separated spatially in space. Multiple frame techniques require more data than single frame techniques. Temporal techniques require that the interference fringes be stable over the time period it takes to acquire the number of images. While single-frame spatial techniques require less data and can be done with a single image, they generally have a reduced amount of resolution and less precision than temporal techniques.



There are literally hundreds of algorithms and techniques for extracting phase data from interference fringe data. The references listed in the Further Reading offer more details of these techniques.

Temporal Phase Measurement

Temporal techniques use data taken as the relative phase between the test and reference beams is modulated (shifted). The phase (or OPD) is calculated at each measured point in the interferogram. As the phase shifter is moved, the phase at a single point in the interferogram changes. The effect looks like the fringes are moving across the interferogram, and because of these techniques are sometimes called fringe scanning or fringe shifting techniques. However, the fringes are not really moving; rather the irradiance at a single detector point is changing (hopefully sinusoidally) in time (see Figure 6). A 180° or π phase causes a bright fringe to become a dark fringe.

Phase Modulation Techniques

There are many ways to introduce a phase modulation (or shift). These include moving a mirror or the

(a) Coherent source (b) Incoherent source

Figure 4 Interference fringes for coherent and incoherent sources as observed at point $x, y, z = 0$ corresponds to equal optical path lengths of the reference and object beams.

sample, tilting a glass plate, moving a diffraction grating, rotating a polarizer, analyzer, or half-wave plate, using a two-frequency (Zeeman) laser source, modulating the source wavelength, and switching an acousto-optic Bragg cell, or magneto-optic/electro-optic cell. While any of these techniques can be used for coherent sources, special considerations need to be made for temporally incoherent sources (*see* **Interferometry:** White Light Interferometry). Figure 7 shows how moving a mirror introduces a relative phase shift between object and reference beams in a Twyman–Green interferometer.

Extracting Phase Information

Including the phase shift, the interference equation is written as

$$I(x, y) = I_0(x, y)\{1 + \gamma_0(x, y)\cos[\phi(x, y) + \alpha(t)]\} \quad [3]$$

where $I(x, y)$ is the irradiance at a single detector point, $I_0(x, y)$ is the average (dc) irradiance, $\gamma_0(x, y)$ is the fringe visibility before detection, $\phi(x, y)$ is the phase of the wavefront being measured, and $\alpha(t)$ is the phase shift as a function of time.

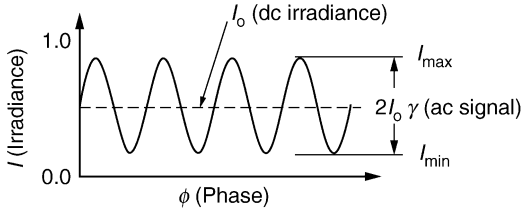


Figure 5 Variable definitions for interference fringes.

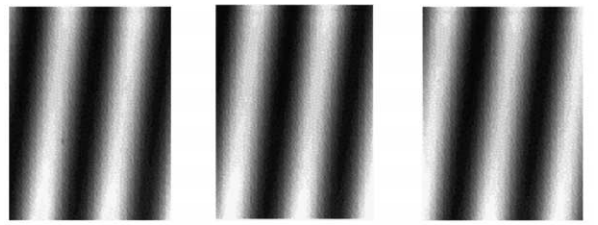

Figure 6 Interference fringe patterns corresponding to different relative phase shifts between test and reference beams.

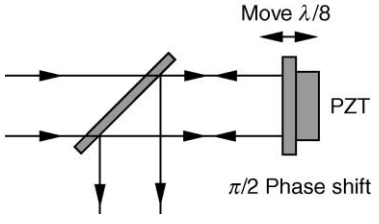

Figure 7 Moving a mirror to shift relative phase by λ/4.

Since the detector has to integrate for some finite time, the detected irradiance at a single point becomes an integral over the integration time Δ (Figure 8) where the average phase shift for the *i*th frame of data is α_i:

$$I_i(x, y) = \frac{1}{\Delta}\int_{\alpha_i-(\Delta/2)}^{\alpha_i+(\Delta/2)} I_0(x, y)\{1 + \gamma_0(x, y) \times \cos[\phi(x, y) + \alpha(t)]\}\mathrm{d}\alpha(t) \quad [4]$$

After integrating over $\alpha(t)$, the irradiance of the detected signal becomes

$$I_i(x, y) = I_0(x, y)\left\{1 + \gamma_0(x, y)\mathrm{sinc}\left(\frac{\Delta}{2}\right) \times \cos[\phi(x, y) + \alpha_i]\right\} \quad [5]$$

where $\mathrm{sinc}(\Delta/2) = \sin(\Delta/2)/(\Delta/2)$, which reduces the detected visibility.

Ramping Versus Stepping

There are two different ways of shifting the phase; either the phase shift can be changed in a constant and linear fashion (ramping) (see Figure 8) or it can be stepped in increments. Ramping provides a continuous smooth motion without any jerking motion. This option may be preferred if the motion does not wash out the interference fringes. However, ramping requires good synchronization of the camera/digitizer and the modulator to get the correct OPD (or phase) changes between data frames. Ramping allows faster data taking but requires electronics that are more sophisticated. In addition, it takes a finite time for a mass to move linearly. When ramping, the first frame or two of data usually needs to be discarded because the shift is not correct until the movement is linear.

The major difference between ramping and stepping the phase shift is a reduction in the modulation of the interference fringes after detection (the $\mathrm{sinc}(\Delta/2)$ term in eqn [5]). When the phase shift is stepped ($\Delta = 0$), the sinc term has a value of one. When the phase shift is ramped ($\Delta = \alpha$) for a phase

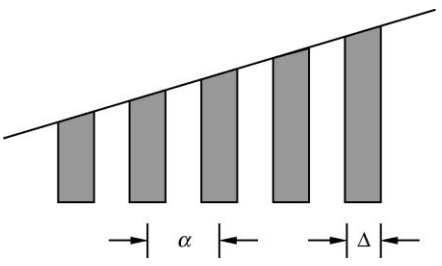

Figure 8 Change in OPD integrating over a Δ phase shift with sample separation α.

shift of $\alpha = 90° = \pi/2$, this term has a value of 0.9. Therefore, ramping slightly reduces the detected fringe visibility.

Signal Modulation

Phase measurement techniques assume that the irradiance of the interference fringes at the camera covers as much of the detector's dynamic range as possible and that the phase of the interference fringe pattern is modulating at each individual pixel as the phase between beams is modulated. If the irradiance at a single detector point does not modulate as the relative phase between beams is shifted, the height of the surface cannot be calculated. Besides the obvious reductions in irradiance modulation due to the detector sampling and pixel size or a bad detector element, scattered light within the interferometer, and defects or dirt on the test object, can also reduce signal modulation. Phase measurement techniques are designed to take into account the modulation of the signal at each pixel. If the signal does not modulate enough at a given pixel, then the data at that pixel are considered unusable, flagged as 'bad' and are often left blank. Phase values for these points may be interpolated from surrounding pixels if there are sufficient data.

Three-Frame Technique

The simplest method to determine phase uses three frames of data. With three unknowns, three sets of recorded fringe data are needed to reconstruct a wavefront providing a phase map. Using phase shifts of $\alpha_i = \pi/4$, $3\pi/4$, and $5\pi/4$, the three fringe measurements at a single point in the interferogram may be expressed as

$$I_1 = I_0\left[1 + \gamma\cos\left(\phi + \frac{\pi}{2}\right)\right] = I_0\left[1 + \frac{\sqrt{2}}{2}\gamma(\cos\phi - \sin\phi)\right] \quad [6]$$

$$I_2 = I_0\left[1 + \gamma\cos\left(\phi + \frac{3\pi}{2}\right)\right] = I_0\left[1 + \frac{\sqrt{2}}{2}\gamma(-\cos\phi - \sin\phi)\right] \quad [7]$$

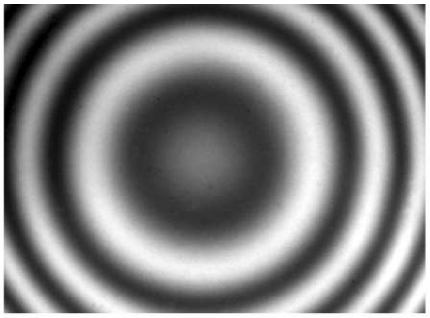
$$I_3 = I_0\left[1 + \gamma\cos\left(\phi + \frac{5\pi}{2}\right)\right] = I_0\left[1 + \frac{\sqrt{2}}{2}\gamma(-\cos\phi + \sin\phi)\right] \quad [8]$$

Note that (x, y) dependencies are still implied. The choice of the specific phase shift values is to make the math simpler. The phase at each detector point is

$$\phi = \tan^{-1}\left(\frac{I_3 - I_2}{I_1 - I_2}\right) \quad [9]$$

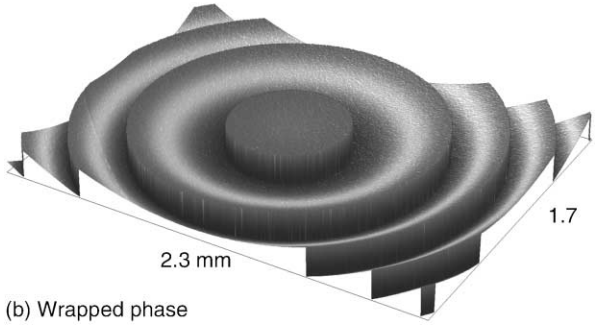
In most fringe analysis techniques, we are basically trying to solve for terms such that we end up with the tangent function of the phase. The numerator and denominator shown above are respectively proportional to the sine and cosine of the phase. Note that the dc irradiance and fringe visibility appear in both the numerator and denominator. This means that variations in fringe visibility and average irradiance from pixel to pixel do not affect the results. As long as the fringe visibility and average irradiance at a single pixel is constant from frame to frame, the results will be good. If the different phase shifts are multiplexed onto multiple cameras, the results will be dependent upon the gain of corresponding pixels.

Bad data points with low signal modulation are determined by calculating the fringe visibility at each data point using:



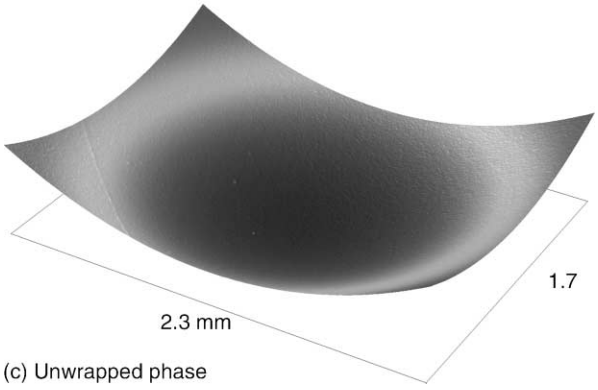
$$\gamma = \frac{\sqrt{(I_3 - I_2)^2 + (I_1 - I_2)^2}}{\sqrt{2}I_0} \quad [10]$$

It is simpler to calculate the ac signal modulation $(2I_0\gamma)$ and then set the threshold on the modulation to a typical value of about 5–10% of the dynamic range. If the modulation is less than this value at any given data point, the data point is flagged as bad. Bad points are usually caused by noisy pixels and can be due to scratches, pits, dust and scattered light.



Although three frames of data are enough to determine the phase, this and other 3-frame algorithms are very sensitive to systematic errors due to nonsinusoidal fringes or nonlinear detection, phase shifter miscalibration, vibrations and noise. In general, the larger the number of frames of data used to determine the phase, the smaller the systematic errors.

Phase Unwrapping



The removal of phase ambiguities is generally called phase unwrapping, and is sometimes known as integrating the phase. The phase ambiguities owing to the modulo 2π arctangent calculation can simply be removed by comparing the phase difference between adjacent pixels. When the phase difference between adjacent pixels is greater than π, a multiple of 2π is added or subtracted to make the difference less than π. For the reliable removal of

(a) Fringes for concave surface

(b) Wrapped phase

(c) Unwrapped phase

Figure 9 Fringes, wrapped, and unwrapped phase maps.

discontinuities, the phase must not change by more than π ($\lambda/2$ in optical path (OPD)) between adjacent pixels. Figure 9 shows an example of wrapped and unwrapped phase values.

Given a trouble-free wrapped phase map, it is enough to search row by row (or column by column) for phase differences of more than π between neighboring pixels. However, fringe patterns usually are not perfect and are affected by systematic errors. Some of the most frequently occurring error sources are noise, discontinuities in the phase map, violation of the sampling theorem and invalid data points (e.g., due to holes in the object or low modulation regions). Some phase maps are not easily unwrapped. In these cases different techniques like wave packet peak sensing in white light interferometry are used.

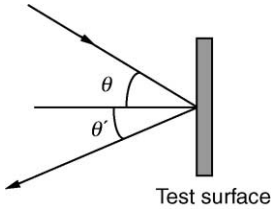


Figure 10 Angles of illumination and viewing.

From Wavefront to Surface

Once the phase of the wavefront is known, surface shape can be determined from the phase map. Surface height H of the test surface relative to the reference surface at a location (x, y) is given by

$$H(x, y) = \frac{\phi(x, y)\lambda}{2\pi(\cos\theta + \cos\theta')} \qquad [11]$$

where λ is the wavelength of illumination, and θ and θ' – the angles of illumination and viewing with respect to the surface normal – are shown in Figure 10. For interferometers (e.g., Twyman–Green or Fizeau) where the illumination and viewing angles are normal to the surface ($\theta = \theta' = 0$), the surface height is simply:

$$H(x, y) = \frac{\lambda}{4\pi}\phi(x, y) \qquad [12]$$

Since the wavefront measured represents the relative difference between the interfering reference and test wavefronts, this phase map only directly corresponds to the surface under test when the reference wavefront is perfectly flat. In practice, the shape of the reference surface needs to be accounted for by measuring it using a known test surface and subtracting this reference measurement from subsequent measurements of the test surface.

Phase Change on Reflection

Phase shifting interferometry measures the phase of reflected light to determine the shape of objects. The reflected wavefront will represent the object surface (within a scaling factor) if the object is made of a single material. If the object is comprised of multiple materials that exhibit different phase changes on reflection, the measured wavefront needs to be corrected for these phase differences (*see* **Interferometry:** White Light Interferometry).

Overview of Phase Measurement Algorithms and Techniques

There are literally hundreds of published algorithms and techniques. The optimal algorithm depends on

the application. Most users prefer fast algorithms using a minimal amount of data that are as accurate and repeatable as possible, immune to noise, adaptable, and easy to implement. In practice, there are trade-offs that must be considered when choosing a specific algorithm or technique. This section provides an overview of the types of algorithms to aid the reader in sifting through published algorithms.

Synchronous Detection

One of the first techniques for temporal phase measurement utilized methods of communication theory to perform synchronous detection. To synchronously detect the phase of a noisy sinusoidal signal, the signal is first correlated (or multiplied) with sinusoidal and cosinusoidal reference signals (signals in quadrature) of the same frequency and then averaged over many periods of oscillation. This method of synchronous detection as applied to phase measurement can be extracted from the least squares estimation result when the phase shifts are chosen such that N measurements are equally spaced over one modulation period. With phase shifts α_i such that:

$$\alpha_i = \frac{2\pi}{N} i, \qquad \text{with } i = 1, \ldots, N \qquad [13]$$

the phase can be calculated from

$$\phi(x, y) = \tan^{-1}\left[\frac{\sum I_i(x, y)\sin \alpha_i}{\sum I_i(x, y)\cos \alpha_i}\right] \qquad [14]$$

Note that N can be any number of frames (or samples). The more frames of data, the smaller the systematic errors. This technique does not take large amounts of memory for a large number of frames, because only the running sums of the fringes multiplied by the sine and cosine of the phase shift need to be remembered. The 4-frame algorithm from Table 1 is an example of a direct adaptation of synchronous detection where simple values of 1, -1 or 0 for every $\pi/2$ phase shift can be assigned to the sine and cosine functions.

Algorithm Design

In the last ten years, a lot of work has been done to generalize the derivation of fringe analysis algorithms. This work has enabled the design of algorithms for specific applications, which are insensitive to specific systematic error sources.

Most algorithms use polynomials for the numerator and denominator. Given fringe data:

$$I_i = I_0[1 + \gamma \cos(\phi + \alpha_i)] \qquad [15]$$

Table 1 Sampling function weights for a few selected algorithms

N frames	*Phase shift*	*Coefficients*
3	$\frac{\pi}{2}$	$\frac{1, -1, 0}{0, 1, -1}$
4	$\frac{\pi}{2}$	$\frac{0, -1, 0, 1}{1, 0, -1, 0}$
5	$\frac{\pi}{2}$	$\frac{0, -2, 0, 2, 0}{1, 0, -2, 0, 1}$
7	$\frac{\pi}{3}$	$\frac{\sqrt{3}[0, 1, 1, 0, -1, -1, 0]}{-1, -1, 1, 2, 1, -1, -1}$
8	$\frac{\pi}{2}$	$\frac{1, 5, -11, -15, 15, 11, -5, -1}{1, -5, -11, 15, 15, -11, -5, 1}$
12	$\frac{\pi}{3}$	$\frac{\sqrt{3}[0, -3, -3, 3, 9, 6, -6, -9, -3, 3, 3, 0]}{2, 1, -7, -11, -1, 16, 16, -1, -11, -7, 1, 2}$

the phase is calculated using

$$\phi = \tan^{-1}\left[\frac{\sum_i n_i I_i}{\sum_i d_i I_i}\right] \qquad [16]$$

The numerator and denominator of the arctangent argument are both polynomials. The numerator is a sum proportional to the sine (imaginary part) and the denominator is a sum proportional to the cosine (real part),

$$\text{num} = 2kI_0\gamma \sin \alpha_i = \sum_i n_i I_i \qquad [17]$$

$$\text{den} = 2kI_0\gamma \cos \alpha_i = \sum_i d_i I_i \qquad [18]$$

where the constant k depends on the values of coefficients. From this the fringe visibility is given by

$$\gamma = \frac{\sqrt{(\text{num})^2 + (\text{den})^2}}{2kI_0} \qquad [19]$$

The coefficient vectors for the numerator and denominator are window functions. For an algorithm such as the 4-frame technique, the weights of all samples are equal [1, 1, 1, 1]. This makes the coefficients all equal. For other algorithms, such as the 5-frame technique, the weights are larger on the middle frames than on the outer frames. The weights for the 5-frame technique are [1, 2, 2, 2, 1]. A property of the coefficient vectors is that the sum of the coefficients for each, the numerator and denominator, should be zero. Examples of coefficient vectors for a few selected algorithms are given in Table 1.

Heterodyne Interferometry

Historically, heterodyne techniques were developed and used before temporal phase-shifting techniques. These techniques generally determine the phase electronically at a single point by counting fringes and fractions of fringes. Areas are analyzed by scanning a detector.

Phase shifts are usually obtained using two slightly different frequencies in the reference and test beams. The beat frequency produced by the interference between the reference and test beams is compared to a reference sinusoidal signal, which may be produced either optically or electronically. The time delay (or distance traveled) between the crossing of the zero phase points of the test and reference sinusoidal signals is a measure of the phase. Every time the test signal passes through another zero in the same direction as the test surface is moved, another fringe can be counted. This is how fringe orders are counted. If the beam is interrupted as the detector is scanned across the interferogram, the fringe count is corrupted and the measurement needs to be started again. Frequency multiplication (harmonics) can also be used to determine fractions of fringes. Today, heterodyne techniques are used mainly in distance measuring interferometers. The precision and accuracy of distance measuring interferometers is at least on the order of 1 part in 10^6.

Fourier-Transform Technique

The Fourier-transform technique is a way to extract phase from a single interferogram. It is used a lot in nondestructive testing and stellar interferometry where it is difficult to get more than a single interferogram. The basic technique is shown schematically in Figure 11. The recorded interferogram distribution is Fourier transformed, and one order (usually the + or − first order) is either isolated and shifted to zero frequency or filtered out using a rectangular window. After an inverse Fourier transform, the result is the phase.

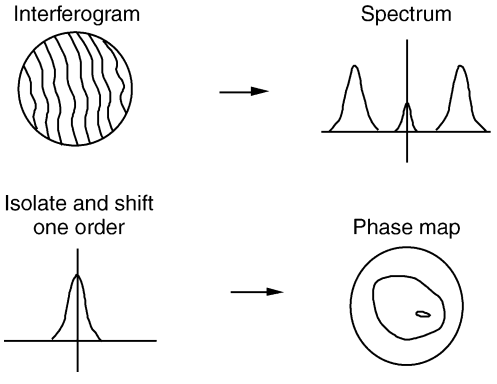

Figure 11 Fourier transform technique.

To illustrate this technique mathematically, the interference equation is rewritten as

$$I(x,y) = I_0(x,y) + c(x,y)\exp(\mathrm{i}2\pi f_0 x) + c^*(x,y)\exp(-\mathrm{i}2\pi f_0 x) \quad [20]$$

where $c(x,y) = I_0(x,y)\gamma(x,y)\exp[\mathrm{i}\phi(x,y)]$ and the $*$ indicates a complex conjugate. The term $c(x,y)$ contains the phase information we wish to extract. After performing a one-dimensional Fourier transform:

$$I(\xi,y) = I_0(\xi,y) + c(\xi - f_0, y) + c^*(\xi - f_0, y) \quad [21]$$

where ξ is the spatial frequency in the x direction, and italics indicate Fourier transforms. The next step is to filter out and isolate the second term, and then inverse Fourier transform to yield $c(x,y)$. The wavefront modulo 2π is then given by

$$\phi(x,y) = \tan^{-1}\left\{\frac{\mathrm{Im}[c(x,y)]}{\mathrm{Re}[c(x,y)]}\right\} \quad [22]$$

where Re and Im refer to the real and imaginary part of the function.

This technique has limitations. If the fringes are nonsinusoidal, there will not be a simple distribution in the frequency space; there will be many orders. Another problem is overlapping orders. There needs to be a carrier frequency present that ensures that the orders are separated in frequency space. This carrier frequency is produced by adding tilt fringes until the orders are separated. This means that the aberration (fringe deviation) has to be less than the fringe spacing. Another problem is aliasing. If the interferogram is not sampled sufficiently, there will be aliasing and it will not be possible to separate the orders in frequency space. Finally, large variations in average fringe irradiance and fringe visibility across the interferogram can also cause problems.

Spatial Carrier-Frequency Technique

This is essentially the equivalent of the Fourier transform technique but is performed in the spatial domain. It is also used when there is only one interferogram available and its major applications include nondestructive testing and measurement of large optics.

These techniques relate closely to the temporal phase-measurement methods; however, instead of using a number of interferograms they can obtain all the information from a single interferogram. As an example, let's assume that the fringes are vertical and parallel to the columns on the detector array.

The carrier frequency (i.e., the number of tilt fringes) is adjusted so that there is an α phase change from the center of one pixel to the next. As long as there is not much aberration (deviation), the phase change from pixel to pixel across the detector array will be approximately constant.

When the fringes are set up this way, the phase can be calculated using adjacent pixels (see Figure 12). If one fringe takes up 4 pixels, the phase shift α between pixels will be 90°. An algorithm such as the three-frame, four-frame, or five-algorithm can be used with adjacent pixels as the input. Therefore, 3, 4, or 5 pixels in a row will yield a single-phase point. Then, the analysis window is shifted sideways one pixel and phase is calculated at the next point. This technique assumes that the dc irradiance and fringe visibility do not change over the few pixels used to calculate each phase value.

Spatial Multichannel Phase-Shift Techniques

These techniques detect all phase maps simultaneously and multiplex the phase shift using static optical elements. This can be done by using either separate cameras as illustrated below or by using different detector areas to record each of the interferograms used to calculate the phase. The phase is usually calculated using the same techniques that are used for the temporal phase techniques.

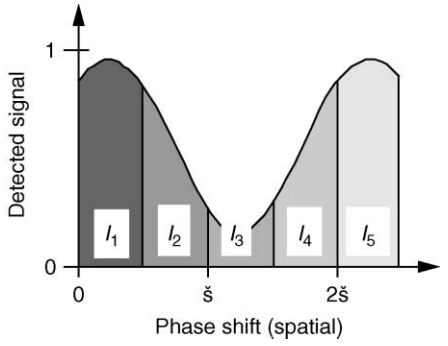

Figure 12 Spatial phase shifting. Different relative phase shifts are on adjacent detector elements.

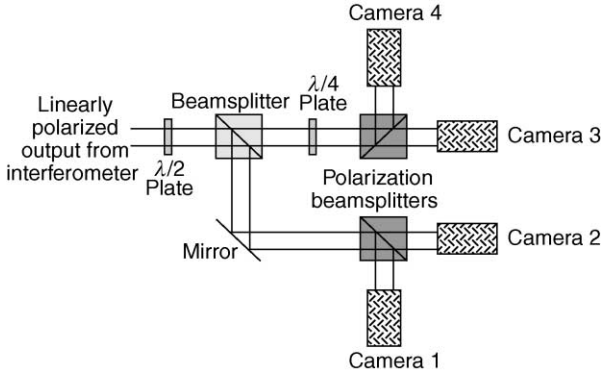

Figure 13 Spatial phase shifting using four cameras.

As an example, a four-channel interferometer can be made using the setup shown in Figure 13 to record four interferograms with 90° phase shifts between them. Camera 1 will yield fringes shifted 180° with respect to camera 2, and cameras 3 and 4 will have phase shifts of 90° and 270°. The optical system may also utilize a holographic optical element to split the beam to multiplex the four phase shifts on four quadrants of a single camera.

Signal Demodulation Techniques

The task of determining phase can be broadened by looking toward the field of signal processing. For communication via radio, radar, and optical fibers electrical engineers have developed a number of ways of compressing and encoding a signal as well as decompressing a signal and decoding it. An interference fringe pattern looks a lot like an am radio signal. Thus, it can be demodulated in similar ways. In recent years many new algorithms have been developed by drawing on techniques from communication theory and applying them to interferogram processing. Many of these use different types of transforms such as Hilbert transforms for straight fringes or circular transforms for closed fringes.

Extended Range Phase Measurement Techniques

A major limitation of phase measurement techniques is that they cannot determine surface discontinuities larger than $\lambda/4$ ($\lambda/2$ in optical path (OPD)) between adjacent pixels. One obvious solution is to use longer wavelength sources in the infrared where optically rough surfaces look smooth and their shape can be measured. An alternative is two-wavelength interferometry where two measurements at different wavelengths are taken and the measurable height limitation is now determined by the equivalent wavelength:

$$\lambda_{eq} = \frac{\lambda_1 \lambda_2}{|\lambda_1 - \lambda_2|} \qquad [23]$$

Another method that allows for measurement of smooth surfaces with large height discontinuities that is limited only by the working distance of the objective combines a white light and a phase measurement interferometric technique in one long scan. The position of the wave packet resolves 2π ambiguities that result from the arctangent function (see Phase unwrapping section above). The phase of the fringe close to the wave packet maximum is determined without ambiguity. Sometimes it is not the step height discontinuity that is a problem but rather the high slope of the measured surface. If we know that the surface is continuous, then the

unwrapping procedure can take advantage of this a priori information to look for a continuous.

Techniques for Deformation Measurement

Some of the techniques for deformation measurement have already been described earlier (see sections on Single frame techniques and Spatial multichannel phase-shift techniques). However, fringes in any interferometer can be analyzed not only in the x, y planes but also in the x, z, or y, z planes for which the carrier frequency of the fringes is introduced. Analysis of fringes in any plane has the same restrictions.

If the initial static object shape is measured using conventional phase measurement techniques, not only can the motion of each object point be determined but also the deformation of the whole object in time. If the motion of the object is periodic, then the object motion can be 'frozen' by using stroboscopic illumination of the same frequency as the object's motion. Once the motion is frozen, any temporal technique can be used to measure object shape at some phase of its motion. Changing the time offset between stroboscopic illumination and the periodic signal driving the motion, the object can be 'frozen' and thus measured at different phases of its periodic motion.

Systematic Errors

Noise Sensitivity

Measurement noise mostly arises from random fluctuations in the detector readout and electronics. This noise reduces precision and repeatability. Averaging multiple measurements can reduce effects of these random fluctuations.

Phase Shifter Errors

Phase shifter errors can be due to both miscalibration of the system and nonlinearities in the phase shift. It is possible to purchase very linear phase shifters. It is also possible to correct nonlinearities by determining the voltage signal making the phase shifter provide a linear phase shift.

Linear phase shifter errors (miscalibration) of the phase shift have an error signature that is at twice the frequency of the fringes. If there are two fringes across the field of view, the error signature will have four across the field of view. Figure 14 shows the difference between a calibrated and an uncalibrated phase shifter as well as the difference in error for two different phase measurement algorithms. Some algorithms are obviously more sensitive than others to this type of error.

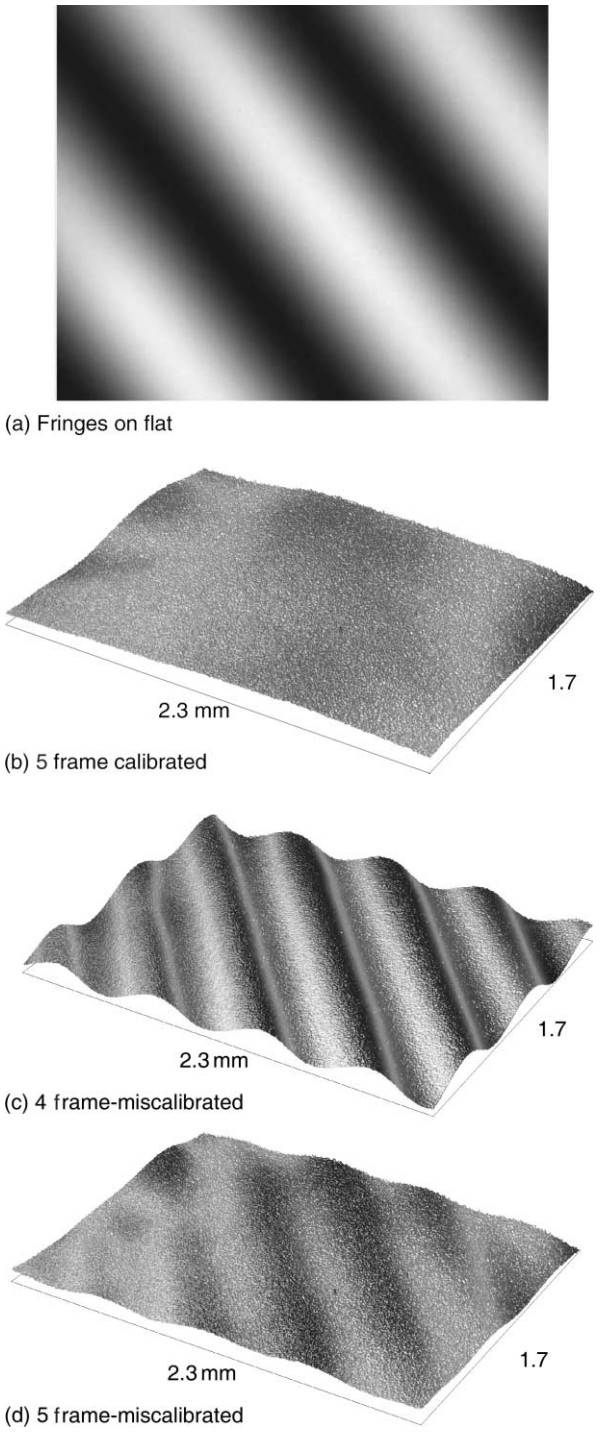

Figure 14 Comparison of phase maps for calibrated and uncalibrated phase shifts using two different phase measurement algorithms.

Other Types of Systematic Errors to Consider

Other types of errors to consider are detector nonlinearities, quantization errors due to analog-to-digital converters, and dissimilar materials (see Phase change upon reflection). For temporal phase measurement techniques errors due to vibration and

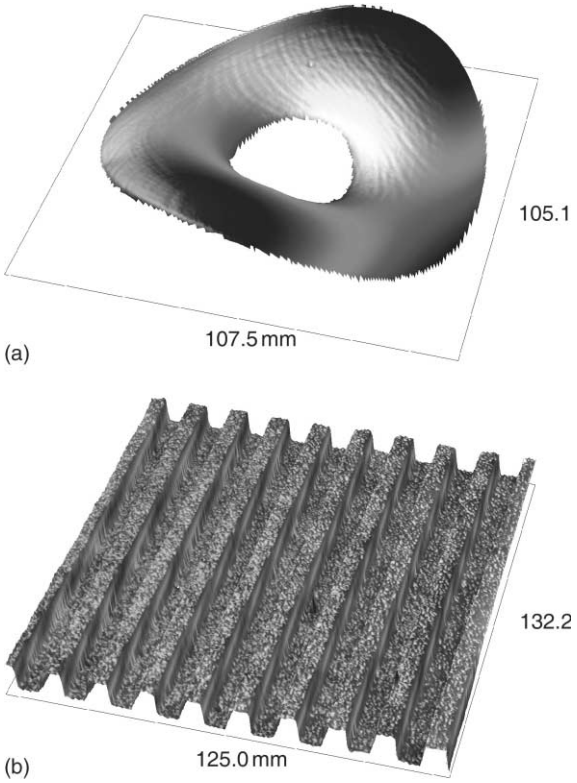

Figure 15 Measurements of (a) hard disc substrate with a vertical range is 2.2 micrometers and (b) binary grating roughness standard.

air turbulence need to be considered as well. Spatial phase measurement techniques are sensitive to miscalibrated tilt (wrong carrier frequency), unequally spaced fringes, and sampling and windowing in Fourier transform techniques.

Choosing an Algorithm or Technique

Each algorithm and type of measurement technique is sensitive to different types of systematic errors. Choosing a proper algorithm or technique for a particular type of measurement depends on the specific conditions of the test itself and reducing the systematic errors for a particular type of measurement. This is the reason that so many algorithms exist. The references in the bibliography will help the reader determine what type of algorithm will work best for a specific application.

Examples of Applications

Phase shifting interferometry can be used for measurements such as hard disk flatness, quality of optical elements, lens curvature, dimensions and quality of air-bearing surfaces of magnetic read/write heads, cantilevers, and semiconductor elements. Figure 15 shows results for measurements of a hard disk substrate and a roughness grating.

Conclusions

Phase measurement interferometry techniques have increased measurement range and precision enabling the production of more complex and more precise components. As work continues on development of interferometric techniques, phase measurement techniques will continue to become more robust and less sensitive to systematic errors. Anticipated advances will enable measurements of objects that were unimaginable 20 or 30 years ago.

Introduction

In 1960 the development of the laser injected new possibility into an old discipline, interferometry (*see* **Interferometry**: Overview). The excellent spatial and temporal coherence (ideally a single point and a single wavelength source) of the laser allowed for the formation of nonlocalized interference fringes. With lasers, researchers could easily generate good contrast fringes practically anywhere where the beams overlapped. These excellent-quality fringes from laser interferometers enabled high-resolution distance and displacement measurements on the order of meters and made possible noncontact surface probing with nanometer and subnanometer resolution. This kind of precision, which was supported by the advent of computers and the advancement of detectors, was previously unimaginable.

However, interference phenomena were used in metrology long before lasers and can be observed without any complicated device or source. On a rainy day we can observe the colorful interference patterns that have formed on a thin layer of gasoline in a puddle. The relationship between colors and the small distance between reflecting surfaces, observed as far back as 1665 by Hook, is still used to approximate layer thicknesses. The colors in interference patterns have been used to determine the spectral components of beams. By the end of the nineteenth century, Michelson and Benoit were using interference phenomena to determine distances, long before the invention of the computer and the laser.

While the application of lasers in interferometry has advanced the science, white light interferometry (WLI), which uses a spatially and temporally incoherent source and creates fringes localized over a few microns in space, has also benefited from technological advancements. The development of solid state detectors, fast computers, electronic signal processing, and precise scanning stages has allowed for incredibly fast analysis of white light interferograms. In fact, WLI is used in many applications from film thickness and surface measurement, through spectroscopy to astronomy.

This chapter focuses on the formation of white light fringes. We first examine the existence of white light fringes in the everyday world. A description of different interferometric setups and their uses follows. The bulk of this article details the formation of white light fringes and examines their different applications with an emphasis on the analysis of object structure. Suggestions for further reading, both within this encyclopedia and from outside sources, can be found at the end of this article. A basic theory of interferometry and coherence is to be found in corresponding articles of this encyclopedia.

White Light Interference in Everyday Life

The effects of interference display spectacular colors when observed in white light, such as the sun. We often see these effects in oil or gasoline spills, in soap bubbles, or between two smooth pieces of glass in contact (separated by a very thin layer of air film) – which are the simplest everyday white light interferometers. The colors we see in these displays are interference colors, and their origin is interference rather than dispersion as in the colors of a rainbow or light reflected from a CD. The picture in Figure 1 is of a gasoline spill under cloudy sky illumination; we see beautiful interference colors that are hard to find in a rainbow: iron-gray, magenta, grayish blue, whitish green, and brownish yellow. Interference colors will differ not only with the thickness of the layer but also with the layer's absorption and dispersion, the relative indices of refraction of the film, the surrounding media, and the illumination. Interference colors can be observed for layers from a fraction of a micron to a few microns thick.

Interferometers for White Light Observation

In a white light interferometer, either the colors or the intensity distribution of the fringes is typically analyzed to retrieve the necessary encoded information, such as the film thickness, birefringence, index of refraction, dispersion, spectral properties, and surface structure. White light interference can be observed only in interferometric designs where the optical paths in both arms of the interferometer are (nearly) equal and the system is (nearly) compensated for dispersion.

Interference in Thin Film

Beams of light of different wavelengths incident on a transparent thin film (such as the ones in the puddle) are partially reflected from the top air/film interface

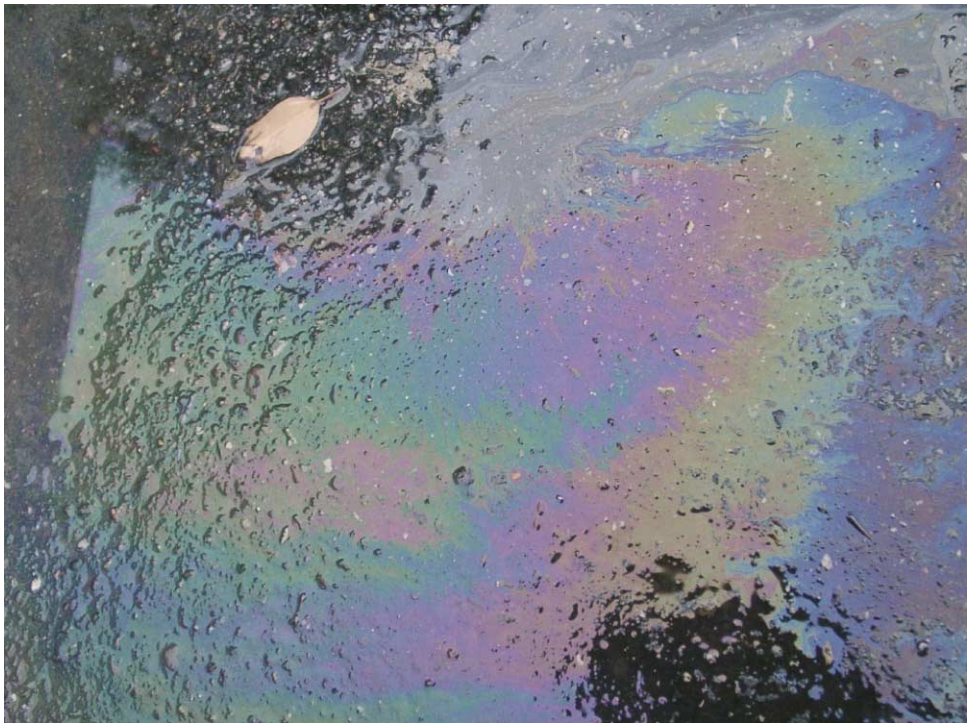

Figure 1 Interference colors in a gasoline spill in a puddle. This picture would closely resemble a picture from an interference microscope, if not for the leaf in the top left corner.

and partially from the bottom film/substrate interface and then beams of the same wavelength interfere with each other. The optical path difference (OPD) traveled by the interfering beams is related to the film thickness, the index of refraction for the given wavelength and the angle of incidence.

Fringes of equal thickness will be observed if the film thickness (distance between interfering wavefronts) varies. These fringes represent points of equal distance between the two surfaces of the film and are formed close to the film (see Figure 2). This situation is typical in any interferometer since rarely are wavefronts perfectly plane and parallel.

For any individual wavelength, λ_i, where the OPD is equal to $m\lambda_i$, and where m is an integer, a bright fringe of the color of the wavelength, λ_i, will be observed due to constructive interference. For white light illumination, the color at a given point will be dominated by the color of the wavelength for which the interference will be constructive. This color can be used to estimate the optical thickness of the film.

An additional factor needs to be taken into account when color is used for estimating optical thickness, namely the phase change on reflection. Different colors will be observed if the ratio of indices of refraction for both film interfaces is <1 (or >1) as opposed to when the ratio of indices is <1 for one interface and >1 for the other.

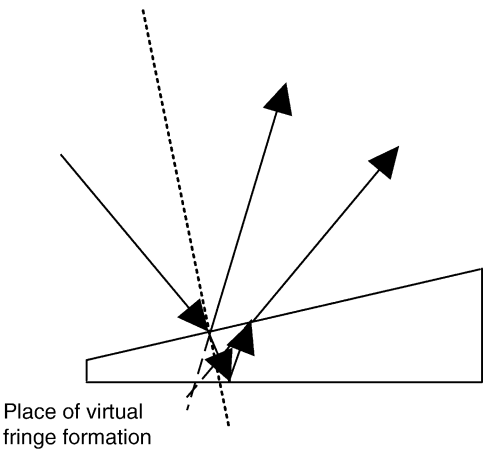

Figure 2 Formation of fringes of equal thickness for film with wedge.

Polarization Microscope

Interference colors that correspond to equal thickness fringes can represent the birefringence of an object; these colors are often observed using a polarization microscope (*see* **Microscopy:** Interference Microscopy). The polarization microscope is a conventional microscope with a set of polarizers with crossed polarization axes, one placed above and the other placed below the tested birefringent object.

Interference colors have been tabulated for many years and for many different purposes. Newton devised his color scale to describe interference fringes for two pieces of glass in contact with each other. Michel-Lévy and Lacroix in 1889, created a color scale to help recognize different rock forming minerals. For more information about colors in white light interference see sections on *White Light Interference* and *Spectral Interference* below.

Michelson Interferometer

A Michelson interferometric setup, shown in Figure 3, is often used to analyze white light interference, but the intensity of the fringes is observed as one mirror is scanned rather than the color of fringes that is usually observed.

Two plane mirrors (equivalent to the top and bottom surfaces of a thin film) return the beams to the beamsplitter, which recombines parts of the returned beams and directs them towards the detector where the interference is observed. Beam S1 travels through the parallel plate three times while beam S2 passes through the plate only once causing the system to be not well compensated (balanced) for dispersion. Thus, for observation of white light interference, an identical plate is placed in the path of beam S2. As one of the plane mirrors moves along the optical axis to change the OPD, the detector collects the irradiance, the intensity. Fringes will be observed if the system is well-compensated for dispersion and for optical path lengths. Any spectral changes or changes in optical path lengths in the interferometer affect the shape or position of the fringes, and the interferometer measures these changes.

Common-path interferometers, like the Mach–Zender or Jamin interferometers, are naturally compensated interferometers and can be used for measurement of dispersion in gases. Other interferometers, such as the Twyman–Green or Fizeau interferometers, make use of their unequal interferometer arms and their nonlocalized fringes from laser sources for testing different optical elements and systems in reflection and transition (*see* **Interferometry:** Phase Measurement Interferometry).

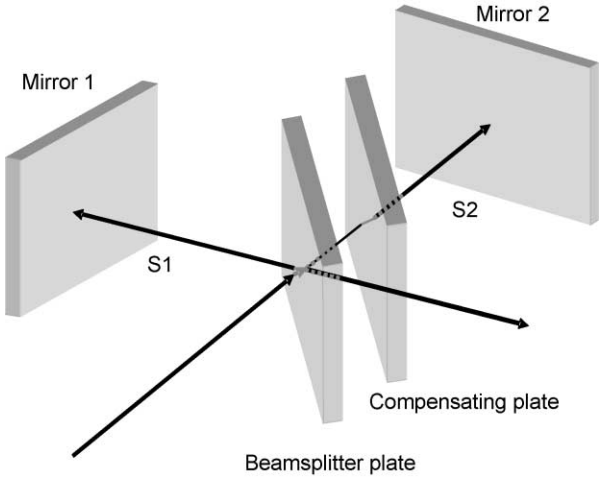

Figure 3 Michelson interferometer.

White Light Interference

A white light source consists of a wide spectrum of wavelengths in visible spectrum, from about 380 up to 750 (violet to red) nanometers. However, the principles of WLI described in this article basically apply when any low coherence source is used. Low coherence refers to a source of not only low temporal but also low spatial coherence; WLI can also be referred to as low coherence interferometry. We will be concerned mainly with temporal effect of the source, the source spectrum.

Since different wavelengths from the source spectrum are mutually incoherent, we will first look at interference between two waves of a selected monochromatic illumination with wave number $k = 2\pi/\lambda$, where λ is the wavelength. The intensity of the interference fringes at point x, y (these coordinates are omitted in all equations), as one of the mirrors is scanned along the optical axis, z can be described as

$$I(k,z) = I_1 + I_2 + 2\sqrt{I_1 I_2}|\gamma(z)|\cos(kz) \qquad [1]$$

or can be written in the form:

$$I(k,z) = I_0\left[1 + \frac{2\sqrt{I_1 I_2}}{I_1 + I_2}|\gamma(z)|\cos(kz)\right] \qquad [2]$$

where I_1 and I_2 are intensities of each of the beams and $I_0 = I_1 + I_2$, $|\gamma(z)|$ is the modulus of the complex mutual coherence function (*see* **Coherence:** Overview) assumed here to equal 1 (perfect coherence for each wavelength). The optical path difference z equals $z_1 - z_2$ where z_1 and z_2 are the optical path lengths that the interfering waves have traveled. The difference in the traveled paths, z, corresponds to the position of the scanning mirror.

White light interference (polychromatic interference) is the overlaying of all the monochromatic fringes created for each wavelength of the source spectrum (Figure 4a). A detector observes the sum of all the fringe intensities.

In mathematical form, this interference can be described as the integral of all the fringes $I(k,z)$ for all

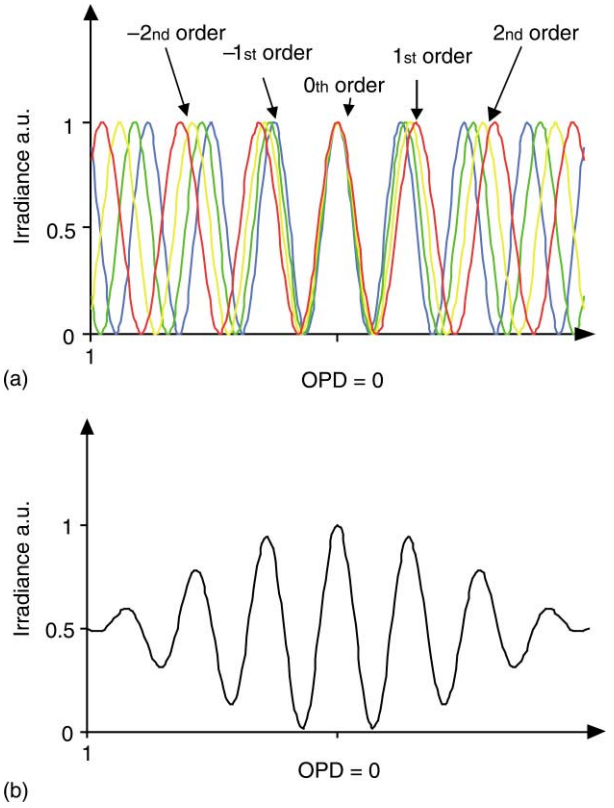

Figure 4 Formation of white light fringes: (a) fringes for individual wavelengths; (b) fringes for white light.

wavenumbers k:

$$I(z) = \int_{k_1}^{k_2} S(k)D(k)I(k,z)\mathrm{d}k \qquad [3]$$

where $S(k)$ is the spectral distribution of the light source, with $S(k) = 0$ outside of k_1 through k_2 range of wave numbers, and $D(k)$ is a spectral response of the detector. We assume that the detector's response $D(k)$ equals 1 over the whole spectrum. Because the spacing of the fringes for each wavelength emitted by the white light source is different, the maxima of fringes will align around only one point for a well-compensated interferometer, as shown in Figure 4a. This alignment around a single point, occurs because in a well-compensated interferometer there is one point for which the OPD is zero for all wavelengths. Away from this point, the observed sum of the intensities quickly falls off, as shown in Figure 4b. The maximum fringe, the fringe that marks the zero OPD, is called the zero-order fringe, and each next fringe of smaller amplitude on either side is called $+1$ and -1, $+2$ and -2 order fringe, and so on.

Because white light fringes are localized and can only be found within microns or tens of microns of the zero OPD, white light interferometers are excellent distance and 3D position sensors. However, this same characteristic makes them more difficult to align than interferometers with nonlocalized fringes.

Envelope of Fringes Due to Source Spectrum

The resultant intensity of interference from a broad spectrum source (see eqn [3]) can be described in general form as

$$I(z) = I_0[1 + V(z)\cos(k_0 z)] \qquad [4]$$

where $I_0 = I_1 + I_2$ is the background intensity, $V(z)$ is the fringe visibility function or coherence envelope, and $k_0 = 2\pi/\lambda_0$ is the central wave number for fringes under the envelope. The $V(z)$ is proportional to the modulus of the Fourier transform of the source spectrum $S(k)$. Generally, if the light source has a Gaussian spectrum $S(k)$, then the envelope of the fringes can be described also as a Gaussian function $V(z)$. If the spectrum of the source is rectangular, then the envelope of the fringes will be a sinc function. The wider that the spectrum of the source is the narrower the width of the envelope will be, as shown in Figure 5. The width of the fringe envelope determines the coherence length of the source (*see* **Coherence:** Overview); for a white light source this width is in the order of 1–2 microns.

Different white light sources, such as tungsten-halogen, incandescent, or arc lamps, have different spectra and thus create different coherence envelopes, as shown in Figure 5. The spectra of semiconductor light sources, such as LEDs and SLDs, are similar in shape to a Gaussian function.

The fact that the coherence envelope is related to the spectrum of the source by its Fourier transform is commonly used in Fourier transform spectroscopy, where the Fourier transform of the detected fringes is calculated to find the spectral components of the beams.

Position of Fringes Under Envelope Due to Reflection of Dielectric

Thus far we have assumed that in WLI the interferometer is compensated for all wavelengths, and thus, for this position the maximum of the fringes aligns with the maximum of the envelope, namely where there is a zero phase shift $\varphi_0 = 0$ between fringe and envelope maxima.

If there is an odd number of reflections from dielectric surfaces in one arm of the interferometer and an even number in the other, the fringes will be shifted by $\varphi_0 = 180°$ under the coherence envelope and the minimum of the fringe will align with the maximum of the coherence envelope. Thus eqn [4]

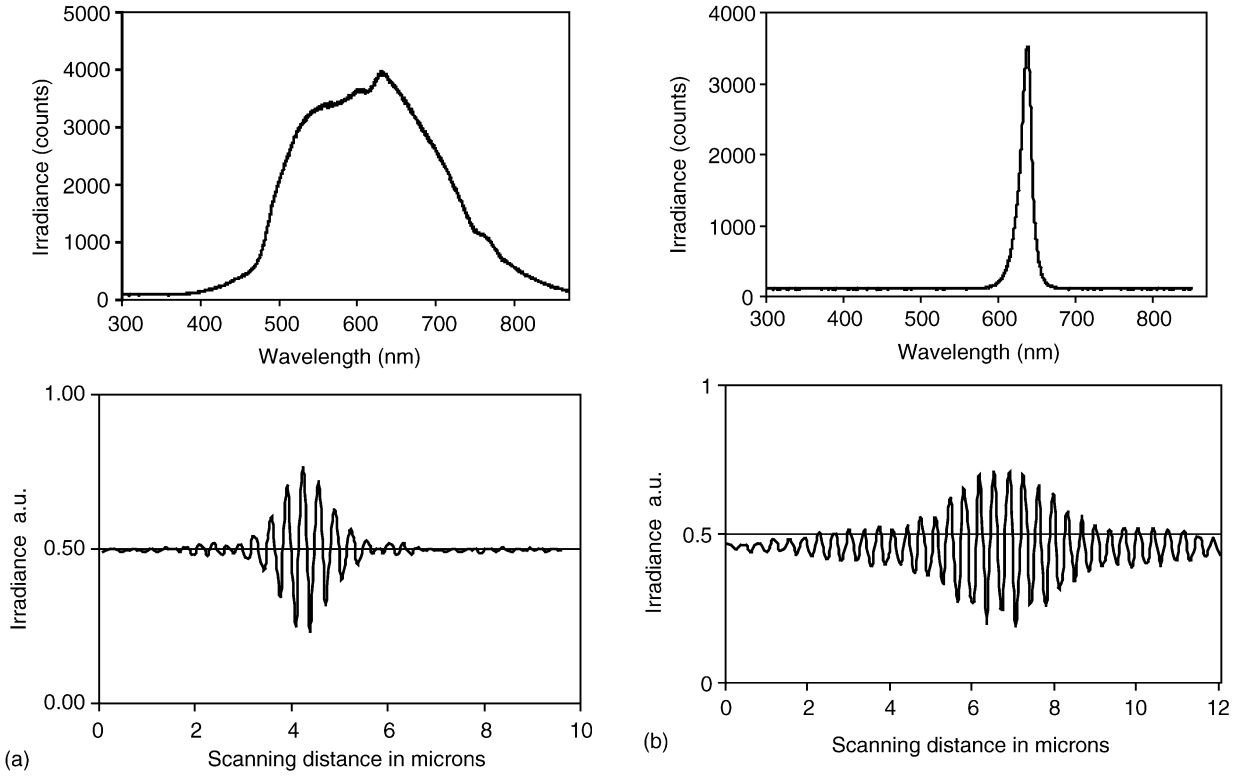

Figure 5 Spectrum and interferogram for (a) tungsten-halogen lamp and for (b) red LED sources.

can be expressed in a more general form:

$$I(z) = I_0[1 + V(z)\cos(k_0 z + \varphi_0)] \qquad [5]$$

Figure 6 shows color fringes for such a case; the dark fringe marks the zero OPD, and this fringe is surrounded by the greenish blue colors of shorter wavelengths. In contrast, the bright fringe at the maximum envelope position or marking the zero OPD would be surrounded by the reddish colors of longer wavelengths.

In a real system the fringes may be shifted with respect to the envelope by any amount of φ_0, and this shift may be due to any number of factors, such as the phase shift on reflection from nondielectric surfaces and dispersion, which we consider next.

Changes in Envelope and Fringes Due to Reflection of Nondielectric Materials

The relative position of the envelope maximum and fringe position will be different if the beam is reflected from different nondielectric materials. This difference exists because the phase change on reflection from a test surface, like metals or heavily doped semiconductors, varies with each wavelength. This variance in fringe and peak coherence position may be predicted and corrected for in surface height calculations. The linear dependence of the phase change on reflection versus wave number shifts the location of the coherence envelope peak position of fringes by different amounts. The constant phase change on reflection and higher-order terms only shift the fringes underneath the coherence envelope. As long as the change on reflection has a small dependence on the second- and higher-order of the wave number, the shape of the coherence envelope is preserved.

Changes in Envelope and Fringes Due to Dispersion

Dispersion in an interferometer that is not balanced, perhaps because a dispersive element was placed in one arm or the compensating plate has an incorrect thickness, will influence fringe formation. The phase delay between interference patterns for individual wavelengths is proportional to the product of the geometrical path and the index of refraction equal to $d \times n(k)$.

The intensity may be described as:

$$I(z) = \int_{k_1}^{k_2} \langle 1 + V(z)\cos\{kz - kd[n(k)]\}\rangle \, \mathrm{d}k \qquad [6]$$

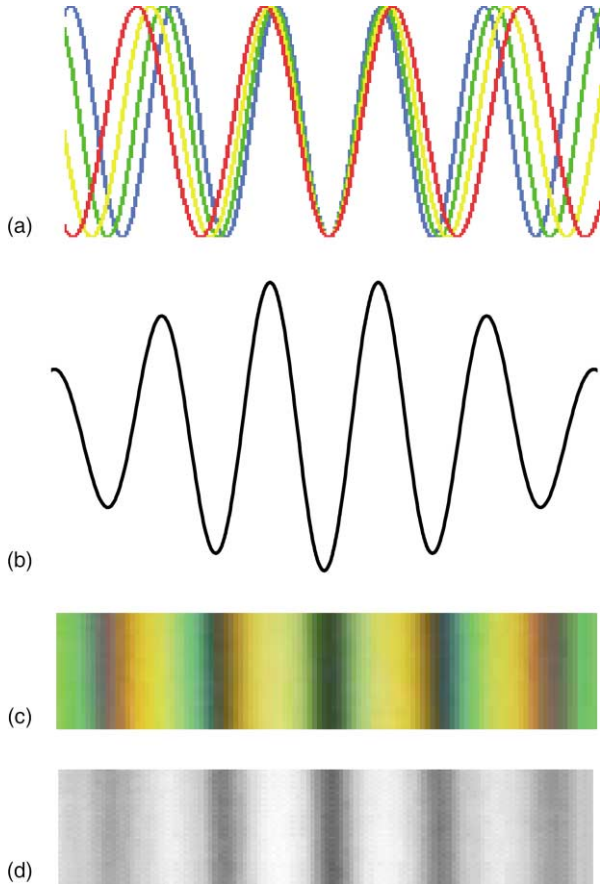

Figure 6 Formation of white light fringes with destructive interference for OPD = 0.

The dependence of the refractive index on the wave number k can be described as a linear expansion:

$$n(k) = n(k_0) + \frac{\mathrm{d}n}{\mathrm{d}k}(k - k_0) \qquad [7]$$

The linear dispersion shifts the envelope by the group index of refraction times the thickness of the dispersive element; this dispersion also shifts the fringes under the envelope slightly. In other words, the linear phase delay for a range of wavelengths causes a group delay of the whole envelope (wave packet). Higher-order dispersion, absorption of the elements, or effects due to thin films can cause the envelope to widen or even become asymmetrical, the position of the fringes under the envelope to shift, the fringes to lose contrast, and the period of the fringes to change or vary with the z position. Dispersion effects will be stronger for sources that have a wider spectrum; however, the observed changes will be different for different shapes of spectra.

The phase of the fringes under the envelope and the position of the envelope itself are parameters often used in astronomy. Highly accurate white light fringe estimation, using the optical path-length delay between the two arms of the interferometer, is a cornerstone of stellar interferometry.

Fourier Analysis of White Light Interferograms

Wavelength-dependent changes in a white light interferogram can be more easily analyzed in the spectrum rather than the spatial domain. The Fourier transform of a white light interferogram yields two symmetrical side lobes at the mean wavelength of the interferogram; analysis of just one of these side lobes is sufficient. The spectral amplitude of the side lobe contains information about the spectral components of the interfering beams, while the spectral phase in regions with appreciable spectral amplitude supplies information about any unbalanced dispersion in the interferometer, as shown in Figure 7. Fourier transform analysis is extensively used in Fourier transform spectrometry (*see* **Spectroscopy:** Fourier Transform Spectroscopy).

For a dispersion-balanced interferometer, the interferogram is symmetrical around the zero OPD position. For a symmetrical interferogram, the spectral phase will be zero if the zero OPD position of the sampled interferogram is in the middle of sampling range; otherwise a linear factor appears in the spectral phase. This linear term, while useful to surface profiling, because it determines the position of the coherence signal with respect to scanner sampling, is unwanted in Fourier spectroscopy and needs to be corrected for. Dispersion and possible thin-film effects will commonly introduce a nonlinearity in the spectral phase.

Controlled Phase Shift of Fringes Under the Envelope – Geometric Phase Shift

Many techniques in interferometry depend on shifting the phase of the interfering wavefronts. Mechanical shifters used in white light interferometry will introduce the same shift measured in nanometers for all wavelengths; however, when measured in degrees or radians, the shift will vary for different wavelengths. Geometric phase shifters (achromatic phase shifters operating on the principle of geometric phase) introduce for all wavelengths the same shift when measured in degrees and are based on polarization elements like a rotating wave plate in circularly polarized light or a rotating polarizer in a circularly polarized beam. Fringes underneath the coherence envelope shift, as shown in Figure 8, while the coherence envelope stays in place.

The advantage to these techniques is that only the phase of fringes changes, not the fringe contrast

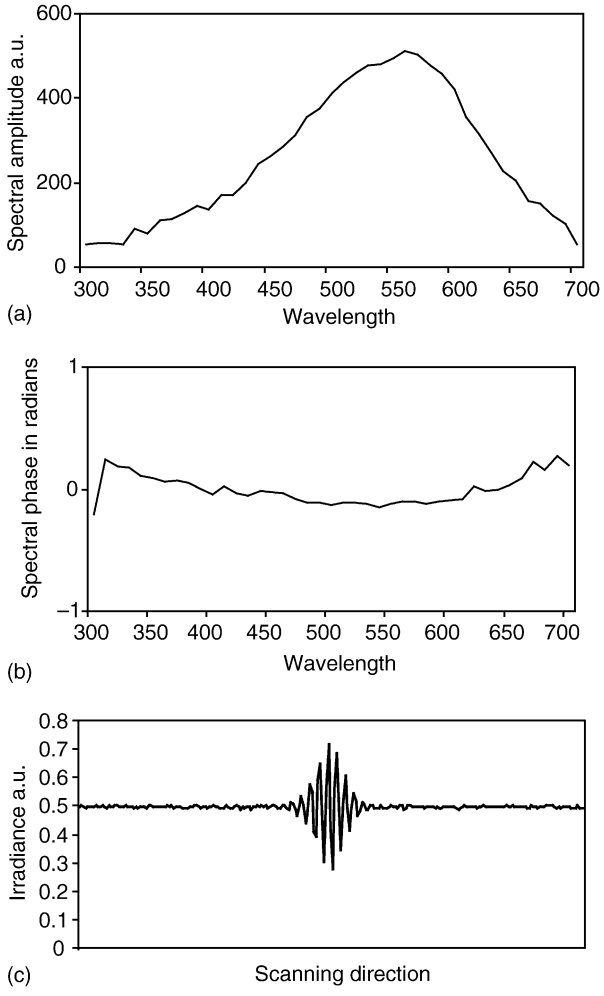

Figure 7 Spectral amplitude (a) and spectral phase (b) for input from unbalanced interferometer (c).

(*see* **Interferometry:** Phase Measurement Interferometry). A geometrical phase shifter can be very useful in polarization microscopes (Figure 9), white light shearing interferometers, or any system where the phase of the white light fringes needs to be measured.

Spectral Interference

White light fringes, because they are made up of fringes of many wavelengths, are observed only over very small path differences. If we filter only a narrow band from the white light spectrum, fringes would be visible over a much larger scan. For different wavelengths we would observe different color and frequency fringes; this is simply the reverse process of the description in the white light interference section.

If we place a spectrometer in the observation plane of the white light interferometer (Figure 10), we will observe fringes with continuously changing wavelengths in dispersed light. These fringes are called

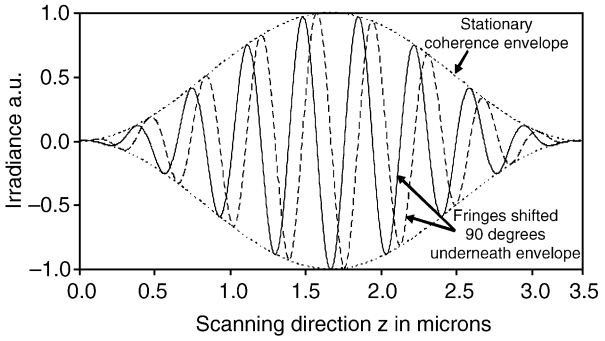

Figure 8 Fringes for two different geometric phase shifts.

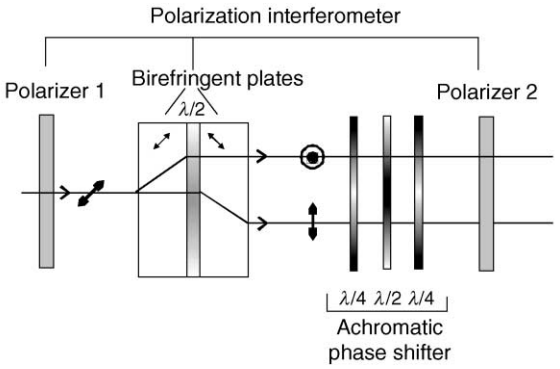

Figure 9 Polarization interferometer with geometric phase shift.

fringes of chromatic order or channeled spectrum fringes and find their application in film thickness measurement or absolute distance measurement in the range up to 1 mm. Channeled spectra were used for analysis of dispersion, thin film, and spectroscopic measurements. The number of observed fringes for a given wavelength is directly proportional to the measured optical path difference. The optical path difference can be determined if the difference in fringe numbers is determined for two well-known wavelengths (this is equivalent to two-wavelength interferometry). The optical path difference can be also quickly estimated from the frequency of fringes for a given wavelength; the larger the optical path difference, the denser the fringes.

Surface Topography and Object Structure Measurement

Although WLI has many applications, this section focuses on white light interference as applied to surface topography measurement. Interference microscopes that use white light illumination are often based on the Michelson setup shown in Figure 11.

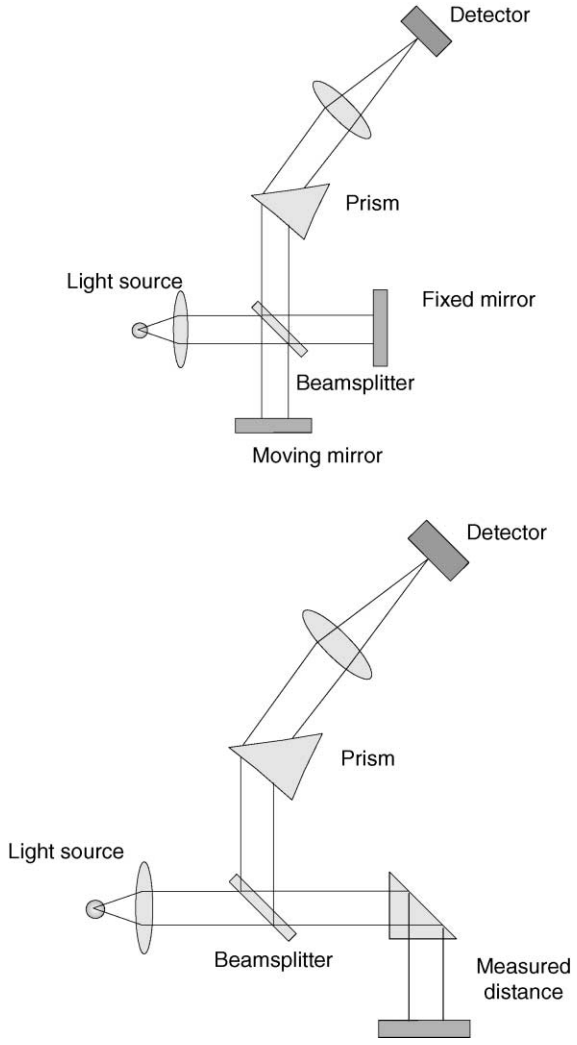

Figure 10 Interferometers with prism spectrometer to observe fringes of equal chromatic order for OPD measurement.

A beamsplitter cube is placed underneath the bright field objective, and one mirror is placed to the side at the focus plane of the objective while the other mirror is replaced by the measured surface with respect to which the whole interference objective is scanned. The narrowly localized fringes at the best focus position for each point of the surface corresponding to a pixel on the CCD camera is observed during the scan. Because of the design of the Michelson objective, in order to accommodate higher magnification objectives constraints, other interference setups like Mirau and Linnik were developed (*see* **Microscopy:** Interference Microscopy). However, these designs are still based on the Michelson interferometer, being also compensated interferometers with equal lengths and amounts of glass in each arm.

These interference microscopes typically have two complementary modes of operation; one mode uses

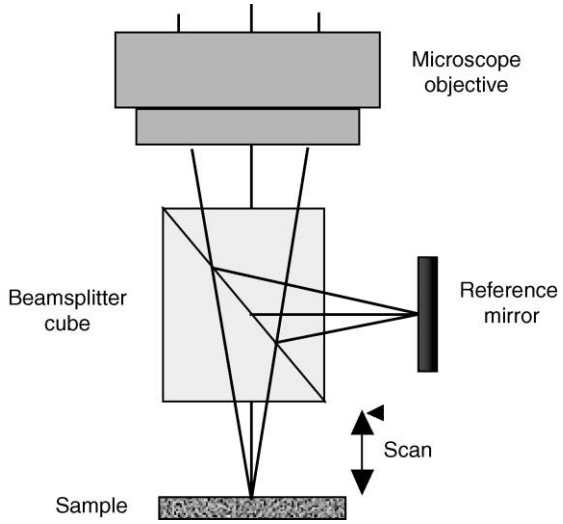

Figure 11 Michelson interferometric objective.

monochromatic illumination and the other employs a white light source. Monochromatic illumination provides excellent vertical resolution but is limited in its range. It cannot correctly assign fringe order to discontinuous surfaces larger than 160 nanometers. Figure 12a shows monochromatic fringes for the surface of the profile shown in Figure 13. We see that with the monochromatic illumination the height of the grooves remains unknown because it is impossible to assign order numbers to these fringes.

To resolve this ambiguity, white light illumination is employed because it allows for easy identification of the zero order fringe. Figure 12b shows white light fringes created for the same surface. We see the zero-order fringe for the zero OPD as well as the next orders due to the decreasing contrast of the fringes. The position of the zero-order fringe can be followed and approximate heights can be determined visually. Thus, white light illumination permits the measurement of a broader range of surfaces that are rough or have large height variations up to a few millimeters.

The white light interferometer is a great focus detector (Figure 14) at each point of the field of view. The principle behind WLI is finding these individual focus positions using localized fringes observed during the surface scan. WLI interferometers provide high lateral resolution and large vertical range in the order of hundreds of nanometers or micrometers (Figure 15). White light interferometers are commonly used to measure magnetic heads, MEMS devices, binary optic, and machined surfaces.

Signal Processing of White Light Interferograms

For WLI topographic measurements, each pixel registers an interferogram whose position varies

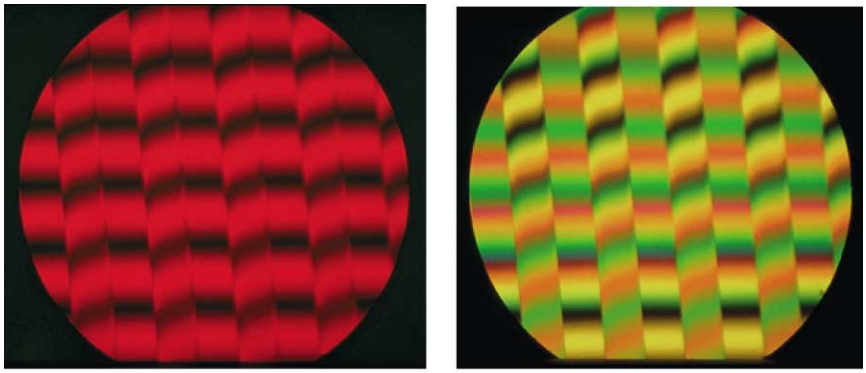

Figure 12 Fringes in quasimonochromatic and white light for object similar to one as presented in Figure 13.

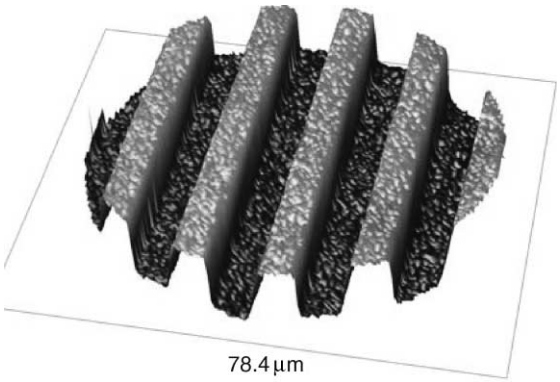

Figure 13 3D object profile – binary grating.

with the surface height. Figure 16 shows two interferograms for two positions in the field of view of a measured step height surface; the first shows the top surface of the step height and the second shows the bottom surface of the step height.

Algorithms have been developed to analyze the signal in different ways. Some focus on finding the fringe envelope position and others examine the position of the fringe underneath the envelope. These algorithms work under the assumption that white light fringes can be described by the same function over the whole field of view of the interferometer. Algorithms are applied to a signal so as to find the position of the coherence envelope for each pixel. This process is called coherence gating, and all algorithms perform coherence gating.

Some algorithms look for the position of the envelope's maximum in a process whereby first the coherence envelope of the fringes is found using signal filtering. Then, the curve is fit to a few points around the envelope's maximum, and finally the position of the envelope's maximum is found. Other algorithms calculate the center of mass of the coherence signal, as described in eqn [8]:

$$H(x,y) = \frac{\sum_{n=1}^{N-1} \left(I_i(x,y) - I_{i+1}(x,y)\right)^2 z_i}{\sum_{n=1}^{N-1} \left(I_i(x,y) - I_{i+1}(x,y)\right)^2} \qquad [8]$$

This method is very fast and computationally efficient. Center of mass calculations are equivalent to calculations of the maximum of the envelope position, but only for a symmetrical signal. For an asymmetrical signal a piston is introduced for each point; however, this piston does not affect the whole measurement. Still another method calculates the spectral phase slope in the Fourier domain to determine the position of the coherence envelope in a process that is equivalent to finding the center of mass. Finally, a different group of algorithms tracks the position of the bright or dark fringe close to the envelope's maximum.

Scanner Speed – Sampling Rate

A practical sampling rate of the white light interference signal is around four pixels per fringe. Because in most algorithms it is not the position of the fringes that we want to determine but rather the position of the envelope of the fringes, sampling the envelope of the fringes with four samples is usually sufficient. However, this sufficiency comes at the expense of lower repeatability (higher noise). The advantage to this sampling rate is short measurement time; higher sampling rates increase measurement time. Measurement speed can be increased by up to 25 times when the envelope of the fringes is widened by filtering light of a bandwidth about 20–40 nm from the white light source.

Scanner Nonlinearity

Scanner motion is assumed to be linear, but nonlinearity in this motion impairs measurement

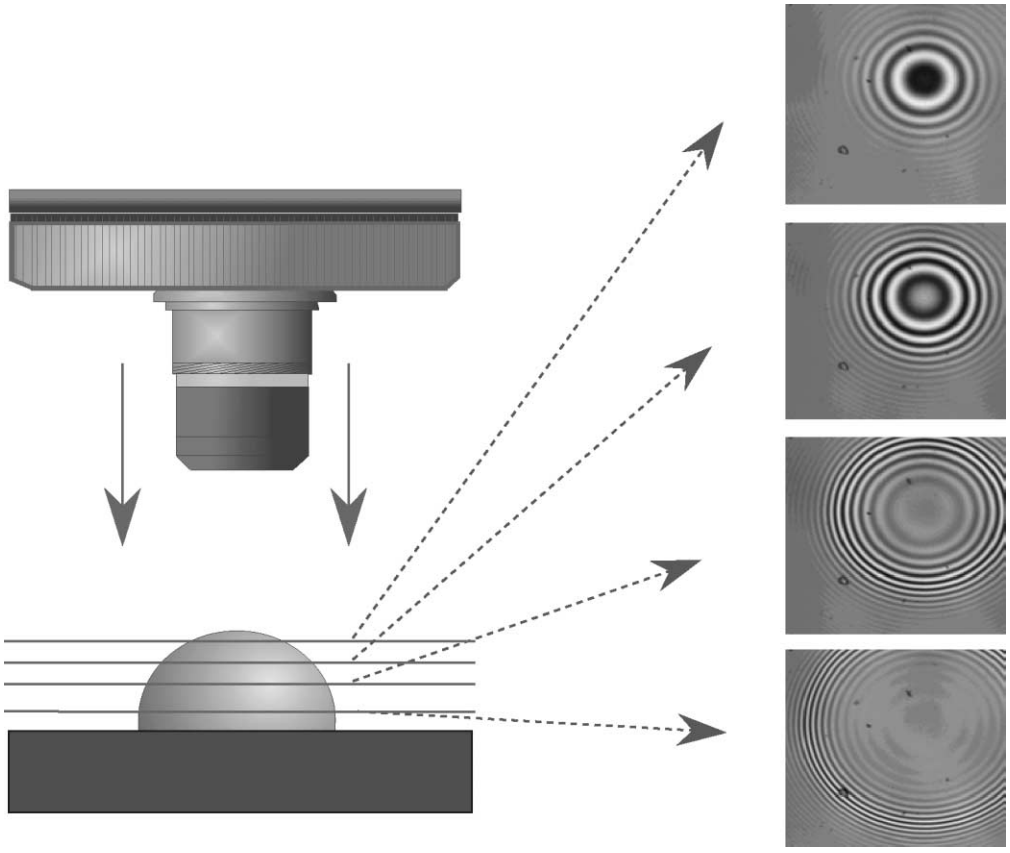

Figure 14 Operation of white light interferometer for surface topography measurement.

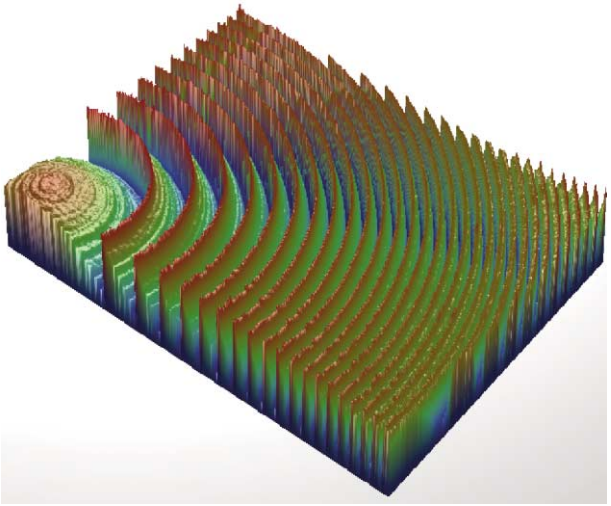

Figure 15 WLI measurement of Fresnel lens in a high-resolution mode. Courtesy of Glimmerglass.

accuracy. To account for this, simple algorithms can calculate the average steps along each interferogram in scanning direction (Figure 17) and measured steps can be used in coherence detection algorithms.

In order to have continuous information about the scan steps, the fringes should be visible somewhere in the field of view at each moment of the scan. This task may require introducing a large tilt for samples with large discontinuities such as stepped surfaces. For large discontinuities where introducing sample tilt may not be sufficient, the envelope of the fringes can be extended by increasing the spatial or temporal coherence of the light source. An alternate solution involves measuring the scanner motion with a distance-measuring interferometer or triggering the camera to collect intensity data at every equal scan step, which can be determined by using the zero-crossing technique, as is commonly done in Fourier transform spectroscopy. Equal scan steps are more suitable for techniques based on transform techniques that assume equal sampling. Other peak detection algorithms, such as center of mass calculations, make use of measured but not necessarily equal steps directly in the algorithm.

Observing the phase along the interferogram can also provide information that is important in optical fiber sensing. These observed changes, which assume that sampling rates of the interferogram are known,

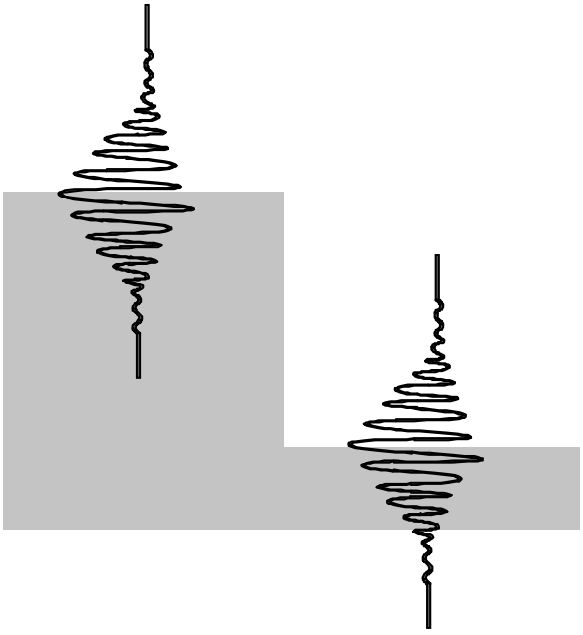

Figure 16 White light fringes as seen by two pixels during scan through focus for object in form of step.

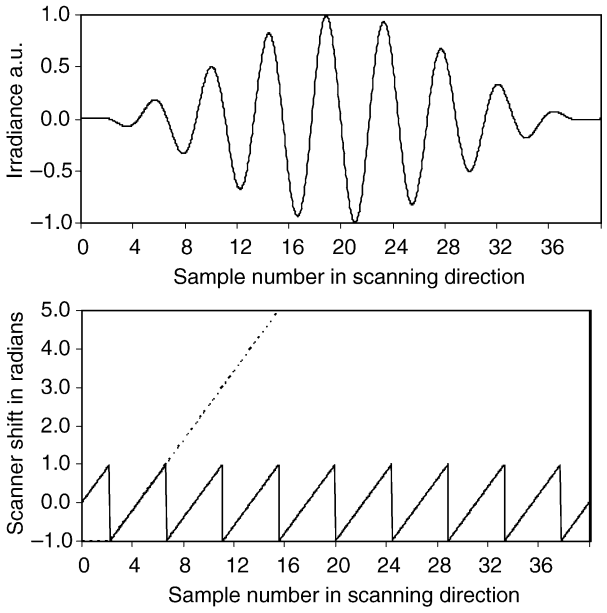

Figure 17 Phase calculated along the white light interferogram. This calculated phase can be used to determine scanner motion.

enable correction for changes in wave number value k_0 which can be due to such things as changes in the working voltage of bulb, an introduced higher-order dispersion, or a large tilt of the sample.

Increased Resolution White Light Interferometry

Interferometric methods that employ a monochromatic light source to detect the phase of the fringes

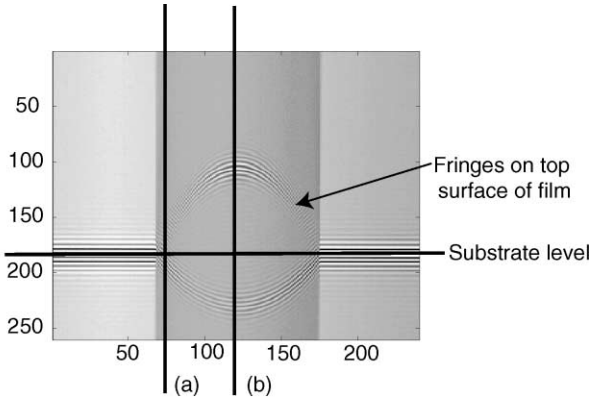

Figure 18 Fringes for (a) thin and (b) thick film.

(*see* **Interferometry:** Phase Measurement Interferometry) can achieve about 10 times better (0.3 nanometers versus 3 nanometers) vertical resolution than the WLI methods described so far. Combining coherence position detection from WLI to determine fringe order with the phase detection of phase shifting techniques allows for the measurement of samples with height discontinuities larger than 160 nanometers with the resolution and accuracy of phase shifting interferometry (PSI). This combination is particularly well-suited for determining the shape of smooth surfaces with large height differences such as binary diffractive optics or micro-electromechanical systems (MEMS) (see Figure 15).

Using this combined method we obtain both a lower-resolution map of the envelope position and a higher-resolution map of the phase (position) of the zero order fringe. These maps may differ slightly due to effects similar to those discussed in sections *Changes in Envelope and Fringes Due to Reflection of Nondielectric* and *Changes in Envelope and Fringes Due to Dispersion* above. In interference microscopes, shifts in the envelope and fringe position may be introduced by field-dependent and chromatic aberrations of the system and the system's effective numerical aperture. These shifts can vary for different points on the tested surface, but for simplicity are assumed to be constant over the field. Some correction for these effects can be applied.

Film Thickness Measurement

White light interferograms that are obtained in an optical profiler can be used to measure transparent film thicknesses because the character of the interferogram changes with the thickness of the film (Figure 18). Two different techniques, a thin or thick film technique, are used depending of the range of the film thickness. A thick film technique is used if two

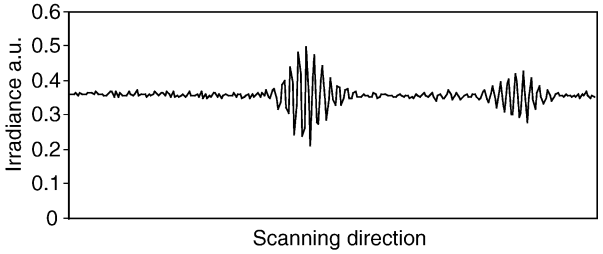

Figure 19 Thick film (see Figure 18b) irradiance.

sets of best contrast white light fringes from each interface are clearly separated, meaning that no interference occurs between the wavefronts reflected from the top and bottom surfaces of the film. A thin film technique is employed when the two sets of fringes overlap.

Thick film measurement

A simple technique for finding the relative position of the peaks of the fringe envelopes can be implemented to find the thickness of a film. Figure 19 shows two clearly separated sets of fringes formed for the air/film and film/substrate interfaces. Whether these two sets of fringes are separated or not depends mainly on the geometrical thickness of the film and its group index of refraction, which is determined by the dispersion of the film. The typical range of measurable film thicknesses runs from 3 to 150 microns, depending on the dispersion of the film. This measurement allows for the detection of flows on the surface and interface of the film. Similar principles based on finding the position of the coherence envelopes are used for distance sensing, thickness measurement of plates, and the cornea of the eye, in low coherence reflectometry and structure measurements in biological samples in optical coherence tomography.

Thin film measurement

For thicknesses of five microns down to tens of nanometers, the white light interferogram is created from the interference between the beams reflected from the reference mirror and the two beams reflected from the thin film layer. Once the interferogram is registered while the objective is scanned vertically with a constant velocity, the spectral phase is calculated by applying a Fourier transform to the measured signal at each pixel as described in the section *Fourier Analysis of White Light Interferograms* above. The phase slope is subtracted and the dispersion of the system needs to be known. The spectral phase for the thin film interference has the form of a polynomial; thus, the polynomial for the chosen film model (n and k) is fitted, and regression

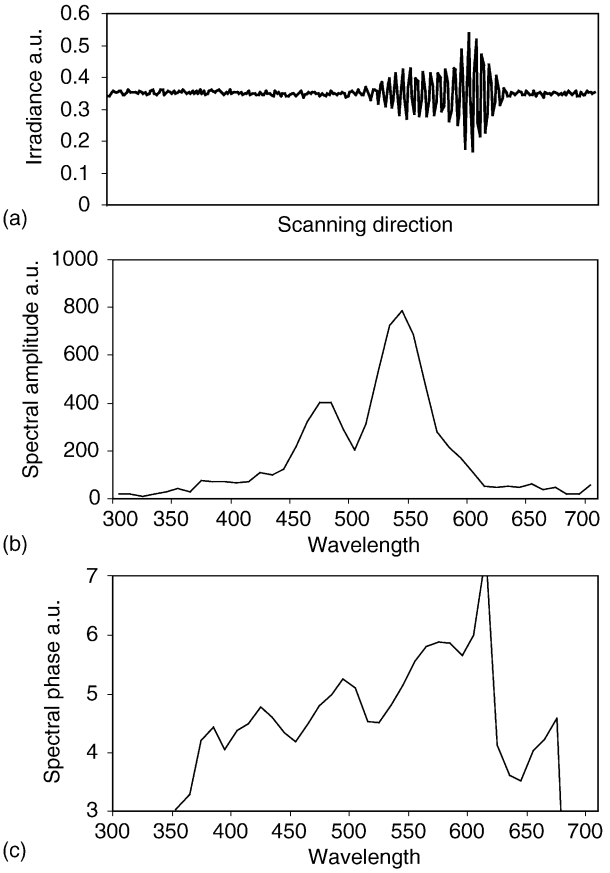

Figure 20 Thin film (see Figure 18a): (a) irradiance, (b) spectral amplitude and (c) spectral phase.

analysis is used to find the best fit and, therefore, the film thickness (Figure 20).

Spatial Coherence Effects in the Interference Microscope

So far we have been discussing temporal coherence effects, but everywhere that the source has a wavelength bandwidth, spatial coherence may play an important role. In an interference microscope for surface topography measurement, the size of the aperture of the condenser is on the order of the aperture of the objective that illuminates the surface with a wide range of angles. For large angles, which are determined by the numerical aperture (NA) of the objective, where NA = 0.5–0.95, the combination of the influence of the spatial and temporal coherence is clearly visible. The additional spatial effects include a reduction of the fringe envelope width and a decrease in fringe spacing corresponding to k_0. Calibration of fringe spacing is typically done on the system and accounts for spatial effects as well as for any uncertainty of k_0 due to the source spectra, the working temperature of the source, the spectral

response of the detector and the influence of other factors like the intensity distribution in the illuminating aperture. The spatial influences can be reduced by stopping down the condenser, which causes an increase in the contrast of the fringes.

Rough Surfaces

Rough surfaces are difficult to measure using interferometric techniques, but under certain coherence conditions white light interference can do the job. For rough surfaces, if the microstructure of the object is not resolved by the imaging system, speckles, rather than fringes, are observed. Each speckle has a random phase which is approximately constant in the whole speckle area. If the rough surface is scanned through focus, each individual speckle exhibits the intensity modulation that is typical for WLI. These speckles enable the measurement, but they also introduce noise proportional to the roughness of the measured surface.

Despite the noise that speckles introduce into the WLI measurement, WLI has an advantage because it rejects the light that has undergone scattering outside of a small sample volume, thus allowing precise noninvasive measurement of object structure, even in dense media.

Applications

WLI is used in many disciplines and instruments such as:

- Fourier transform spectroscopy – source and material properties;
- Michelson stellar interferometer – angular size of star, binary stars, delay measurement in optical paths of interferometer;
- Shearing interferometry – structure measurement;
- DIC Nomarski interferometry – structure measurement;
- Speckle interferometry – structure measurement;
- Holography – structure measurement;
- Optical sensors – temperature, pressure, distance;
- Optical coherence tomography – structure measurement.

Introduction

This article gives a brief history of the development of the laser and goes on to describe the characteristics of the carbon dioxide laser and the molecular dynamics that permit it to operate at comparatively high power and efficiency. It is these commercially attractive features and its low cost that has led to its adoption as one of most popular industrial power beams. This outline also describes the main types of carbon dioxide laser and briefly discusses their characteristics and uses.

Brief History

In 1917 Albert Einstein developed the concept of stimulated emission which is the phenomenon used in lasers. In 1954 the MASER (Microwave Amplification by Stimulated Emission of Radiation) was the first device to use stimulated emission. In that year Townes and Schawlow suggested that stimulated emission could be used in the infrared and optical portions of the electromagnetic spectrum. The device was originally termed the optical maser, this term being dropped in favor of LASER, standing for: Light Amplification by Stimulated Emission of Radiation. Working against the wishes of his manager at Hughes Research Laboratories, the electrical engineer Ted Maiman created the first laser on the 15 May 1960. Maiman's flash lamp pumped ruby laser produced pulsed red electromagnetic radiation at a wavelength of 694.3 nm. During the most active period of laser systems discovery Bell Labs made a very

significant contribution. In 1960, Ali Javan, William Bennet and Donald Herriot produced the first Helium Neon laser, which was the first continuous wave (CW) laser operating at 1.15 μm. In 1961, Boyle and Nelson developed a continuously operating Ruby laser and in 1962, Kumar Patel, Faust, McFarlane and Bennet discovered five noble gas lasers and lasers using oxygen mixtures. In 1964, C.K.N. Patel created the high-power carbon dioxide laser operating at 10.6 μm. In 1964, J.F. Geusic and R.G. Smith produced the first Nd:Yag laser using neodymium doped yttrium aluminum garnet crystals and operating at 1.06 μm.

Characteristics

Due to its operation between low lying vibrational energy states of the CO_2 molecule, the CO_2 laser has a high quantum efficiency, ~40%, which makes it extremely attractive as a high-power industrial materials processing laser (1 to 20 kW), where energy and running costs are a major consideration. Due to the requirement for cooling to retain the population inversion, the efficiency of electrical pumping and optical losses – commercial systems have an overall efficiency of approximately 10%. Whilst this may seem low, for lasers this is still a high efficiency. The CO_2 laser is widely used in other fields, for example, surgical applications, remote sensing, and measurement. It emits infrared radiation with a wavelength that can range from 9 μm up to 11 μm. The laser transition may occur on one of two transitions: $(00^01) \rightarrow (10^00)$, $\lambda = 10.6$ μm; $(00^01) \rightarrow (02^00)$, $\lambda = 9.6$ μm, see Figure 1. The 10.6 μm transition has the maximum probability of oscillation and gives the strongest output; hence, this is the usual wavelength of operation, although for specialist applications the laser can be forced to operate on the 9.6 μm line.

Figure 1 illustrates an energy level diagram with four vibrational energy groupings that include all the significantly populated energy levels. The internal relaxation rates within these groups are considered to be infinitely fast when compared with the rate of energy transfer between these groups. In reality the internal relaxation rates are at least an order of magnitude greater than the rates between groups.

Excitation of the upper laser level is usually provided by an electrical glow discharge. However, gas dynamic lasers have been built where expanding a hot gas through a supersonic nozzle creates the population inversion; this creates a nonequilibrium region in the downstream gas stream with a large population inversion, which produces a very high-power output beam (135 kW – Avco Everett Research Lab). For some time the gas dynamic laser was seriously considered for use in the space-based Strategic Defence Initiative (SDI-USA). The gas mixture used in a CO_2 laser is usually a mixture of carbon dioxide, nitrogen, and helium. The proportions of these gases varies from one laser system to another, however, a typical mixture is 10%-CO_2;

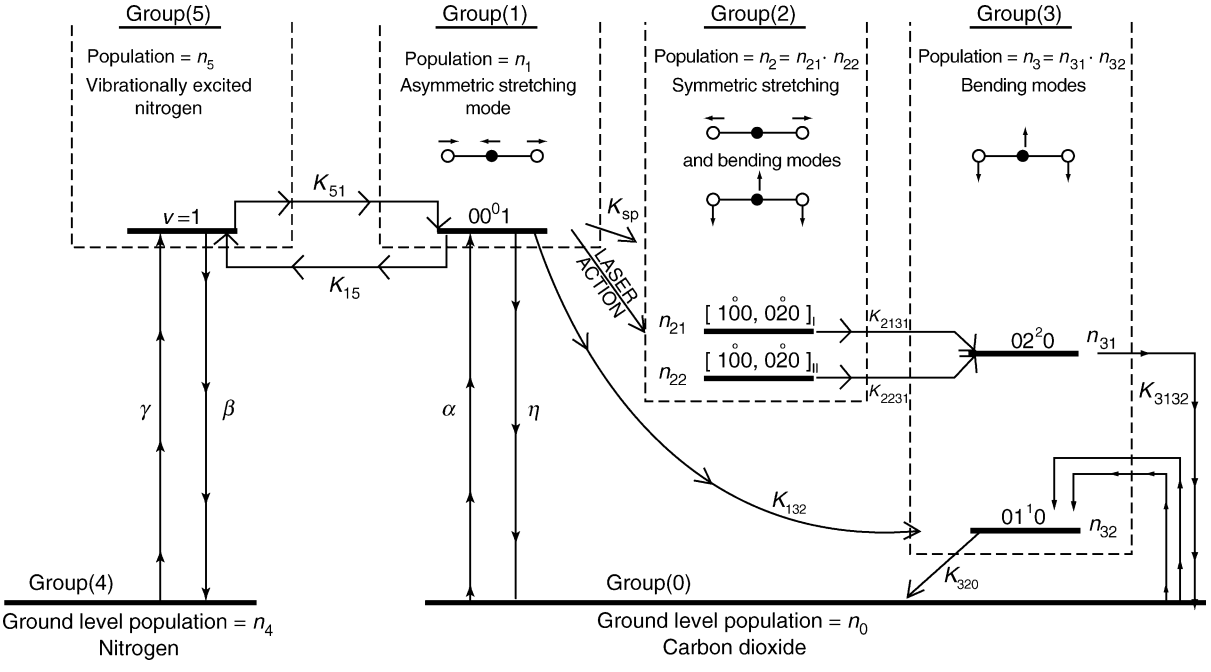

Figure 1 Six level model used for the theoretical description of CO_2 laser action.

10%-N_2; 80%-He. Helium plays a vital role in the operation of the CO_2 laser in that it maintains the population inversion by depopulating the lower laser level by nonradiative collision processes. Helium is also important for stabilization of the gas discharge; furthermore it greatly improves the thermal conductivity of the gas mixture, which assists in the removal of waste heat via heat exchangers.

Small quantities of other gases are often added to commercial systems in order to optimize particular performance characteristics or stabilize the gas discharge; for brevity we only concern ourselves here with this simple gas mixture.

Molecular Dynamics

Direct Excitation and De-excitation

It is usual for excitation to be provided by an electrical glow discharge. The direct excitation of carbon dioxide (CO_2) and nitrogen (N_2) ground state molecules proceeds via inelastic collisions with fast electrons. The rates of kinetic energy transfer are α and γ, respectively, and are given by eqns [1] and [2]:

$$\alpha = \frac{F_{CO_2} \times \mathrm{IP}}{E_{00^01} \times n_0} (\mathrm{sec}^{-1}) \qquad [1]$$

$$\gamma = \frac{F_{N_2} \times \mathrm{IP}}{E_{v=1} \times n_4} (\mathrm{sec}^{-1}) \qquad [2]$$

where:

F_{CO_2} = Fraction of the input power (IP) coupled into the excitation of the energy level E_{00^01}, n_0 is the CO_2 ground level population density;

F_{N_2} = Fraction of the input power (IP) coupled into the excitation of the energy level $E_{v=1}$; and n_4 is the N_2 ground level population density.

The reverse process of the above occurs when molecules lose energy to the electrons and the electrons gain an equal amount of kinetic energy; the direct de-excitation rates are given by η and β, eqns [3] and [4], respectively:

$$\eta = \alpha \times \exp\left(\frac{E_{00^01}}{E_e}\right) (\mathrm{sec}^{-1}) \qquad [3]$$

$$\beta = \gamma \times \exp\left(\frac{E_{v=1}}{E_e}\right) (\mathrm{sec}^{-1}) \qquad [4]$$

where E_e is the average electron energy in the discharge.

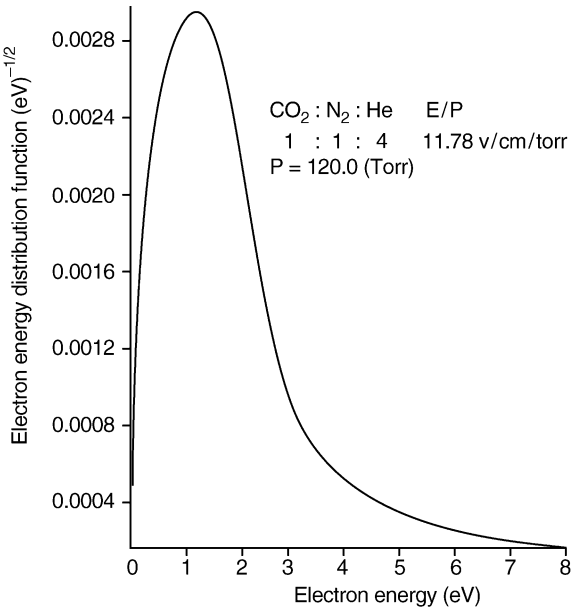

Figure 2 Electron energy distribution function.

E_e, F_{CO_2}, and F_{N_2} are obtained by solution of the Boltzmann transport equation (BTE); the average electron energy can be optimized to maximize the efficiency (F_{CO_2}, F_{N_2}) with which electrical energy is utilized to create a population inversion. Hence, the discharge conditions required to maximize efficiency can be predicted from the transport equation. Figure 2 shows one solution of the BTE for the electron energy distribution function.

Resonant Energy Transfer

Resonant energy transfer between the CO_2 (00^01) and N_2 ($v = 2$) energy levels (denoted 1 and 5 in Figure 1) proceeds via excited molecules colliding with ground state molecules. A large percentage of the excitation of the upper laser level takes place via collisions between excited N_2 molecules and ground state CO_2 molecules. The generally accepted rate of this energy transfer is given by eqns [5] and [6]:

$$K_{51} = 19\,000\, P_{CO_2} (\mathrm{sec}^{-1}) \qquad [5]$$

$$K_{15} = 19\,000\, P_{N_2} (\mathrm{sec}^{-1}) \qquad [6]$$

where P_{CO_2} and P_{N_2} are the respective gas partial pressures in Torr.

Hence, CO_2 molecules are excited into the upper laser level by both electron impact and impact with excited N_2 molecules. The contribution from N_2 molecules can be greater than 40% depending on the discharge conditions.

Collision–Induced Vibrational Relaxation of the Upper and Lower Laser Levels

The important vibrational relaxation processes are illustrated by Figure 1 and can be evaluated from eqns [7–10]; where the subscripts refer to the rate between energy levels 1 and 32; 21 and 31; 22 and 31; 32 and 0, respectively:

$$K_{132} = 367\,P_{CO_2} + 110\,P_{N_2} + 67\,P_{He}\ (\sec^{-1}) \qquad [7]$$

$$K_{2131} = 6\times10^5\,P_{CO_2}\ (\sec^{-1}) \qquad [8]$$

$$K_{2231} = 5.15\times10^5\,P_{CO_2}\ (\sec^{-1}) \qquad [9]$$

$$K_{320} = 200\,P_{CO_2} + 215\,P_{N_2} + 3270\,P_{He}\ (\sec^{-1}) \qquad [10]$$

K_{132}, K_{2131}, and K_{2231} are vibration/vibration transfer rates and K_{320} is a vibration/translation transfer rate. Note the important effect of helium on eqn [10]; helium plays a major role in depopulating the lower laser level, thus enhancing the population inversion. P_{He} is the partial pressure of helium in Torr.

Radiative Relaxation

Spontaneous radiative decay is not a major relaxation process in the CO_2 laser but it is responsible for starting laser action via spontaneous emission. The Einstein 'A' coefficient for the laser transition is given by eqn [11]:

$$A = (\tau_{sp})^{-1} = 0.213\ (\sec^{-1}) \qquad [11]$$

Gain

The gain (g) is evaluated from the product of the absorption coefficient (σ) and the population inversion, eqn [12]:

$$g = \sigma\left(n_{00^01} - \frac{g_1}{g_2}n_{10^00}\right)\ \mathrm{cm}^{-1} \qquad [12]$$

For most commercial laser systems the absorption coefficient is that for high-pressure collision-broadening ($P > 5.2$ Torr) where the intensity distribution function describing the line shape is Lorentzian. The following expression describes the absorption coefficient, eqn [13]:

$$\sigma = \frac{692.5}{Tn_{CO_2}\left(1 + 1.603\frac{n_{N_2}}{n_{CO_2}} + 1.4846\frac{n_{He}}{n_{CO_2}}\right)}\ (\mathrm{cm}^2) \qquad [13]$$

where T is the absolute temperature and n refers to the population density of the gas designated by the subscript.

This expression takes account of the different constituent molecular velocity distributions and different collision cross-sections for $CO_2 \rightarrow CO_2$, $N_2 \rightarrow CO_2$ and $He \rightarrow CO_2$ type collisions. Equation [13] also takes account of the significant line broadening effect of helium.

Neglecting the unit change in rotational quantum number, the energy level degeneracies g_1 and g_2 may be dropped. n_{10^00} is partitioned such that $n_{10^00} = 0.1452n_2$ and eqn [12] can be re-cast as eqn [14]:

$$g = \sigma(n_1 - 0.1452n_2)\ \mathrm{cm}^{-1} \qquad [14]$$

where n_1 and n_2 are the population densities of energy groups '1' and '2' respectively.

Stimulated Emission

Consider a laser oscillator with two plane mirrors, one placed at either end of the active gain medium, with one mirror partially transmitting (see Figure 4). Laser action is initiated by spontaneous emission that happens to produce radiation whose direction is normal to the end mirrors and falls within the resonant modes of the optical resonator. The rate of change of photon population density (I_p) within the laser cavity can be written as eqn [15]:

$$\frac{dI_p}{dt} = I_p cg - \frac{I_p}{T_0} \qquad [15]$$

where the first term on the right-hand side accounts for the effect of stimulated emission and the second term represents the number of photons that decay out of the laser cavity, T_0 is the photon decay time, given by eqn [16], and is defined as the average time a photon remains inside the laser cavity before being lost either through the laser output window or due to dispersion; if dispersion is ignored, I_p/T_0, is the laser output:

$$T_0 = \frac{2L}{c\log_e\left(\frac{1}{R_B R_F}\right)} \qquad [16]$$

where L is the distance between the back and the front mirrors, which have reflectivities of R_B and R_F, respectively. The dominant laser emission occurs on a rotational–vibrational P branch transition $P(22)$, that is $(J = 21) \rightarrow (J = 22)$ line of the $(00^01) \rightarrow (10^00)$, $\lambda = 10.6\ \mu$m transition, where J is the rotational quantum number. The rotational level relaxation rate is so rapid that equilibrium is maintained between rotational levels so that they

feed all their energy through the $P(22)$ transition. This model simply assumes constant intensity, basing laser performance on the performance of an average unit volume. By introducing the stimulated emission term into the molecular rate equations, which describe the rate of transfer of molecules between the various energy levels illustrated in Figure 1, a set of molecular rate eqns [17–21] can be written that permit simulation of the performance of a carbon dioxide laser:

$$\frac{dn_1}{dt} = \alpha n_0 - \eta n_1 + K_{51} n_5 - K_{15} n_1 - K_{sp} n_1 - K_{132}\left(n_1 - \left[\frac{n_1}{n_{32}}\right]_e n_{32}\right) - I_p c g \qquad [17]$$

$$\frac{dn_2}{dt} = K_{sp} n_1 + I_p c g - K_{2131}\left(n_{21} - \left[\frac{n_{21}}{n_{31}}\right]_e n_{31}\right) - K_{2231}\left(n_{22} - \left[\frac{n_{22}}{n_{31}}\right]_e n_{31}\right) \qquad [18]$$

$$\frac{dn_3}{dt} = 2K_{2131}\left(n_{21} - \left[\frac{n_{21}}{n_{31}}\right]_e n_{31}\right) - 2K_{2231}\left(n_{22} - \left[\frac{n_{22}}{n_{31}}\right]_e n_{31}\right) + K_{132}\left(n_1 - \left[\frac{n_1}{n_{32}}\right]_e n_{32}\right) - K_{320}\left(n_{32} - \left[\frac{n_{32}}{n_0}\right]_e n_0\right) \qquad [19]$$

$$\frac{dn_5}{dt} = \gamma n_4 - \beta n_5 - K_{51} n_5 + K_{15} n_1 \qquad [20]$$

$$\frac{dI_p}{dt} = I_p c g - \frac{I_p}{T_0} \qquad [21]$$

The terms in square brackets ensure that the system maintains thermodynamic equilibrium; subscript 'e' refers to the fact that the populations in the square brackets are the values for thermodynamic equilibrium. The set of five simultaneous differential equations can be solved using a Runge–Kutta method. They can provide valuable performance prediction data that is helpful in optimizing laser design, especially when operated in the pulsed mode. Figure 3a illustrates some simulation results for the transverse flow laser shown in Figure 9. The results illustrate the effect of altering the gas mixture and how this can be used to control the gain switched spike that would result in unwelcome work piece plasma generation if allowed to become too large. Figure 3b shows an experimental laser output pulse from the high pulse repetition frequency (prf–5kHz) laser illustrated in Figure 9. This illustrates that even a quite basic physical model can give a good prediction of laser output performance.

Optical Resonator

Figure 4 shows a simple schematic of an optical resonator. This simple optical system consists of two mirrors (the full reflector is often a water cooled gold coated copper mirror), which are aligned to be orthogonal to the optical axis that runs centrally along the length of the active gain medium in which there is a population inversion. The output coupler is a partial reflector (usually dielectrically coated zinc selenide – ZnSe–that may be edge cooled) so that some of the electromagnetic radiation can escape as an output beam. The ZnSe output coupler has a natural reflectivity of about 17% at each air–solid interface. For high power lasers (2 kW) 17% is sufficient for laser operation; however, depending on the required laser performance the inside surface is often given a reflective coating. The reflectivity of the inside face depends on the balance between the gain (eqn [14]), the output power and the power stability requirements. The outside face of the partial reflector must be anti-reflection (AR) coated.

Spontaneous emission occurs within the active gain medium and radiates randomly in all directions; a fraction of this spontaneous emission will be in the same direction as the optical axis, perpendicular to the end mirrors, and will also fall into a resonant mode of the optical resonator. Spontaneous emission photons interact with CO_2 molecules in the excited upper laser level, excited state (00^01), which stimulates these molecules to give up a quanta of vibrational energy as photons via the radiative transition $(00^01) \rightarrow (10^00)$, $\lambda = 10.6\mu m$. The radiation given up will have exactly the same phase and direction as the stimulating radiation and thus will be coherent with it. The reverse process of absorption also occurs, but so long as there is a population inversion there will be a net positive output. This process is called light amplification by stimulated emission of radiation (LASER). The mirrors continue to redirect the photons parallel to the optical axis and so long as the population inversion is not depleted, more and more photons are stimulated by stimulated emission which dominates the process and also dominates the spontaneous emission, which is important to initiate laser action.

Light emitted by lasers contains several optical frequencies, which are a function of the different modes of the optical resonator; these are simply the standing wave patterns that can exist within the resonator structure. There are two types of

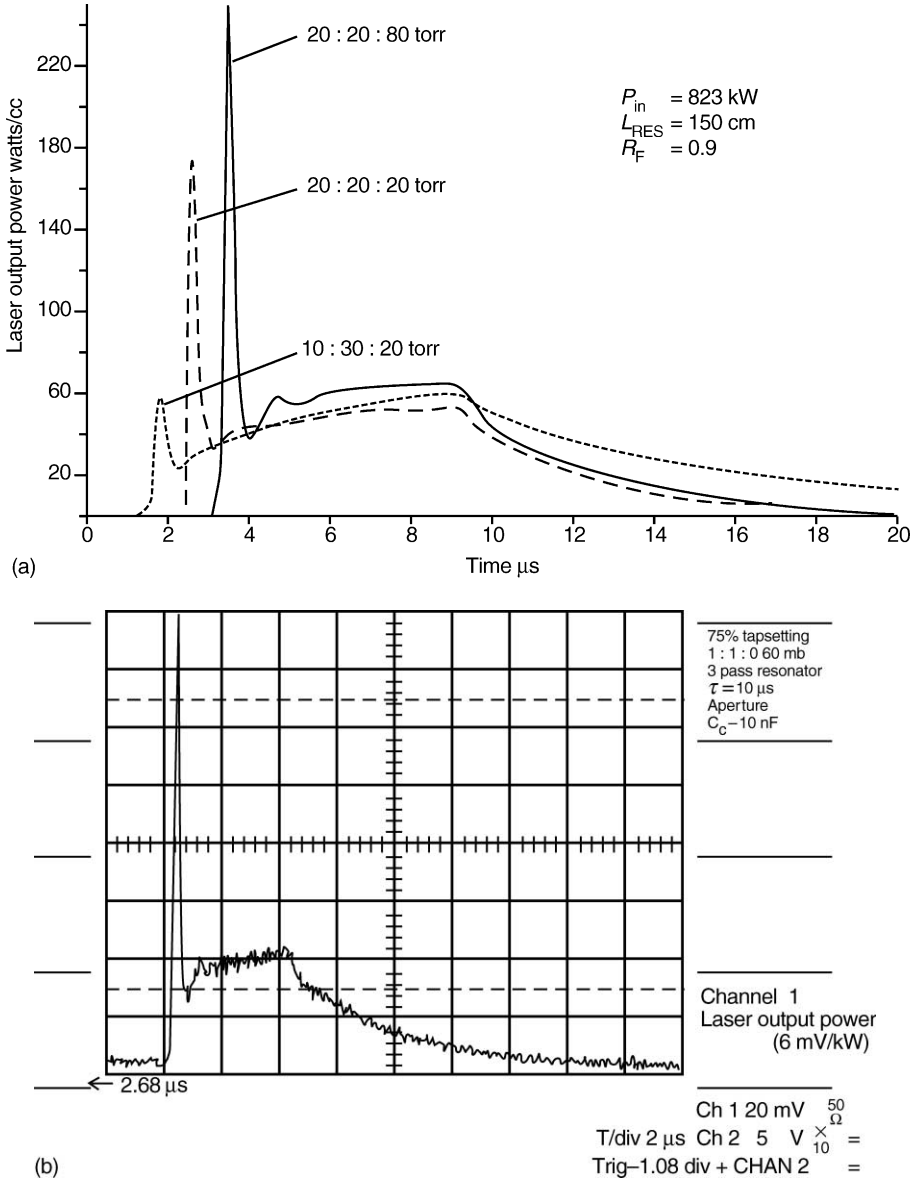

Figure 3 (a) Predicted output pulses for transverse flow CO_2 laser for different gas mixtures, (b) Experimental output pulse from transverse flow CO_2 laser.

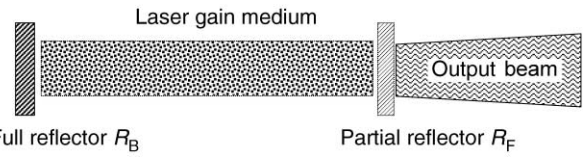

Figure 4 Optical resonator.

resonator modes: longitudinal and transverse. Longitudinal modes differ from one another in their frequency of oscillation whereas transverse modes differ from one another in their oscillation frequency and field distribution in a plane orthogonal to the direction of propagation. Typically CO_2 lasers have a large number of longitudinal modes; in CO_2 laser applications these are of less interest than the transverse modes, which determine the transverse beam intensity and the nature of the beam when focused. In cylindrical coordinates the transverse modes are labelled TEM_{pl}, where subscript '*p*' is the number of radial nodes and '*l*' is the number of angular nodes. The lowest order mode is the TEM_{00}, which has a Gaussian-like intensity profile with its maximum on the beam axis. A light beam emitted from an optical resonator with a Gaussian profile is said to be operating in the 'fundamental mode' or the TEM_{00} mode. The decrease in irradiance (I) with distance 'r' from the axis (I_0) of the Gaussian beam is

described by eqn [22]:

$$I(r) = I_0 \exp(2r^2/w^2) \qquad [22]$$

where w is the radial distance, where the power density is decreased to $1/e^2$ of its axial value. Ideally a commercial laser should be capable of operation in the fundamental mode as, with few exceptions, this results in the best performance in applications. Laser cutting benefits from operation in the fundamental mode; however, welding or heat treatment applications may benefit from operation with higher-order modes. Output beams are usually controlled to be linearly or circularly polarized, depending upon the requirements of the application. For materials processing applications the laser beam is usually focused via a water cooled ZnSe lens or, for very high power lasers, a parabolic gold coated mirror. Welding applications will generally use a long focal length lens and cutting applications will use a short focal length, which generates a higher irradiance at the work piece than that necessary for welding. The beam delivery optics are usually incorporated into a nozzle assembly that can deliver cooling water and assist gases for cutting and anti-oxidizing shroud gases for welding or surface engineering applications.

Laser Configuration

CO_2 lasers are available in many different configurations and tend to be classified on the basis of their physical form and the gas flow arrangement, both of which greatly affect the output power available and beam quality. The main categories are: sealed off lasers, waveguide lasers, slow axial flow, fast axial flow, diffusion cooled, transverse flow, transversely excited atmospheric lasers, and gas dynamic lasers.

Sealed-Off and Waveguide Lasers

Depopulation of the lower laser level is via collision with the walls of the discharge tube, so the attainable output power scales with the length of the discharge column and not its diameter. Output powers are in the range 5 W to 250 W. Devices may be constructed from concentric glass tubes with the inner tube providing the discharge cavity and the outer tube acting to contain water-cooling of the inner discharge tube. The inner tube walls act as a heat sink for the discharge thermal energy (see Figure 5). The DC electrical discharge is provided between a cathode and anode situated at either end of the discharge tube. A catalyst must be provided to ensure regeneration of CO_2 from CO. This may be accomplished by adding about 1% of H_2O to the gas mixture, or alternatively,

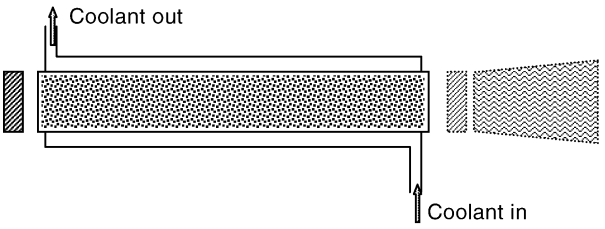

Figure 5 Schematic of sealed-off CO_2 laser, approximately 100 W per meter of gain length, gas cooled by diffusion to the wall.

recombination can be achieved via a hot (300 °C) Ni cathode, which acts as a catalyst. RF-excited all metal sealed-off tube systems can deliver lifetimes greater than 45 000 hours.

Diffusion-cooled slab laser technology will also deliver reliable sealed operation for 20 000 hrs. Excitation of the laser medium occurs via RF excitation between two water-cooled electrodes. The water-cooled electrodes dissipate (diffusion cooled) the heat generated in the gas discharge. An unstable optical resonator provides the output coupling for such a device (see Figure 6). Output powers are in the range 5 W to 300 W and can be pulsed from 0 to 100 kHz. These lasers are widely used for marking, rapid prototyping, and cutting of nonmetals (paper, glass, plastics, ceramics) and metals.

Waveguide CO_2 lasers use small bore tubes (2–4 mm) made of BeO or SiO_2 where the laser radiation is guided by the tube walls. Due to the small tube diameter, a gas total pressure of 100 to 200 Torr is necessary, hence the gain per unit length is high. This type of laser will deliver 30 W of output power from a relatively short (50 cm long) compact sealed-off design; such a system is useful for microsurgery and scientific applications. Excitation can be provided from a longitudinal DC discharge or from an RF source that is transverse to the optical axis; RF excitation avoids the requirement for an anode and cathode and results in a much lower electrode voltage.

Slow Axial Flow Lasers

In slow flow lasers the gas mixture flows slowly through the laser cavity. This is done to remove the products of dissociation that will reduce laser efficiency or prevent it from operating at all, and the main contaminant is CO. The dissociated gases (mainly CO and O_2) can be recombined using a catalyst pack and then reused via continuous recirculation. Heat is removed via diffusion through the walls of the tube containing the active gain medium. The tube is frequently made of Pyrex glass with a concentric outer tube to facilitate water-cooling of the

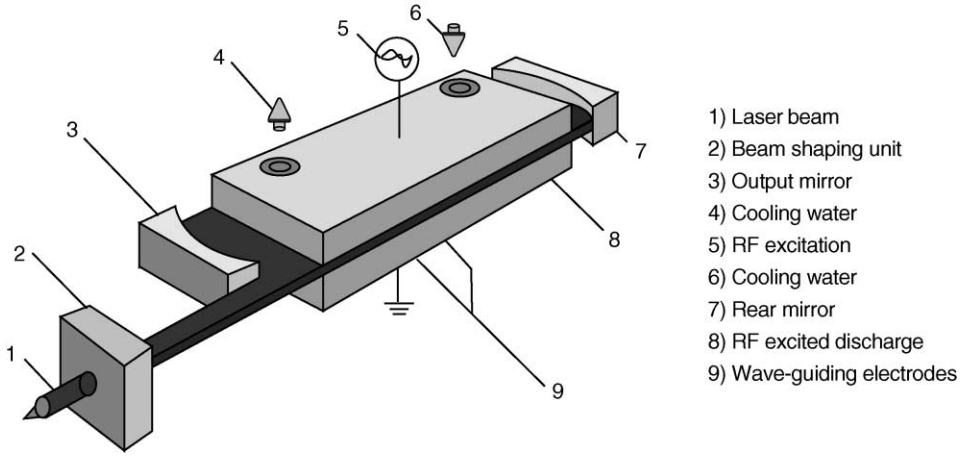

Figure 6 Schematic for sealed-off slab laser and diffusion cooled laser with RF excitation (courtesy of Rofin).

laser cavity (see Figure 7). Slow flow lasers operate in the power range 100 W to 1500 W, and tend to use a longitudinal DC electrical discharge which can be made to run continuously or pulsed if a thyratron switch is build into the power supply; alternatively, electrical power can be supplied via transverse RF excitation. The power scales with length, hence high power slow flow lasers have long cavities and require multiple cavity folds in order to reduce their physical size.

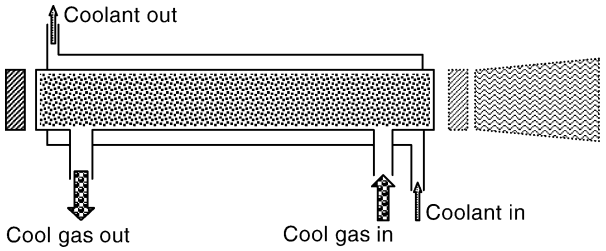

Figure 7 Slow flow CO_2 laser, approximately 100 W per meter of gain length, gas cooled by diffusion to the wall.

Fast Axial Flow Lasers

The fast axial flow laser, Figure 8, can provide output powers from 1 kW to 20 kW; it is this configuration that dominates the use of CO_2 lasers for industrial applications. Industrial lasers are usually in the power range 2–4 kW. The output power from these devices scales with mass flow, hence the gas mixture is recycled through the laser discharge region at sonic or supersonic velocities. Historically this was achieved using Rootes blowers to compress the gas upstream of the laser cavity. Rootes compressors are inherently inefficient and the more advanced laser systems utilize turbine compressors, which deliver greater efficiency and better laser stability. Rootes compressors can be a major source of vibration. With this arrangement heat exchangers are required to remove heat after the laser discharge region and also after the compressor stage, as the compression process heats up the laser gases. Catalyst packs are used to regenerate gases but some gas replacement is often required. These laser systems have short cavities and use folded stable resonator designs to achieve higher output powers with extremely high-quality beams that are particularly suitable for cutting applications. They also give excellent results when used for welding and surface treatments.

Fast axial flow lasers can be excited by a longitudinal DC discharge or a transverse RF discharge. Both types of electrical excitation are common. For materials processing applications it is often important to be able to run a laser in continuous wave (CW) mode or as a high pulse repetition rate (prf) pulsed laser and to be able to switch between CW and pulsed in real time; for instance, laser cutting of accurate internal corners is difficult using CW operation but very easy using the pulsed mode of operation. Both methods of discharge excitation can provide this facility.

Diffusion Cooled Laser

The diffusion-cooled slab laser is RF excited and gives an extremely compact design capable of delivering 4.5 kW pulsed from 8 Hz to 5 kHz prf or CW with good beam quality (see Figure 6). The optical resonator is formed by the front and rear mirrors and two parallel water cooled RF-electrodes. Diffusion cooling is provided by the RF-electrodes, removing the requirement for conventional gas recirculation via Rootes blowers or turbines.

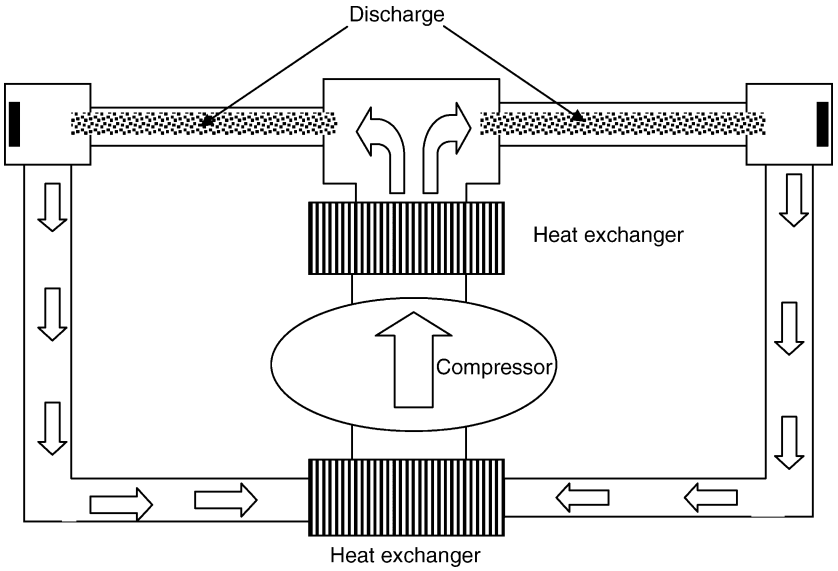

Figure 8 Fast axial flow carbon dioxide laser.

This design of laser results in a device with an extremely small footprint that has low maintenance and running costs. Applications include: cutting, welding, and surface engineering.

Fast Transverse Flow Laser

In the fast transverse flow laser (Figure 9a) the gas flow, electrical discharge, and the output beam are at right angles to each other (Figure 9b). The transverse discharge can be high voltage DC, RF, or pulsed up to 8 kHz (Figure 9c). Very high output power per unit discharge length can be obtained with an optimal total pressure (P) of ~100 Torr; systems are available delivering 10 kW of output power, CW or pulsed (see Figures 3a and b). The increase in total pressure requires a corresponding increase in the gas discharge electric field, E, as the ratio E/P must remain constant, since this determines the temperature of the discharge electrons, which have an optimum mean value (optimum energy distribution, Figure 2) for efficient excitation of the population inversion. With this high value of electric field, a longitudinal-discharge arrangement is impractical (500 kV for a 1 m discharge length); hence, the discharge is applied perpendicular to the optical axis. Fast transverse flow gas lasers provided the first multikilowatt outputs but tend to be expensive to maintain and operate. In order to obtain a reasonable beam quality, the output coupling is often obtained using a multipass unstable resonator. As the population inversion is available over a wide rectangular cross-section, this is a disadvantage of this arrangement and beam quality is not as good as that obtainable from fast axial flow designs. For this reason this type of laser is suitable for a wide range of welding and surface treatment applications.

Transversely Excited Atmospheric (TEA) Pressure

If the gas total pressure is increased above ~100 Torr it is difficult to sustain a stable glow discharge, because above this pressure instabilities degenerate into arcs within the discharge volume. This problem can be overcome by pulse excitation; using submicrosecond pulse duration, instabilities do not have sufficient time to develop; hence, the gas pressure can be increased above atmospheric pressure and the laser can be operated in a pulsed mode. In a mode locked format optical pulses shorter than 1 ns can be produced. This is called a TEA laser and with a transverse gas flow is capable of producing short high power pulses up to a few kHz repetition frequency. In order to prevent arc formation, TEA lasers usually employ ultraviolet or e-beam preionization of the gas discharge just prior to the main current pulse being applied via a thyratron switch. Output coupling is usually via an unstable resonator. TEA lasers are used for marking, remote sensing, range-finding, and scientific applications.

Conclusions

It is 40 years since Patel operated the first high power CO_2 laser. This led to the first generation of lasers which were quickly exploited for industrial laser materials processing, medical applications, defense,

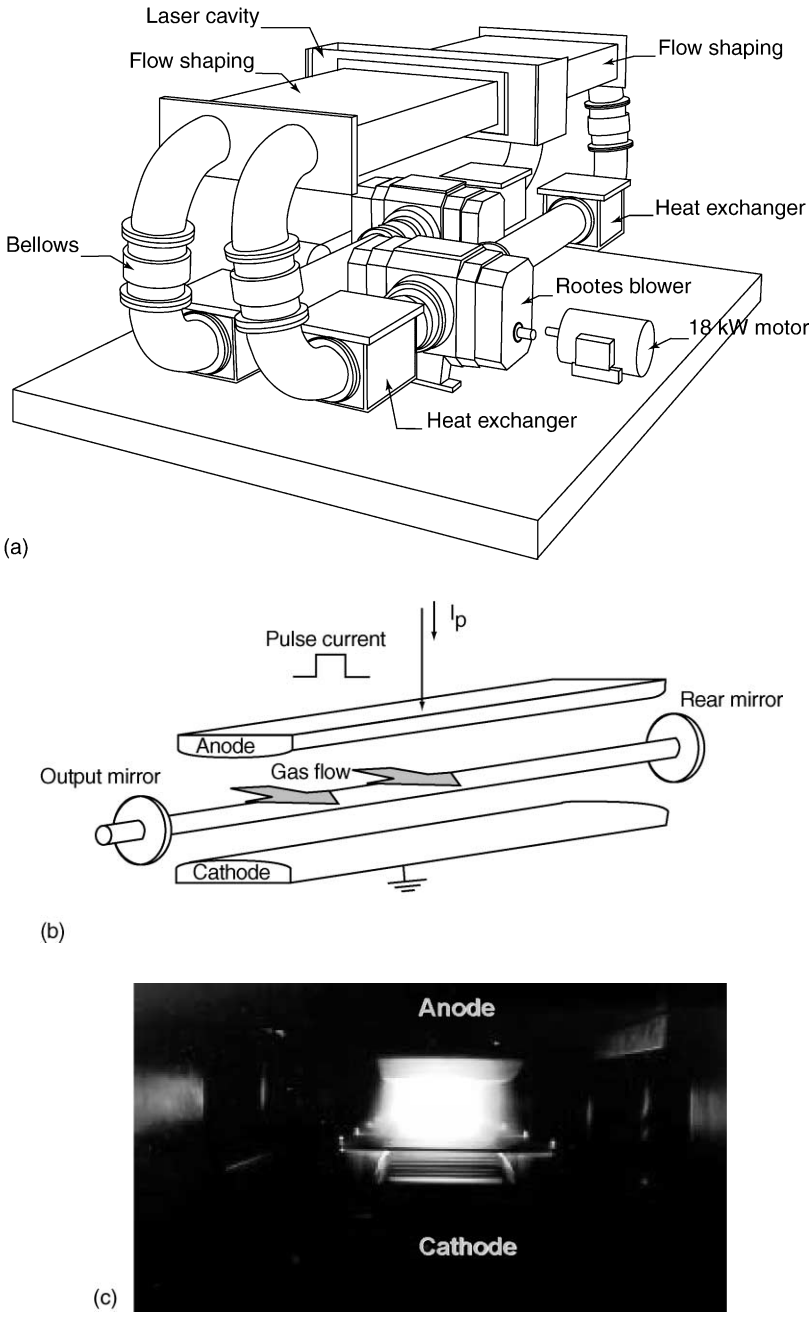

Figure 9 (a) Transverse flow carbon dioxide laser gas recirculator, (b) Transverse flow carbon dioxide electrodes, (c) Transverse flow carbon dioxide gas discharge as seen from the output window.

and scientific research applications; however, the first generation of lasers were quite unreliable and temperamental. After many design iterations, the CO_2 laser has now matured into a reliable, stable laser source available in many different geometries and power ranges. The low cost of ownership of the latest generation of CO_2 laser makes them a very attractive commercial proposition for many industrial and scientific applications. Commercial lasers incorporate many novel design features that are beyond the scope of this article and are often peculiar to the particular laser manufacturer. This includes gas additives and catalysts that may be required to stabilize the gas discharge of a particular laser design; it is this optimization of the laser design that has produced such reliable and controllable low-cost performance from the CO_2 laser.

List of Units and Nomenclature

α	The direct excitation of carbon dioxide (CO_2) ground state molecules (sec^{-1})
β	The direct de-excitation of nitrogen (N_2) (sec^{-1})
γ	The direct excitation of nitrogen (N_2) ground state molecules (sec^{-1})
η	The direct de-excitation of carbon dioxide (CO_2) (sec^{-1})
λ	wavelength (m)
σ	absorption coefficient (cm^2)
τ	Electrical current pulse length (μs)
τ_{sp}	Spontaneous emission life time of the upper laser level (sec)
$A = (\tau_{sp})^{-1} = 0.213(sec^{-1})$	The Einstein 'A' coefficient for the laser transition
c	velocity of light ($cm\ sec^{-1}$)
C_c	Coupling capacitance (nF)
CO_2	Carbon dioxide
e	subscript 'e' refers to the fact that the populations in the square brackets are the values for thermodynamic equilibrium
E	Electric Field ($V\ cm^{-1}$)
F_{CO_2}	Fraction of the input power (IP) coupled into the excitation of the energy level E_{00^01}
F_{N_2}	Fraction of the input power (IP) coupled into the excitation of the energy level $E_{v=1}$
g	gain (cm^{-1})
g_1 and g_2	energy level degeneracy's of levels 1 and 2
He	Helium
I	beam irradiance ($W\ cm^{-2}$)
I_0	beam irradiance at the center of a Gaussian laser beam ($W\ cm^{-2}$)
I_p	Photon population density ($photons\ cm^{-3}$)
I_p	Input current (A)
IP	Electrical input power ($W\ cm^{-3}$)
J	the rotational quantum number
K_{51}, K_{15}	Resonant energy transfer between the CO_2 (00^01) and $N_2(v = 2)$ energy levels proceeds via excited molecules colliding with ground state molecules (sec^{-1})
K_{132}, K_{2131}, K_{2231}	are vibration/vibration transfer rates (sec^{-1}) between energy levels 1 and 32; 21 and 31; 22 and 31, respectively (see Figure 1)
K_{320}	is a vibration/translation transfer rate (sec^{-1}) between energy levels 32 and 0 (see Figure 1)
K_{sp}, A	Spontaneous emission rate (sec^{-1})
L	The distance between the back and the front mirrors, which have reflectivity's of R_B and R_F (cm)
n	molecular population ($molecules\ cm^{-3}$)
N_2	Nitrogen
P	Pressure (Torr)
P_{CO_2}, P_{He} and P_{N_2}	The respective gas partial pressures (Torr)
P_{in}	Electrical input power (kW)
r	radius of laser beam (cm)
R_B	Back mirror reflectivity
R_F	Front mirror reflectivity
t	time (sec)
T	Temperature (deg K)
T_0	the photon decay time (sec)
w	the radial distance where the power density is decreased to $1/e^2$ of its axial value

Introduction

Background

Dye lasers are the original tunable lasers. Discovered in the mid-1960s these tunable sources of coherent radiation span the electromagnetic spectrum from the near-ultraviolet to the near-infrared (Figure 1). Dye lasers spearheaded and sustained the revolution in atomic and molecular spectroscopy and have found use in many and diverse fields from medical to military applications. In addition to their extraordinary spectral versatility, dye lasers have been shown to oscillate from the femtosecond pulse domain to the continuous wave (cw) regime. For microsecond pulse emission, energies of up to hundreds of joules per pulse have been demonstrated. Further, operation at high pulsed repetition frequencies (prfs), in the multi-kHz regime, has provided average powers at kW levels. This unrivaled operational versatility is summarized in Table 1.

Dye lasers are excited by coherent optical energy from an excitation, or pump, laser or by optical energy from specially designed lamps called flashlamps. Recent advances in semiconductor laser

technology have made it possible to construct very compact all-solid-state excitation sources that, coupled with new solid-state dye laser materials, should bring the opportunity to build compact tunable laser systems for the visible spectrum. Further, direct diode-laser pumping of solid-state dye lasers should prove even more advantageous to enable the development of fairly inexpensive tunable narrow-linewidth solid-state dye laser systems for spectroscopy and other applications requiring low powers. Work on electrically excited organic gain media might also provide new avenues for further progress.

The literature of dye lasers is very rich and many review articles have been written describing and discussing traditional dye lasers utilizing liquid gain media. In particular, the books *Dye Lasers*, *Dye Laser Principles*, *High Power Dye Lasers*, and *Tunable Lasers Handbook* provide excellent sources of authoritative and detailed description of the physics and technology involved. In this article we offer only a survey of the operational capabilities of the dye lasers using liquid gain media in order to examine with more attention the field of solid-state dye lasers.

Brief History of Dye Lasers

1965: Quantum theory of dyes is discussed in the context of the maser (R. P. Feynman).
1966: Dye lasers are discovered (P. P. Sorokin and J. R. Lankard; F. P. Schäfer and colleagues).
1967: The flashlamp-pumped dye laser is discovered (P. P. Sorokin and J. R. Lankard; W. Schmidt and F. P. Schäfer).
1967–1968: Solid-state dye lasers are discovered (B. H. Soffer and B. B. McFarland; O. G. Peterson and B. B. Snavely).
1968: Mode-locking, using saturable absorbers, is demonstrated in dye lasers (W. Schmidt and F. P. Schäfer).
1970: The continuous-wave (cw) dye laser is discovered (O. G. Peterson, S. A. Tuccio, and B. B. Snavely).
1971: The distributed feedback dye laser is discovered (H. Kogelnik and C. V. Shank).
1971–1975: Prismatic beam expansion in dye lasers is introduced (S. A. Myers; E. D. Stokes and colleagues; D. C. Hanna and colleagues).
1972: Passive mode-locking is demonstrated in cw dye lasers (E. P. Ippen, C. V. Shank, and A. Dienes).
1972: The first pulsed narrow-linewidth tunable dye laser is introduced (T. W. Hänsch).
1973: Frequency stabilization of cw dye lasers is demonstrated (R. L. Barger, M. S. Sorem, and J. L. Hall).
1976: Colliding-pulse-mode locking is introduced (I. S. Ruddock and D. J. Bradley).
1977–1978: Grazing-incidence grating cavities are introduced (I. Shoshan and colleagues; M. G. Littman and H. J. Metcalf; S. Saikan).
1978–1980: Multiple-prism grating cavities are introduced (T. Kasuya and colleagues; G. Klauminzer; F. J. Duarte and J. A. Piper).
1981: Prism pre-expanded grazing-incidence grating oscillators are introduced (F. J. Duarte and J. A. Piper).
1982: Generalized multiple-prism dispersion theory is introduced (F. J. Duarte and J. A. Piper).
1983: Prismatic negative dispersion for pulse compression is introduced (W. Dietel, J. J. Fontaine, and J-C. Diels).
1987: Laser pulses as short as six femtoseconds are demonstrated (R. L. Fork, C. H. Brito Cruz, P. C. Becker, and C. V. Shank).
1994: First narrow-linewidth solid-state dye laser oscillator (F. J. Duarte).
1999–2000: Distributed feedback solid-state dye lasers are introduced (Wadsworth and colleagues; Zhu and colleagues).

Molecular Energy Levels

Dye molecules have large molecular weights and contain extended systems of conjugated double bonds. These molecules can be dissolved in an adequate organic solvent (such as ethanol, methanol, ethanol/water, and methanol/water) or incorporated into a solid matrix (organic, inorganic, or hybrid). These molecular gain media have a strong absorption generally in the visible and ultraviolet regions, and exhibit large fluorescence bandwidths covering the entire visible spectrum. The general energy level diagram of an organic dye is shown in Figure 2. It consists of electronic singlet and triplet states with each electronic state containing a multitude of overlapping vibrational–rotational levels giving rise to broad continuous energy bands. Absorption of visible or ultraviolet pump light excites the molecules from the ground state S_0 into some rotational–vibrational level belonging to an upper excited singlet state, from where the molecules decay nonradiatively to the lowest vibrational level of the first excited singlet state S_1 on a picosecond time-scale. From S_1 the molecules can decay radiatively, with a radiative lifetime on the nanosecond time-scale, to a higher-lying vibrational–rotational level of S_0. From this level they rapidly thermalize into the lowest vibrational–rotational levels of S_0. Alternatively, from S_1, the molecules can experience nonradiative relaxation either to the triplet state T_1 by an intersystem crossing process or to the ground state by an internal conversion process. If the intensity of the pumping radiation is high enough a population inversion between S_1 and S_0 may be attained and stimulated emission occurs. Internal conversion and intersystem crossing compete with the fluorescence decay mode of the molecule and therefore reduce the efficiency of the laser emission. The rate for internal conversion to the electronic ground state is usually negligibly small so that the most important loss process is intersystem crossing into T_1 that populates the lower metastable triplet state. Thus, absorption on the triplet–triplet allowed transitions could cause considerable losses if these absorption bands overlap the lasing band, inhibiting or even halting the lasing process. This triplet loss can be reduced by adding small quantities of appropriate chemicals that favor nonradiative transitions that shorten the effective lifetime of the T_1 level. For pulsed excitation with nanosecond pulses, the triplet–triplet absorption can be neglected because for a typical dye the intersystem crossing rate is not fast enough to build up an appreciable triplet population in the nanosecond time domain.

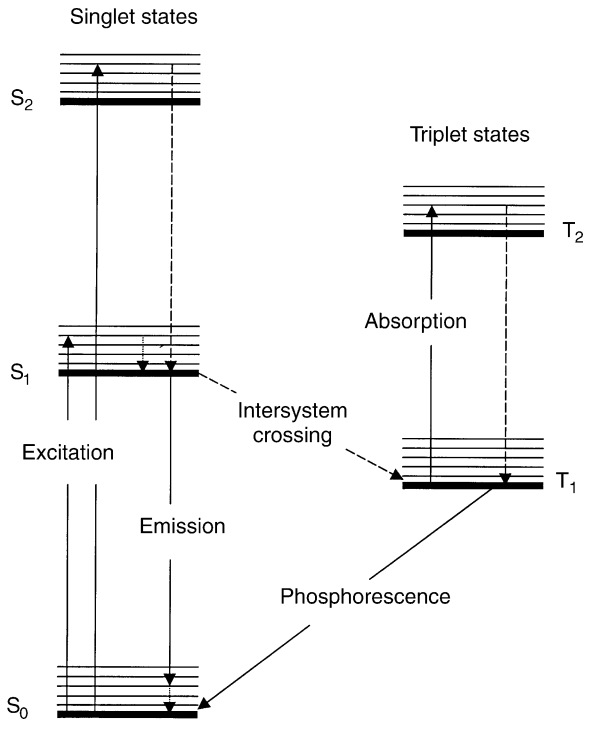

Figure 2 Schematic energy level diagram for a dye molecule. Full lines: radiative transitions; dashed lines: nonradiative transitions; dotted lines: vibrational relaxation.

Dye molecules are large (a typical molecule incorporates 50 or more atoms) and are grouped into families with similar chemical structures. A survey of the major classes of laser dyes is given later. Solid-state laser dye gain media are also considered later.

Liquid Dye Lasers

Laser-Pumped Pulsed Dye Lasers

Laser-pumped dye lasers use a shorter wavelength, or higher frequency, pulsed laser as the excitation or pump source. Typical pump lasers for dye lasers are gas lasers such as the excimer, nitrogen, or copper lasers. One of the most widely used solid-state laser pumps is the frequency doubled Nd:YAG laser which emits at 532 nm.

In a laser-pumped pulsed dye laser the active medium, or dye solution, is contained in an optical cell often made of quartz or fused silica, which provides an active region typically some 10 mm in length and a few mm in width. The active medium is then excited either longitudinally, or transversely, via a focusing lens using the pump laser. In the case of transverse excitation the pump laser is focused to a beam $\sim$10 mm in width and $\sim$0.1 mm in height. Longitudinal pumping requires focusing of the excitation beam to a diameter in the 0.1–0.15 mm range. For lasers operated at low prfs (a few pulses per

second), the dye solution might be static. However, for high-prf operation (a few thousand pulses per second) the dye solution must be flowed at speeds of up to a few meters per second in order to dissipate the heat. A simple broadband optically pumped dye laser can be constructed using just the pump laser, the active medium, and two mirrors to form a resonator. In order to achieve tunable, narrow-linewidth, emission, a more sophisticated resonator must be employed. This is called a dispersive tunable oscillator and is depicted in Figure 3. In a dispersive tunable oscillator the exit side of the cavity is comprised of a partial reflector, or an output coupler, and the other end of the resonator is composed of a multiple-prism grating assembly. It is the dispersive characteristics of this multiple-prism grating assembly and the dimensions of the emission beam produced at the gain medium that determine the tunability and the narrowness, or spectral purity, of the laser emission.

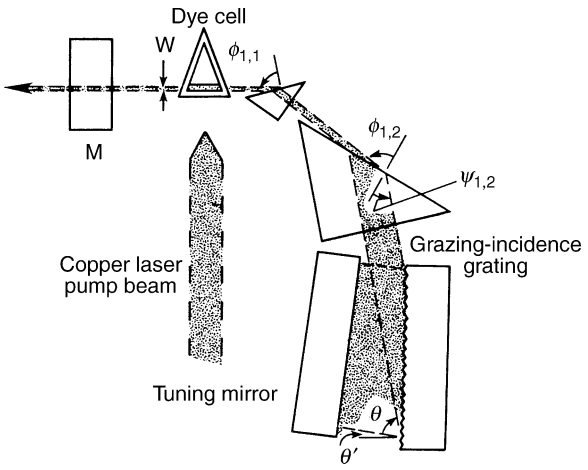

Figure 3 Copper-vapor-laser pumped hybrid multiple-prism near grazing incidence (HMPGI) grating dye laser oscillator. Adapted with permission from Duarte FJ and Piper JA (1984) Narrow linewidth high prf copper laser-pumped dye-laser oscillators. *Applied Optics* 23: 1391–1394.

In order to selectively excite a single vibrational–rotational level of a molecule such as iodine (I_2), at room temperature, one needs a laser linewidth of $\Delta\nu \approx 1.5$ GHz (or $\Delta\lambda \approx 0.0017$ nm at $\lambda = 590$ nm). The hybrid multiple-prism near-grazing-incidence (HMPGI) grating dye laser oscillator illustrated in Figure 4 yields laser linewidths in the 400 MHz $\leq \Delta\nu \leq$ 650 MHz range at 4–5% conversion efficiencies whilst excited by a copper-vapor laser operating at a prf of 10 kHz. Pulse lengths are ~10 ns at full-width half-maximum (FWHM). The narrow-linewidth emission from these oscillators is said to be single-longitudinal-mode lasing because only one electromagnetic mode is allowed to oscillate.

The emission from oscillators of this class can be amplified many times by propagating the tunable narrow-linewidth laser beam through single-pass amplifier dye cells under the excitation of pump lasers. Such amplified laser emission can reach enormous average powers. Indeed, a copper-vapor-laser pumped dye laser system at the Lawrence Livermore National Laboratory (USA), designed for the laser isotope separation program, was reported to

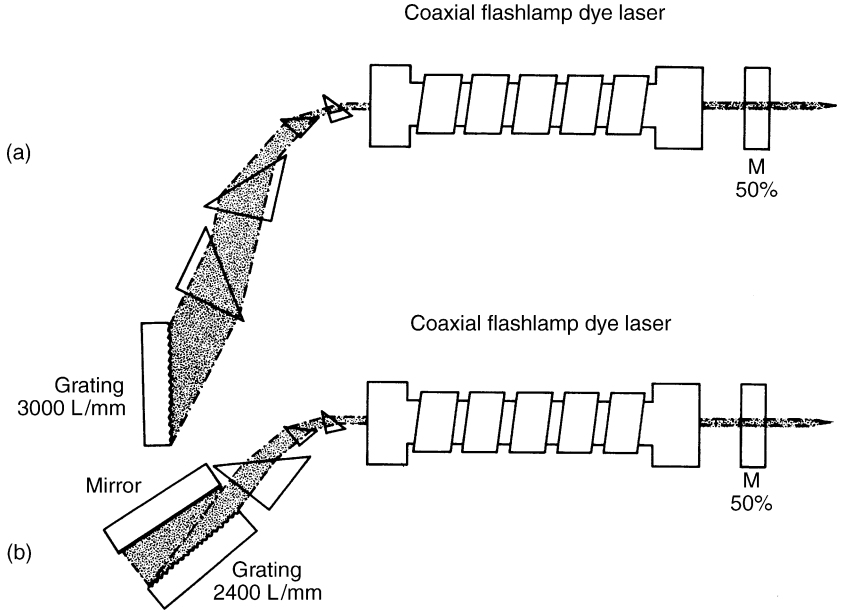

Figure 4 Flashlamp-pumped multiple-prism grating oscillators. From Duarte FJ, Davenport WE, Ehrlich JJ and Taylor TS (1991) Ruggedized narrow-linewidth dispersive dye laser oscillator. *Optics Communications* 84: 310–316. Reproduced with permission from Elsevier.

yield average powers in excess of 2.5 kW, at a prf of 13.2 kHz, at a better than 50% conversion efficiency as reported by Bass and colleagues in 1992. Besides high conversion efficiencies, excitation with copper-vapor lasers, at $\lambda = 510.554$ nm, has the advantage of inducing little photodegradation in the active medium thus allowing very long dye lifetimes.

Flashlamp-Pumped Dye Lasers

Flashlamps utilized in dye laser excitation emit at black-body temperatures in the 20 000 K range, thus yielding intense ultraviolet radiation centered around 200 nm. One further requirement for flashlamps, and their excitation circuits, is to deliver light pulses with a fast rise time. For some flashlamps this rise time can be less than a few nanoseconds.

Flashlamp-pumped dye lasers differ from laser-pumped pulsed dye lasers mainly in the pulse energies and pulse lengths attainable. This means that flashlamp-pumped dye lasers, using relatively large volumes of dye, can yield very large energy pulses. Excitation geometries use either coaxial lamps, with the dye flowing in a quartz cylinder at the center of the lamp, or two or more linear lamps arranged symmetrically around the quartz tube containing the dye solution. Using a relatively weak dye solution of rhodamine-6G (2.2×10^{-5} M), a coaxial lamp, and an active region defined by a quartz tube 6 cm in diameter and a length of 60 cm, Baltakov and colleagues, in 1974, reported energies of 400 J in pulses 25 μs long at FWHM.

Flashlamp-pumped tunable narrow-linewidth dye laser oscillators described by Duarte and colleagues, in1991, employ a cylindrical active region 6 mm in diameter and 17 cm in length. The dye solution is made of rhodamine 590 at a concentration of 1×10^{-5} M. This active region is excited by a coaxial flashlamp. Using multiple-prism grating architectures (see Figure 4) these authors achieve a diffraction limited TEM_{00} laser beam and laser linewidths of $\Delta\nu \approx 300$ MHz at pulsed energies in the 2–3 mJ range. The laser pulse duration is reported to be $\Delta t \approx 100$ ns. The laser emission from this class of multiple-prism grating oscillator is reported to be extremely stable. The tunable narrow-linewidth emission from these dispersive oscillators is either used directly in spectroscopic, or other scientific applications, or is utilized to inject large flashlamp-pumped dye laser amplifiers to obtain multi-joule pulse energies with the laser linewidth characteristics of the oscillator.

Continuous Wave Dye Lasers

CW dye lasers use dye flowing at linear speeds of up to 10 meters per second which are necessary to remove the excess heat and to quench the triplet states. In the original cavity reported by Peterson and colleagues, in 1970, a beam from an Ar^+ laser was focused on to an active region which is contained within the resonator. The resonator comprised dichroic mirrors that transmit the blue-green radiation of the pump laser and reflect the red emission from the dye molecules. Using a pump power of about 1 W, in a TEM_{00} laser beam, these authors reported a dye laser output of 30 mW. Subsequent designs replaced the dye cell with a dye jet, an introduced external mirror, and integrated dispersive elements in the cavity. Dispersive elements such as prisms and gratings are used to tune the wavelength output of the laser. Frequency-selective elements, such as etalons and other types of interferometers, are used to induce frequency narrowing of the tunable emission. Two typical cw dye laser cavity designs are described by Hollberg, in 1990, and are reproduced here in Figure 5. The first design is a linear three-mirror folded cavity. The second one is an eight-shaped ring dye laser cavity comprised of mirrors M_1, M_2, M_3, and M_4. Linear cavities exhibit the effect of *spatial hole burning* which allows the cavity to lase in more than one longitudinal mode. This problem can be overcome in ring cavities (Figure 5b) where the laser emission is in the form of a traveling wave.

Two aspects of cw dye lasers are worth emphasizing. One is the availability of relatively high powers in single longitudinal mode emission and the other is the

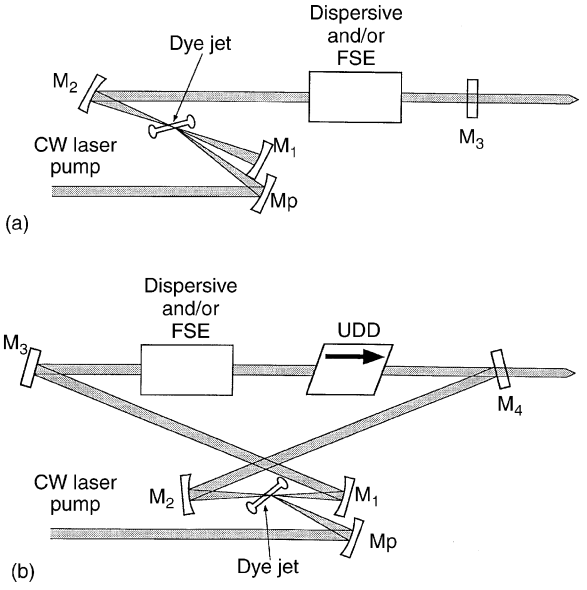

Figure 5 CW laser cavities: (a) linear cavity and (b) ring cavity. Adapted from Hollberg LW (1990) CW dye lasers. In: Duarte FJ and Hillman LW (eds) *Dye Laser Principles*, pp. 185–238. New York: Academic Press. Reproduced with permission from Elsevier.

demonstration of very stable laser oscillation. First, Johnston and colleagues, in 1982, reported 5.6 W of stabilized laser output in a single longitudinal mode at 593 nm at a conversion efficiency of 23%. In this work eleven dyes were used to span the spectrum continuously from ~400 nm to ~900 nm. In the area of laser stabilization and ultra narrow-linewidth oscillation it is worth mentioning the work of Hough and colleagues, in 1984, that achieved laser linewidths of less than 750 Hz employing an external reference cavity.

Ultrashort-Pulse Dye Lasers

Ultrashort-pulse, or femtosecond, dye lasers use the same type of technology as cw dye lasers configured to incorporate a saturable absorber region. One such configuration is the ring cavity depicted in Figure 6. In this cavity the gain region is established between mirrors M_1 and M_2 whilst the saturable absorber is deployed in a counter-propagating arrangement. This arrangement is necessary to establish a collision between two counter-propagating pulses at the saturable absorber thus yielding what is known as colliding-pulse mode locking (CPM) as reported by Ruddock and Bradley, in 1976. This has the effect of creating a transient grating, due to interference, at the absorber thus shortening the pulse. Intracavity prisms were incorporated in order to introduce negative dispersion, by Dietel and colleagues in 1983, and thus subtract dispersion from the cavity and ultimately provide the compensation needed to produce femtosecond pulses.

The shortest pulse obtained from a dye laser, 6 fs, has been reported by Fork and colleagues, in 1987, using extra-cavity compression. In that experiment, a dye laser incorporating CPM and prismatic compensation was used to generate pulses that were amplified by a copper-vapor laser at a prf of 8 kHz. The amplified pulses, of a duration of 50 fs, were then propagated through two grating pairs and a four-prism sequence for further compression.

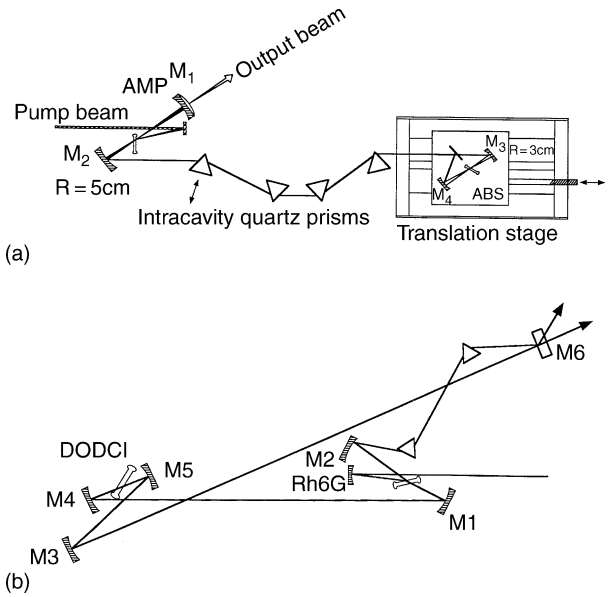

Figure 6 Femtosecond dye laser cavities: (a) linear femtosecond cavity and (b) ring femtosecond cavity. Adapted from Diels J-C (1990) Femtosecond dye lasers. In: Duarte FJ and Hillman LW (eds) *Dye Laser Principles*, pp. 41–132. New York: Academic Press. Reproduced with permission from Elsevier.

Solid-State Dye Laser Oscillators

In this section the principles of linewidth narrowing in dispersive resonators are outlined. Albeit the discussion focuses on multiple-prism grating solid-state dye laser oscillators, in particular, the physics is applicable to pulsed high-power dispersive tunable lasers in general.

Multiple-Prism Dispersion Grating Theory

The spectral linewidth in a dispersive optical system is given by

$$\Delta\lambda \approx \Delta\theta(\nabla_\lambda \theta)^{-1} \qquad [1]$$

where $\Delta\theta$ is the light beam divergence, $\nabla_\lambda = \partial/\partial\lambda$, and $\nabla_\lambda\theta$ is the overall dispersion of the optics. This identity can de derived either from the principles of geometrical optics or from the principles of generalized interferometry as described by Duarte, in 1992.

The cumulative single-pass generalized multiple-prism dispersion at the mth prism, of a multiple-prism array as illustrated in Figure 7, as given by Duarte and Piper, in 1982,

$$\nabla_\lambda \phi_{2,m} = H_{2,m}\nabla_\lambda n_m + (k_{1,m}k_{2,m})^{-1} \times \left(H_{1,m}\nabla_\lambda n_m \pm \nabla_\lambda \phi_{2,(m-1)}\right) \qquad [2]$$

In this equation

$$k_{1,m} = \cos\psi_{1,m}/\cos\phi_{1,m} \qquad [3a]$$

$$k_{2,m} = \cos\phi_{2,m}/\cos\psi_{2,m} \qquad [3b]$$

$$H_{1,m} = \tan\phi_{1,m}/n_m \qquad [4a]$$

$$H_{2,m} = \tan\phi_{2,m}/n_m \qquad [4b]$$

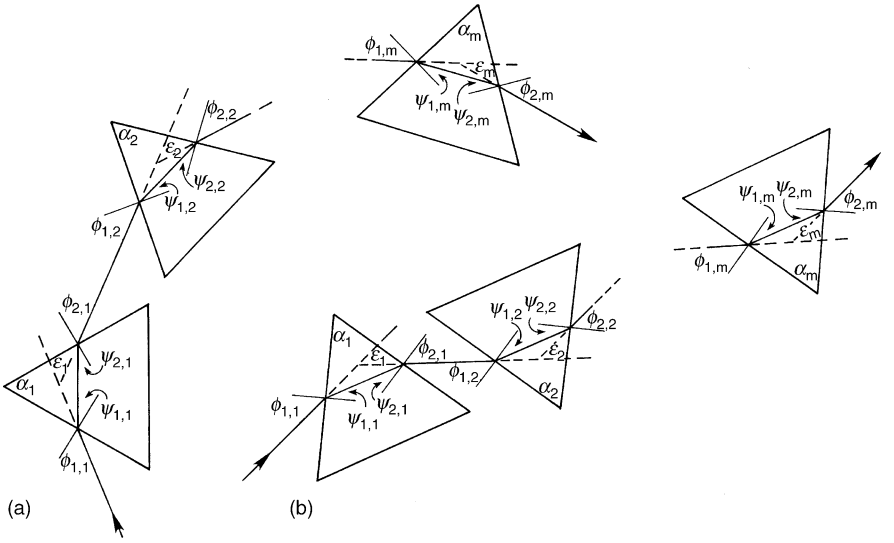

Figure 7 Generalized multiple-prism arrays in (a) additive and (b) compensating configurations. From Duarte FJ (1990) Narrow-linewidth pulsed dye laser oscillators. In: Duarte FJ and Hillman LW (eds) *Dye Laser Principles*, pp. 133–183. New York: Academic Press. Reproduced with permission from Elsevier.

Here, $k_{1,m}$ and $k_{2,m}$ represent the physical beam expansion experienced by the incident and the exit beams, respectively.

Equation [2] indicates that $\nabla_\lambda \phi_{2,m}$, the cumulative dispersion at the mth prism, is a function of the geometry of the mth prism, the position of the light beam relative to this prism, the refractive index of the prism, and the cumulative dispersion up to the previous prism $\nabla_\lambda \phi_{2,(m-1)}$.

For an array of r identical isosceles, or equilateral, prisms arranged symmetrically, in an additive configuration, so that the angles of incidence and emergence are the same, the cumulative dispersion reduces to

$$\nabla_\lambda \phi_{2,r} = r \nabla_\lambda \phi_{2,1} \qquad [5]$$

Under these circumstances the dispersions add in a simple and straightforward manner. For configurations incorporating right-angle prisms, the dispersions need to be handled mathematically in a more subtle form.

The generalized double-pass, or return-pass, dispersion for multiple-prism beam expanders was introduced by Duarte, in 1985:

$$\nabla_\lambda \Phi_P = 2M_1 M_2 \sum_{m=1}^{r} (\pm 1) H_{1,m} \left(\prod_{j=m}^{r} k_{1,j} \prod_{j=m}^{r} k_{2,j} \right)^{-1} \nabla_\lambda n_m + 2 \sum_{m=1}^{r} (\pm 1) H_{2,m} \left(\prod_{j=1}^{m} k_{1,j} \prod_{j=1}^{m} k_{2,j} \right) \nabla_\lambda n_m \qquad [6]$$

Here, M_1 and M_2 are the beam magnification factors given by

$$M_1 = \prod_{m=1}^{r} k_{1,m} \qquad [7a]$$

$$M_2 = \prod_{m=1}^{r} k_{2,m} \qquad [7b]$$

For a multiple prism expander designed for an orthogonal beam exit, and Brewster's angle of incidence, eqn [6] reduces to the succinct expression given by Duarte, in 1990:

$$\nabla_\lambda \Phi_P = 2 \sum_{m=1}^{r} (\pm 1)(n_m)^{m-1} \nabla_\lambda n_m \qquad [8]$$

Equation [6] can be used to either quantify the overall dispersion of a given multiple-prism beam expander or to design a prismatic expander yielding zero dispersion, that is, $\nabla_\lambda \Phi_P = 0$, at a given wavelength.

Physics and Architecture of Solid-State Dye-Laser Oscillators

The first high-performance narrow-linewidth tunable laser was introduced by Hänsch in 1972. This laser yielded a linewidth of $\Delta\nu \approx 2.5$ GHz (or $\Delta\lambda \approx 0.003$ nm at $\lambda \approx 600$ nm) in the absence of an intracavity etalon. Hänsch demonstrated that the laser linewidth from a tunable laser was narrowed significantly when the beam incident on the tuning grating was expanded using an astronomical

telescope. The linewidth equation including the intracavity beam magnification factor can be written as

$$\Delta\lambda \approx \Delta\theta(M\nabla_\lambda\Theta_G)^{-1} \qquad [9]$$

From this equation, it can be deduced that a narrow $\Delta\lambda$ is achieved by reducing $\Delta\theta$ and increasing the overall intracavity dispersion ($M\nabla_\lambda\Theta_G$). The intracavity dispersion is optimized by expanding the size of the intracavity beam incident on the diffractive surface of the tuning grating until it is totally illuminated.

Hänsch used a two-dimensional astronomical telescope to expand the intracavity beam incident on the diffraction grating. A simpler beam expansion method consists in the use of a single-prism beam expander as disclosed by several authors (Myers, 1971; Stokes and colleagues, 1972; Hanna and colleagues, 1975). An extension and improvement of this approach was the introduction of multiple-prism beam expanders as reported by Kasuya and colleagues, in 1978, Klauminzer, in 1978, and Duarte and Piper, in 1980. The main advantages of multiple-prism beam expanders, over two-dimensional telescopes, are simplicity, compactness, and the fact that the beam expansion is reduced from two dimensions to one dimension. Physically, as explained previously, prismatic beam expanders also introduce a dispersion component that is absent in the case of the astronomical telescope. Advantages of multiple-prism beam expanders over single-prism beam expansion are higher transmission efficiency, lower amplified spontaneous emission levels, and the flexibility to either augment or reduce the prismatic dispersion.

In general, for a pulsed multiple-prism grating oscillator, Duarte and Piper, in 1984, showed that the return-pass dispersive linewidth is given by

$$\Delta\lambda = \Delta\theta_R(MR\nabla_\lambda\Theta_G + R\nabla_\lambda\Phi_P)^{-1} \qquad [10]$$

where R is the number of return-cavity passes. The grating dispersion in this equation, $\nabla_\lambda\Theta_G$, can be either from a grating in Littrow or near grazing-incidence configuration. The multiple-return-pass equation for the beam divergence was given by Duarte, in 2001:

$$\Delta\theta_R = (\lambda/\pi w)\left(1 + (L_R/B_R)^2 + (A_R L_R/B_R)^2\right)^{1/2} \qquad [11]$$

Here, $L_R = (\pi w^2/\lambda)$ is the Rayleigh length of the cavity, w is the beam waist at the gain region, while A_R and B_R are the corresponding multiple-return-pass elements derived from propagation matrices.

At present, very compact and optimized multiple-prism grating tunable laser oscillators are found in two basic cavity architectures. These are the multiple-prism Littrow (MPL) grating laser oscillator, reported by Duarte in 1999 and illustrated in Figure 8, and the hybrid multiple-prism near grazing-incidence (HMPGI) grating laser oscillator, introduced by Duarte in 1997 and depicted in Figure 9. In early MPL grating oscillators the individual prisms integrating the multiple-prism expander were deployed in an additive configuration thus adding the cumulative dispersion to that of the grating and thus contributing to the overall dispersion of the cavity. In subsequent architectures the prisms were deployed in compensating configurations so as to yield zero dispersion and thus allow the tuning characteristics of the cavity to be

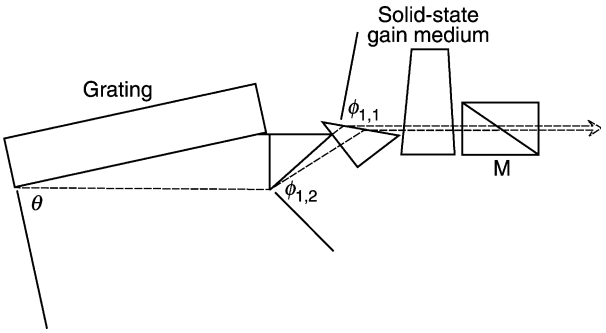

Figure 8 MPL grating solid-state dye laser oscillator: optimized architecture. The physical dimensions of the optical components of this cavity are shown to scale. The length, of the solid-state dye gain medium, along the optical axis, is 10 mm. Reproduced with permission from Duarte FJ (1999) Multiple-prism grating solid-state dye laser oscillator: optimized architecture. *Applied Optics* 38: 6347–6349.

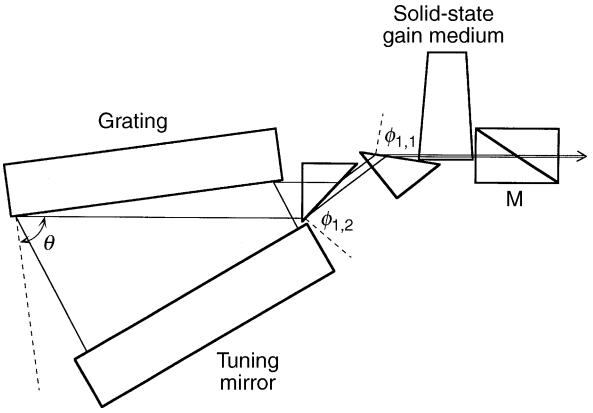

Figure 9 HMPGI grating solid-state dye laser. Schematics to scale. The length of the solid state dye gain medium, along the optical axis, is 10 mm. determined by the grating exclusively. In this approach the principal role of the multiple-prism array is to expand the beam incident on the grating thus augmenting significantly the overall dispersion of the cavity as described in eqns [9] or [10]. In this regard, it should be mentioned that beam magnification factors of up to 100, and beyond, have been reported in the literature. Using solid-state laser dye gain media, these MPL and HMPGI grating laser oscillators deliver tunable single-longitudinal-mode emission at laser linewidths 350 MHz $\leq \Delta\nu \leq$ 375 MHz and pulse lengths in the 3–7 ns (FWHM) range. Long-pulse operation of this class of multiple-prism grating oscillators has been reported by Duarte and colleagues, in 1998. In these experiments laser linewidths of $\Delta\nu \approx$ 650 MHz were achieved at pulse lengths in excess of 100 ns (FWHM) under flashlamp-pumped dye laser excitation.

The dispersive cavity architectures described here have been used with a variety of laser gain media in the gas, the liquid, and the solid state. Applications to tunable semiconductor lasers have also been reported by Zorabedian, in 1992, Duarte, in 1993, and Fox and colleagues, in 1997.

Concepts important to MPL and HMPGI grating tunable laser oscillators include the emission of a single-transverse-mode (TEM_{00}) laser beam in a compact cavity, the use of multiple-prism arrays, the expansion of the intracavity beam incident on the grating, the control of the intracavity dispersion, and the quantification of the overall dispersion of the multiple-prism grating assembly via generalized dispersion equations. Sufficiently high intracavity dispersion leads to the achievement of return-pass dispersive linewidths close to the free-spectral range of the cavity. Under these circumstances single-longitudinal-mode lasing is readily achieved as a result of multipass effects.

A Note on the Cavity Linewidth Equation

So far we have described how the cavity linewidth equation

$$\Delta\lambda \approx \Delta\theta(\nabla_\lambda \theta)^{-1}$$

and the dispersion equations can be applied to achieve highly coherent, or very narrow-linewidth, emission. It should be noted that the same physics can be applied to achieve ultrashort, or femtosecond, laser pulses. It turns out that intracavity prisms can be configured to yield negative dispersion as described by Duarte and Piper, in 1982, Dietel and colleagues, in 1983, and Fork and colleagues in 1984. This negative dispersion can reduce significantly the overall dispersion of the cavity. Under those circumstances, eqn [1] predicts broadband emission which according to the uncertainty principle, in the form of,

$$\Delta\nu\Delta t \approx 1 \qquad [12]$$

can lead to very short pulse emission since $\Delta\nu$ and $\Delta\lambda$ are related by the identities

$$\Delta\lambda \approx \lambda^2/\Delta x \qquad [13]$$

and

$$\Delta\nu \approx c/\Delta x \qquad [14]$$

Distributed-Feedback Solid-State Dye Lasers

Recently, narrow-linewidth laser emission from solid-state dye lasers has also been obtained using a distributed-feedback (DFB) configuration by Wadsworth and colleagues, in 1999, and Zhu and colleagues, in 2000. As is well known, in a DFB laser no external cavity is required, the feedback being provided by Bragg reflection from a permanently or dynamically written grating structure within the gain medium as reported by Kogelnik and Shank, in 1971. By using a DFB laser configuration where the interference of two pump beams induces the required periodic modulation in the gain medium, laser emission with linewidth in the 0.01–0.06 nm range have been reported. Specifically, Wadsworth and colleagues reported a laser linewidth of 12 GHz (0.016 nm at 616 nm) using Perylene Red doped PMMA at a conversion efficiency of 20%.

It should also be mentioned that the DFB laser is also a dye laser development that has found wide and extensive applicability in semiconductor lasers employed in the telecommunications industry.

Laser Dye Survey

Cyanines

These are red and near-infrared dyes which present long conjugated methine chains (!CH = CH!) and are useful in the spectral range longer than 800 nm, where no other dyes compete with them. An important laser dye belonging to this class is 4-dicyanomethylene-2-methyl-6-(*p*-dimethylamino-styryl)-4H-pyran (DCM, **Figure 10a**), with laser emission in the 600–700 nm range depending on the pump and solvent, liquid or solid, used.

Xanthenes

These dyes have a xanthene ring as the chromophore and are classified into rhodamines, incorporating

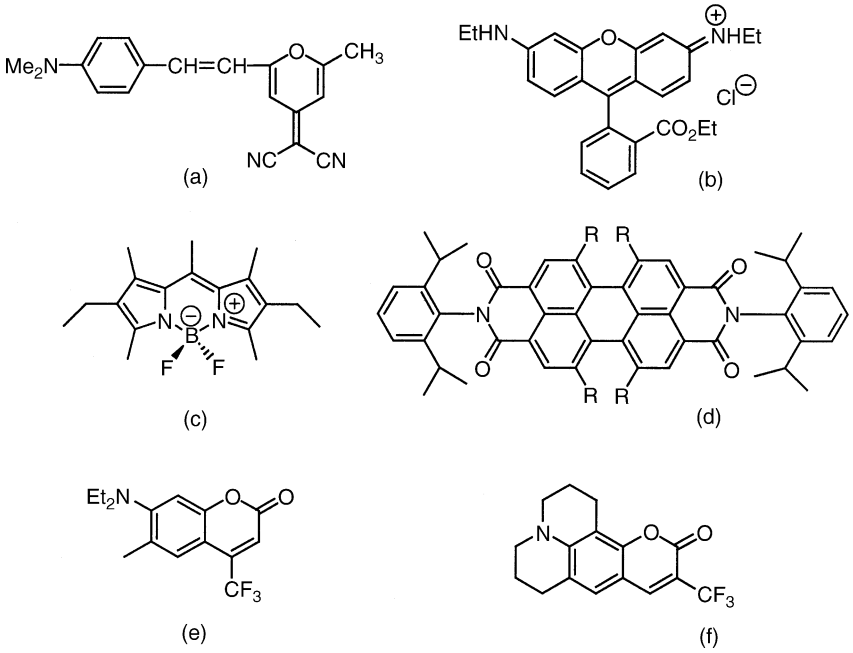

Figure 10 Molecular structures of some common laser dyes: (a) DCM; (b) Rh6G; (c) PM567; (d) Perylene Orange (R = H) and Perylene Red (R = C_4H_6O); (e) Coumarin 307 (also known as Coumarin 503); (f) Coumarin 153 (also known as Coumarin 540A).

amino radicals substituents, and fluoresceins, with hydroxyl (OH) radical substituents. They are generally very efficient and chemically stable and their emission covers the wavelength region from 500 to 700 nm.

Rhodamine dyes are the most important group of all laser materials, with rhodamine 6G (Rh6G, Figure 10b), also called rhodamine 590 chloride, being probably the best known of all laser dyes. Rh6G exhibits an absorption peak, in ethanol, at 530 nm and a fluorescence peak at 556 nm, with laser emission typically in the 550–620 nm region. It has been demonstrated to lase efficiently both in liquid and solid solutions.

Pyrromethenes

Pyrromethene.BF_2 complexes are a new class of laser dyes synthesized and characterized more recently as reported by Shah and colleagues, in 1990, Pavlopoulos and colleagues, in 1990, and Boyer and colleagues, in 1993. These laser dyes exhibit reduced triplet–triplet absorption over their fluorescence and lasing spectral region while retaining a high quantum fluorescence yield. Depending on the substituents on the chromophore, these dyes present laser emission over the spectral region from the green/yellow to the red, competing with the rhodamine dyes and have been demonstrated to lase with good performance when incorporated into solid hosts. Unfortunately, they are relatively unstable because of the aromatic amine groups in their structure, which render them vulnerable to photochemical reactions with oxygen as indicated by Rahn and colleagues, in 1997. The molecular structure of a representative and well-known dye of this class, 1,3,5,7,8-pentamethyl-2,6-diethylpyrromethene-difluoroborate complex (pyrromethene 567, PM567) is shown in Figure 10c. Recently, analogs of dye PM567 substituted at position 8 with an acetoxypolymethylene linear chain or a polymerizable methacryloyloxy polymethylene chain have been developed. These new dipyrromethene.BF_2 complexes have demonstrated improved efficiency and better photostability than the parent compound both in liquid and solid state.

Conjugated Hydrocarbons

This class of organic compounds includes perylenes, stilbenes, and *p*-terphenyl. Perylene and perylimide dyes are large, nonionic, nonpolar molecules (Figure 10d) characterized by their extreme photostability and negligible singlet–triplet transfer, as discussed by Seybold and Wagenblast and colleagues, in 1989, which have high quantum efficiency because of the absence of nonradiative relaxation. The perylene dyes exhibit limited solubility in conventional solvents but dissolve well in acetone, ethyl acetate, and methyl methacrylate, with emission wavelengths in the orange and red spectral regions.

Stilbene dyes are derivatives of uncyclic unsaturated hydrocarbons such as ethylene and butadiene, with emission wavelengths in the 400–500 nm range. Most of them end in phenyl radicals. Although they

are chemically stable, their laser performance is inferior to that of coumarins. *p*-Terphenyl is a valuable and efficient *p*-oligophenylene dye with emission in the ultraviolet.

Coumarins

Coumarin derivatives are a popular family of laser dyes with emission in the blue-green region of the spectrum. Their structure is based on the coumarin ring (**Figure 10e,f**) with different substituents that strongly affect its chemical characteristics and allow covering an emission spectral range between 420 and 580 nm. Some members of this class rank among the most efficient laser dyes known, but their chemical photobleaching is rapid compared with xanthene and pyrromethene dyes. An additional class of blue-green dyes is the tetramethyl derivatives of coumarin dyes introduced by Chen and colleagues, in 1988. The emission from these dyes spans the spectrum in the 453–588 nm region. These coumarin analogs exhibit improved efficiency, higher solubility, and better lifetime characteristics than the parent compounds.

Azaquinolone Derivatives

The quinolone and azaquinolone derivatives have a structure similar to that of coumarins but with their laser emission range extended toward the blue by 20–30 nm. The quinolone dyes are used when laser emission in the 400–430 nm region is required. Azaquinolone derivatives, such as 7-dimethylamino-1-methyl-4-metoxy-8-azaquinolone-2 (LD 390), exhibit laser action below 400 nm.

Oxadiazole Derivatives

These are compounds which incorporate an axodiazole ring with aryl radical substituents and which lase in the 330–450 nm spectral region. Dye 2-(4-biphenyl)-5-(4-*t*-butylphenyl)-1,3,4-oxadiazole (PBD), with laser emission in the 355–390 nm region, belongs to this family.

Solid-State Laser Dye Matrices

Although some first attempts to incorporate dye molecules into solid matrices were already made in the early days of development of dye lasers, it was not until the late 1980s that host materials with the required properties of optical quality and high damage threshold to laser radiation began to be developed. In subsequent years, the synthesis of new high-performance dyes and the implementation of new ways of incorporating the organic molecules into the solid matrix resulted in significant advances towards the development of practical tunable solid-state dye lasers. A recent detailed review of the work done in this field has been given by Costela *et al.*

Inorganic glasses, transparent polymers, and inorganic–organic hybrid matrices have been successfully used as host matrices for laser dyes. Inorganic glasses offer good thermal and optical properties but present the difficulty that the high melting temperature employed in the traditional process of glass making would destroy the organic dye molecules. It was not until the development of the low-temperature sol-gel technique for the synthesis of glasses that this limitation was overcome. The sol-gel process, based on inorganic polymerization reactions performed at about room temperature and starting with metallo-organic compounds such as alkoxides or salts, as reported by Brinker and Scherrer, in 1989, provides a safe route for the preparation of rigid, transparent, inorganic matrix materials incorporating laser dyes. Disadvantages of these materials are the possible presence of impurities embedded in the matrix or the occurrence of interactions between the dispersed dye molecules and the inorganic structure (hydrogen bonds, van der Waals forces) which, in certain cases, can have a deleterious effect on the lasing characteristics of the material.

The use of matrices based on polymeric materials to incorporate organic dyes offers some technical and economical advantages. Transparent polymers exhibit high optical homogeneity, which is extremely important for narrow-linewidth oscillators, as explained by Duarte, in 1994, good chemical compatibility with organic dyes, and allow control over structure and chemical composition making possible the modification, in a controlled way, of relevant properties of these materials such as polarity, free volume, molecular weight, or viscoelasticity. Furthermore, the polymeric materials are amenable to inexpensive fabrication techniques, which facilitate miniaturization and design of integrated optical systems. The dye molecules can be either dissolved in the polymer or linked covalently to the polymeric chains.

In the early investigations on the use of solid polymer matrices for laser dyes, the main problem to be solved was that of the low resistance to laser radiation exhibited by the then existing materials. In the late 1980s and early 1990s new modified polymeric organic materials began to be developed with a laser-radiation-damage threshold comparable to that of inorganic glasses and crystals as reported by Gromov and colleagues, in 1985, and Dyumaev and colleagues, in 1992. This, together with the above-mentioned advantages, made the use of polymers in solid-state dye lasers both attractive and competitive.

An approach that intends to bring about materials in which the advantages of both inorganic glasses and polymers are preserved but the difficulties are avoided is that of using inorganic–organic hybrid matrices. These are silicate-based materials, with an inorganic Si–O–Si backbone, prepared from organosilane precursors by sol-gel processing in combination with organic cross-linking of polymerizable monomers as reported by Novak, in 1993, Sanchez and Ribot, in 1994, and Schubert, in 1995. In one procedure, laser dyes are mixed with organic monomers, which are then incorporated into the porous structure of a sol-gel inorganic matrix by immersing the bulk in the solution containing monomer and catalyst or photoinitiator as indicated by Reisfeld and Jorgensen, in 1991, and Bosch and colleagues, in 1996. Alternatively, hybrids can be obtained from organically modified silicon alkoxides, producing the so-called ORMOCERS (organically modified ceramics) or ORMOSILS (organically modified silanes) as reported by Reisfeld and Jorgensen, in 1991. An inconvenient aspect of these materials is the appearance of optical inhomogeneities in the medium due to the difference in the refractive index between the organic and inorganic phases as well as to the difference in density between monomer and polymer which causes stresses and the formation of optical defects. As a result, spatial inhomogeneities appear in the laser beam, thereby decreasing its quality as discussed by Duarte, in 1994.

Organic Hosts

The first polymeric materials with improved resistance to damage by laser radiation were obtained by Russian workers, who incorporated rhodamine dyes into modified poly(methyl methacrylate) (MPMMA), obtained by doping PMMA with low-molecular weight additives. Some years later, in 1995, Maslyukov and colleagues demonstrated lasing efficiencies in the range 40–60% with matrices of MPMMA doped with rhodamine dyes pumped longitudinally at 532 nm, with a useful lifetime (measured as a 50% efficiency drop) of 15 000 pulses at a prf of 3.33 Hz.

In 1995, Costela and colleagues used an approach based on adjusting the viscoelastic properties of the material by modifying the internal plasticization of the polymeric medium by copolymerization with appropriate monomers. Using dye Rh6G dissolved in a copolymer of 2-hydroxyethyl methacrylate (HEMA) and methyl methacrylate (MMA) and transversal pumping at 337 nm, they demonstrated laser action with an efficiency of 21% and useful lifetime of 4500 pulses (20 GJ/mol in terms of total input energy per mole of dye molecule when the output energy is down to 50% of its initial value). The useful lifetime increased to 12 000 pulses when the Rh6G chromophore was linked covalently to the polymeric chains as reported by Costela and colleagues, in 1996.

Comparative studies on the laser performance of Rh6G incorporated either in copolymers of HEMA and MMA or in MPMMA were carried out by Giffin and colleagues, in 1999, demonstrating higher efficiency of the MPMMA materials but superior normalized photostability (up to 240 GJ/mol) of the copolymer formulation.

Laser conversion efficiencies in the range 60–70% for longitudinal pumping at 532 nm were reported by Ahmad and colleagues, in 1999, with PM567 dissolved in PMMA modified with 1,4-diazobicyclo[2,2,2] octane (DABCO) or perylene additives. When using DABCO as an additive, a useful lifetime of up to 550 000 pulses, corresponding to a normalized photostability of 270 GJ/mol, was demonstrated at a 2 Hz prf.

Much lower efficiencies and photostabilities have been obtained with dyes emitting in the blue-green spectral region. Costela and colleagues, in 1996, performed some detailed studies on dyes coumarin 540A and coumarin 503 incorporated into methacrylate homopolymers and copolymers, and demonstrated efficiencies of at most 19% with useful lifetimes of up to 1200 pulses, at a 2 Hz prf, for transversal pumping at 337 nm. In 2000, Somasundaram and Ramalingam obtained useful lifetimes of 5240 and 1120 pulses, respectively, for coumarin 1 and coumarin 490 dyes incorporated into PMMA rods modified with ethyl alcohol, under transversal pumping at 337 nm and a prf of 1 Hz.

A detailed study of photo-physical parameters of R6G-doped HEMA-MMA gain media was performed by Holzer and colleagues, in 2000. Among the parameters determined by these authors are quantum yields, lifetimes, absorption cross-sections, and emission cross-sections. A similar study on the photophysical parameters of PM567 and two PM567 analogs incorporated into solid matrices of different acrylic copolymers and in corresponding mimetic liquid solutions was performed by Bergmann and colleagues, in 2001.

Preliminary experiments with rhodamine 6G-doped MPMMA at high prfs were conducted using a frequency-doubled Nd:YAG laser at 5 kHz by Duarte and colleagues, in 1996. In those experiments, involving longitudinal excitation, the pump laser was allowed to fuse a region at the incidence window of the gain medium so that a lens was formed. This lens and the exit window of the gain medium comprised a

short unstable resonator that yielded broadband emission. In 2001, Costela and colleagues demonstrated lasing in rhodamine 6G- and pyrromethene-doped polymer matrices under copper-vapor-laser excitation at prfs in the 1.0–6.2 kHz range. In these experiments, the dye-doped solid-state matrix was rotated at 1200 rpm. Average powers of 290 mW were obtained at a prf of 1 kHz and a conversion efficiency of 37%. For a short period of time average powers of up to 1 W were recorded at a prf of 6.2 kHz. In subsequent experiments by Abedin and colleagues the rpf was increased to 10 kHz by using as pump laser a diode-pumped, *Q*-switched, frequency doubled, solid state Nd:YLF laser. Initial average powers of 560 mW and 430 mW were obtained for R6G-doped and PM567-doped polymer matrices, respectively. Lasing efficiency was 16% for R6G and the useful lifetime was 6.6 min (or about 4.0 million shots).

Inorganic and Hybrid Hosts

In 1990, Knobbe and colleagues and McKiernan and colleagues, from the University of California at Los Angeles, incorporated different organic dyes, via the sol-gel techniques, into silicate (SiO_2), aluminosilicate (Al_2O_3–SiO_2), and ORMOSIL host matrices, and investigated the lasing performance of the resulting materials under transversal pumping. Lasing efficiencies of 25% and useful lifetimes of 2700 pulses at 1 Hz repetition rate were obtained from Rh6G incorporated into aluminosilicate gel and ORMOSIL matrices, respectively. When the dye in the ORMOSIL matrices was coumarin 153, the useful lifetime was still 2250 pulses. Further studies by Altman and colleagues, in 1991, demonstrated useful lifetimes of 11 000 pulses at a 30 Hz prf when rhodamine 6G perchlorate was incorporated into ORMOSIL matrices. The useful lifetime increased to 14 500 pulses when the dye used was rhodamine B.

When incorporated into xerogel matrices, pyrromethene dyes lase with efficiencies as high as the highest obtained in organic hosts but with much higher photostability: a useful lifetime of 500 000 pulses at 20 Hz repetition rate was obtained by Faloss and colleagues, in 1997, with PM597 using a pump energy of 1 mJ. The efficiency of PM597 dropped to 40% but its useful lifetime increased to over 1 000 000 pulses when oxygen-free samples were prepared, in agreement with previous results that documented the strong dependence of laser parameters of pyrromethene dyes on the presence of oxygen. A similar effect was observed with perylene dyes: deoxygenated xerogel samples of Perylene Red exhibited a useful lifetime of 250 000 pulses at a prf of 5 Hz and 1 mJ pump energy, to be compared with a useful lifetime of only 10 000 pulses obtained with samples prepared in normal conditions. Perylene Orange incorporated into polycom glass and pumped longitudinally at 532 nm gave an efficiency of 72% and a useful lifetime of 40 000 pulses at a prf of 1 Hz as reported by Rhan and King, in 1998.

A direct comparison study of laser performance of Rh6G, PM567, Perylene Red, and Perylene Orange in organic, inorganic, and hybrid hosts was carried out by Rahn and King in 1995. They found that the nonpolar perylene dyes had better performance in partially organic hosts, whereas the ionic rhodamine and pyrromethene dyes performed best in the inorganic sol-gel glass host. The most promising combinations of dye and host for efficiency and photostability were found to be Perylene Orange in polycom glass and Rh6G in sol-gel glass.

An all-solid-state optical configuration, where the pump was a laser diode array side-pumped, Q-switched, frequency-doubled, Nd:YAG slab laser, was demonstrated by Hu and colleagues, in 1998, with dye DCM incorporated into ORMOSIL matrices. A lasing efficiency of 18% at the wavelength of 621 nm was obtained, and 27 000 pulses were needed for the output energy to decrease by 10% of its initial value at 30 Hz repetition rate. After 50 000 pulses the output energy decreased by 90% but it could be recovered after waiting for a few minutes without pumping.

Violet and ultraviolet laser dyes have also been incorporated into sol-gel silica matrices and their lasing properties evaluated under transversal pumping by a number of authors. Although reasonable efficiencies have been obtained with some of these laser dyes, the useful lifetimes are well below 1000 pulses.

More recently, Costela and colleagues have demonstrated improved conversion efficiencies in dye-doped inorganic–organic matrices using pyrromethene 567 dye. The solid matrix in this case is poly-trimethylsilyl-methacrylate cross-linked with ethylene glycol and copolymerized with methyl methacrylate. Also, Duarte and James have reported on dye-doped polymer-nanoparticle laser media where the polymer is PMMA and the nanoparticles are made of silica. These authors report TEM_{00} laser beam emission and improved dn/dT coefficients of the gain media that results in reduced $\Delta\theta$.

Dye Laser Applications

Dye lasers generated a renaissance in diverse applied fields such as isotope separation, medicine,

photochemistry, remote sensing, and spectroscopy. Dye lasers have also been used in many experiments that have advanced the frontiers of fundamental physics.

Central to most applications of dye lasers is their capability of providing coherent narrow-linewidth radiation that can be tuned continuously from the near ultraviolet, throughout the visible, to the near infrared. These unique coherent and spectral properties have made dye lasers particularly useful in the field of high-resolution atomic and molecular spectroscopy. Dye lasers have been successfully and extensively used in absorption and fluorescence spectroscopy, Raman spectroscopy, selective excitations, and nonlinear spectroscopic techniques. Well documented is their use in photochemistry, that is, the chemistry of optically excited atoms and molecules, and in biology, studying biochemical reaction kinetics of biological molecules. By using nonlinear optical techniques, such as harmonic and sum frequency and difference frequency generation, the properties of dye lasers can be extended to the ultraviolet.

Medical applications of dye lasers include cancer photodynamic therapy, treatment of vascular lesions, and lithotripsy as described by Goldman in 1990.

The ability of dye lasers to provide tunable sub-GHz linewidths in the orange-red portion of the spectrum, at kW average powers, made them particularly suited to atomic vapor laser isotope separation of uranium as reported by Bass and colleagues, in 1992, Singh and colleagues, in 1994, and Nemoto and colleagues, in 1995. In this particular case the isotopic shift between the two uranium isotopes is a few GHz. Using dye lasers yielding $\Delta\nu \leq 1\,\text{GHz}$ the ^{235}U can be selectively excited in a multistep process by tuning the dye laser(s) to specific wavelengths, in the orange-red spectral region, compatible with a transition sequence leading to photoionization. Also, high-prf narrow-linewidth dye lasers, as described by Duarte and Piper, in 1984, are ideally suited for guide star applications in astronomy. This particular application requires a high-average power diffraction-limited laser beam at $\lambda \approx 589\,\text{nm}$ to propagate for some 95 km, above the surface of the Earth, and illuminate a layer of sodium atoms. Ground detection of the fluorescence from the sodium atoms allows measurements on the turbulence of the atmosphere. These measurements are then used to control the adaptive optics of the telescope thus compensating for the atmospheric distortions.

A range of industrial applications is also amenable to the wavelength agility and high-average power output characteristics of dye lasers. Furthermore, tunability coupled with narrow-linewidth emission, at large pulsed energies, make dye lasers useful in military applications such as directed energy and damage of optical sensors.

The Future of Dye Lasers

Predicting the future is rather risky. In the early 1990s, articles and numerous advertisements in commercial laser magazines predicted the demise and even the oblivion of the dye laser in a few years. It did not turn out this way. The high power and wavelength agility available from dye lasers have ensured their continued use as scientific and research tools in physics, chemistry, and medicine. In addition, the advent of narrow-linewidth solid-state dye lasers has sustained a healthy level of research and development in the field. Today, some 20 laboratories around the world are engaged in this activity.

The future of solid-state dye lasers depends largely on synthetic and manufacturing improvements. There is a need for strict control of the conditions of fabrication and a careful purification of all the compounds involved. In the case of polymers, in particular, stringent control of thermal conditions during the polymerization step is obligatory to ensure that adequate optical uniformity of the polymer matrix is achieved, and that intrinsic anisotropy developed during polymerization is minimized. From an engineering perspective what are needed are dye-doped solid-state media with improved photostability characteristics and better thermal properties. By better thermal properties is meant better dn/dT factors. To a certain degree progress in this area has already been reported. As in the case of liquid dye lasers, the lifetime of the material can be improved by using pump lasers at compatible wavelengths. In this regard, direct diode laser pumping of dye-doped solid-state matrices should lead to very compact, long-lifetime, tunable lasers emitting throughout the visible spectrum. An example of such a device would be a green laser-diode-pumped rhodamine-6G doped MPMMA tunable laser configured in a multiple-prism grating architecture.

As far as liquid lasers are concerned, there is a need for efficient water-soluble dyes. Successful developments in this area were published in the literature with coumarin-analog dyes by Chen and colleagues, in 1988, and some encouraging results with rhodamine dyes have been reported by Ray and colleagues, in 2002. Efficient water-soluble dyes could lead to significant improvements and simplifications in high-power tunable lasers.

Edge Emitters

Introduction

The semiconductor edge emitting diode laser is a critical component in a wide variety of applications, including fiber optics telecommunications, optical data storage, and optical remote sensing. In this section, we describe the basic structures of edge emitting diode lasers and the physical mechanisms for converting electrical current into light. Laser waveguides and cavity resonators are also outlined. The power, efficiency, gain, loss, and threshold characteristics of laser diodes are presented along with the effects of temperature and modulation. Quantum well lasers are outlined and a description of grating coupled lasers is provided.

Like all forms of laser, the edge emitting diode laser is an oscillator and has three principal components; a mechanism for converting energy into light, a medium that has positive optical gain, and a mechanism for obtaining optical feedback. The basic edge emitting laser diode is shown schematically in Figure 1. Current flow is vertical through a pn junction and light is emitted from the ends. The dimensions of the laser in Figure 1 are distorted, in proportion to typical real laser diodes, to reveal more detail. In practical laser diodes, the width of the stripe contact is actually much smaller than shown and the thickness is smaller still. Typical dimensions are (stripe width × thickness × length) $2 \times 100 \times 1000\ \mu m$. Light emission is generated only within a few micrometers of the surface, which means that 99.98% of the volume of this small device is inactive.

Energy conversion in diode lasers is provided by current flowing through a forward-biased pn junction. At the electrical junction, there is a high density of injected electrons and holes which can recombine in a direct energy gap semiconductor material to give an emitted photon. Charge neutrality requires equal numbers of injected electrons and holes. Figure 2 shows a simplified energy versus momentum (E–k) diagrams for (a) direct, and (b) indirect semiconductors. In a direct energy gap material, such as GaAs, the energy minima have the same momentum vector, so recombination of an electron in the conduction band and a hole in the valence band takes place directly. In an indirect material, such as silicon, momentum conservation requires the participation of a third particle – a phonon. This third-order process is far less efficient than direct recombination and, thus far, too inefficient to support laser action.

Optical gain in direct energy gap materials is obtained when population inversion is reached.

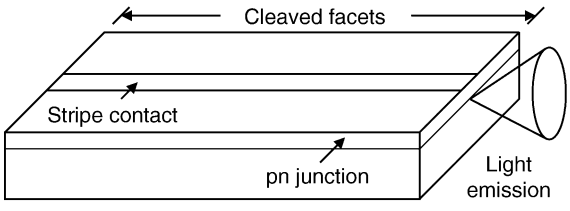

Figure 1 Schematic drawing of an edge emitting laser diode.

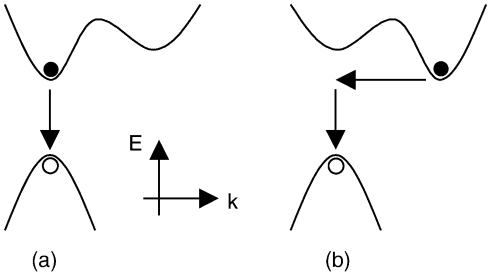

Figure 2 Energy versus momentum for (a) direct, and (b) indirect semiconductors.

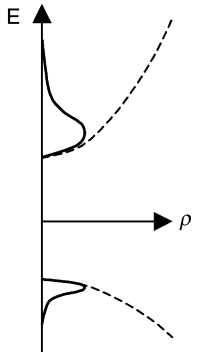

Figure 3 Density of states versus energy for conduction and valence bands.

Population inversion is the condition where the probability for stimulated emission exceeds that of absorption. The density of excited electrons n, in the conduction band is given by

$$n = \int_{E_c}^{\infty} \rho_n(E) f_n(E) \mathrm{d}E \ \mathrm{cm}^{-3} \qquad [1]$$

where $\rho_n(E)$ is the conduction band density of states function and $f_n(E)$ is the Fermi occupancy function. A similar equation can be written for holes in the valence band. Figure 3 shows the density of states ρ versus energy as a dashed line for conduction and valence bands. The solid lines in Figure 3 are the $\rho(E)f(E)$ products, and the areas under the solid curves are the carrier densities n and p.

The Fermi functions are occupation probabilities based on the quasi-Fermi levels E_{Fn} and E_{Fp}, which are, in turn, based on the injected carrier densities, δn and δp. Population inversion implies that the difference between the quasi-Fermi levels must exceed the emission energy which, for semiconductors, must be greater than the bandgap energy:

$$E_{Fn} - E_{Fp} \geq \hbar\omega \sim E_g \qquad [2]$$

Charge neutrality requires that $\delta n = \delta p$. Transparency is the point where these two conditions are just met and any additional injected current results in optical gain. The transparency current density J_o, is given by

$$J_o = \frac{q n_o L_z}{\tau_{spon}} \qquad [3]$$

where n_o is the transparency carrier density ($\delta n = \delta p = n_o$ at transparency), L_z is the thickness of the optically active layer, and τ_{spon} is the spontaneous carrier lifetime in the material (typically 5 nsec).

A resonant cavity for optical feedback is obtained simply by taking advantage of the natural crystal formation in single crystal semiconductors. Most III–V compound semiconductors form naturally into a zincblende lattice structure. With the appropriate choice of crystal planes and surfaces, this lattice structure can be cleaved such that nearly perfect plane–parallel facets can be formed at arbitrary distances from each other. Since the refractive index of these materials is much larger (~3.5) than that of air, there is internal optical reflection for normal incidence of approximately 30%. This type of optical cavity is called a Fabry–Perot resonator.

Effective lasers of all forms make use of optical waveguides to optimize the overlap of the optical field with material gain and cavity resonance. The optical waveguide in an edge emitting laser is best described by considering it in terms of a transverse waveguide component, defined by the epitaxial growth of multiple thin heterostructure layers, and a lateral waveguide component, defined by conventional semiconductor device processing methods. One of the simplest, and yet most common, heterostructure designs is shown in Figure 4. This five-layer separate confinement heterostructure (SCH) offers excellent carrier confinement in the active layer as well as a suitable transverse waveguide.

Clever choice of different materials for each layer results in the energy band structure, index of refraction

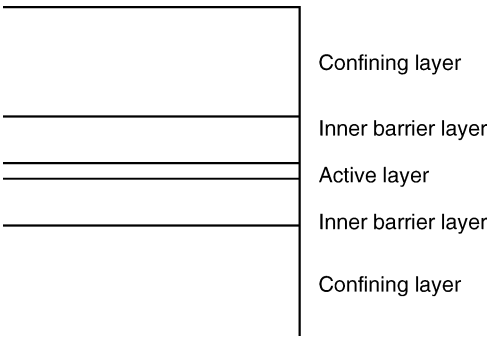

Figure 4 Schematic cross-section of a typical five-layer separate confinement heterostructure (SCH) laser.

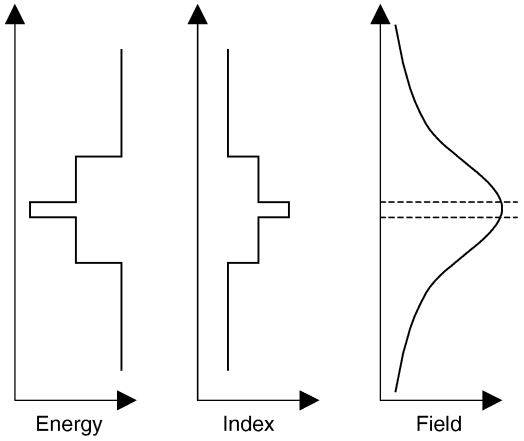

Figure 5 Energy band structure, index of refraction profile, and optical field mode profile of the SCH laser of **Figure 4**.

profile, and optical field mode profile shown in Figure 5. The outer confining layers are the thickest ($\sim 1\ \mu m$) and have the largest energy bandgap and lowest refractive index. The inner barrier layers are thinner ($\sim 0.1\ \mu m$), have intermediate bandgap energy and index of refraction, and serve both an optical role in defining the optical waveguide and an electronic role in confining carriers to the active layer. The active layer is the narrowest bandgap, highest index material, and is the only layer in the structure designed to provide optical gain. It may be a single layer or, as in the case of a multiple quantum well laser, a combination of layers. The bandgap energy, E, of this active layer plays a key role in determining the emission wavelength, λ, of the laser:

$$E = \frac{hc}{\lambda} \qquad [4]$$

where h is Planck's constant and c is the speed of light.

The bandgap energy of the SCH structure is shown in Figure 5. The lowest energy active layer collects injected electrons and holes and the carrier confinement provided by the inner barrier layers allows the high density of carriers necessary for population inversion and gain. The layers in the structure also have the refractive index profile shown in Figure 5 which forms a five-layer slab dielectric waveguide. With appropriate values for thicknesses and indices of refraction, this structure can be a very strong fundamental mode waveguide with the field profile shown. A key parameter of edge emitting diode lasers is Γ, the optical confinement factor. This parameter is the areal overlap of the optical field with the active layer, shown as dashed lines in the figure and can be as little as a few percent, even in very high performance lasers.

Lateral waveguiding in a diode laser can be accomplished in a variety of ways. A common example of an index guided laser is the ridge waveguide laser shown in Figure 6. After the appropriate transverse waveguide heterostructure sample is grown, conventional semiconductor processing methods are used to form parallel etched stripes from the surface near, but not through, the active layer. An oxide mask is patterned such that electrical contact is formed only to the center (core) region between the etched stripes, the core stripe being only a few microns wide. The lateral waveguide that results arises from the average index of refraction (effective index) in the etched regions outside the core being smaller than that of the core. Figure 7 shows the asymmetric near field emission profile of the ridge waveguide laser and cross-sectional profiles of the laser emission and effective index of refraction.

The optical spectrum of an edge emitting diode laser below and above threshold is the superposition of the material gain of the active layer and the resonances provided by the Fabry–Perot resonator. The spectral variation of material gain with injected carrier density (drive current) is shown in Figure 8. As the drive is increased, the intensity and energy of peak gain both increase.

The Fabry–Perot resonator has resonances every half wavelength, given by

$$L = \frac{m}{2}\frac{\lambda}{n} \qquad [5]$$

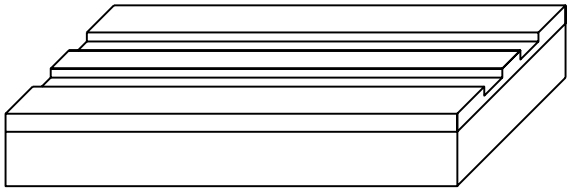

Figure 6 Schematic diagram of a real index guided ridge waveguide diode laser.

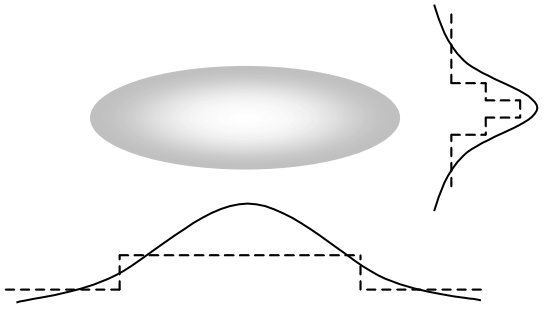

Figure 7 Near field emission pattern, cross-sectional emission profiles (solid lines), and refractive index profiles (dashed lines) from an index guided diode laser.

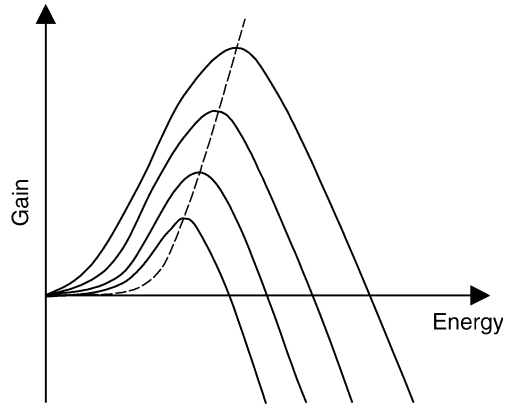

Figure 8 Gain versus emission energy for four increasing values of carrier (current) density. Peak gain is shown as a dashed line.

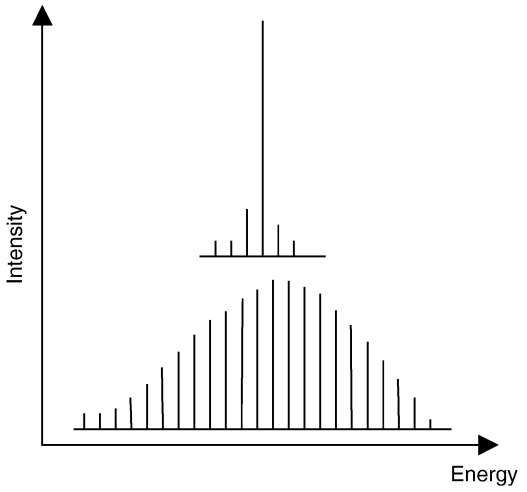

Figure 9 Emission spectra from a Fabry–Perot edge emitting laser structure at, and above, laser threshold.

where L is the cavity length, λ/n is the wavelength in the medium (n is the refractive index), and m is an integer. For normal length edge emitter cavities, these cavity modes are spaced only 1 or 2 Å apart. The result is optical spectra, near laser threshold and above, that look like the spectra of Figure 9. Many cavity modes resonate up to threshold, while above threshold, the superlinear increase in emission intensity with drive current tends to greatly favor one or two of the Fabry–Perot longitudinal cavity modes.

Laser threshold can be determined from a relatively simple analysis of the round trip gain and losses in the Fabry–Perot resonator. If the initial intensity is I_o, after one round trip the intensity will be given by

$$I = I_o R_1 R_2 e^{(g-\alpha_i)2L} \qquad [6]$$

where R_1 and R_2 are the reflectivities of the two facets, g is the optical gain, α_i are losses associated with optical absorption (typically 3–15 cm^{-1}), and L is the cavity length. At laser threshold, $g = g_{th}$ and $I = I_o$, i.e., the round trip gain exactly equals the losses. The result is

$$g_{th} = \alpha_i + \frac{1}{2L} \ln \frac{1}{R_1 R_2} \qquad [7]$$

where the second term represents the mirror losses α_m. Of course, mirror losses are desirable in the sense that they represent useable output power. Actually, the equation above does not take into account the incomplete overlap of the optical mode with the gain in the active layer. The overlap is defined by the confinement factor Γ, described above, and the equation must be modified to become

$$\Gamma g_{th} = \alpha_i + \frac{1}{2L} \ln \frac{1}{R_1 R_2} \qquad [8]$$

For quantum well lasers, the material peak gain, shown in Figure 8, as a function of drive current is given approximately by

$$g_t = \beta J_o \ln \frac{J}{J_o} \qquad [9]$$

where J_o is the transparency current density. The threshold current density J_{th}, which is the current density where the gain exactly equals all losses, is given by

$$J_{th} = \frac{J_o}{\eta_i} \exp \frac{\alpha + \frac{1}{2L} \ln \frac{1}{R_1 R_2}}{\Gamma \beta J_o} \qquad [10]$$

Note that an additional parameter η_i has appeared in this equation. Not all of the carriers injected by the drive current participate in optical processes; some are lost to other nonradiative processes. This is accounted for by including the internal quantum efficiency term η_i, which is typically at least 90%. The actual drive current, of course, must include the geometry of the device and is given by

$$I_{th} = wLJ_{th} \qquad [11]$$

where L is the cavity length, and w is the effective width of the active volume. The effective width is basically the stripe width of the core but also includes current spreading and carrier diffusion under the stripe.

The power–current characteristic (P–I) for a typical edge emitting laser diode is shown in Figure 10. As the drive current is increased

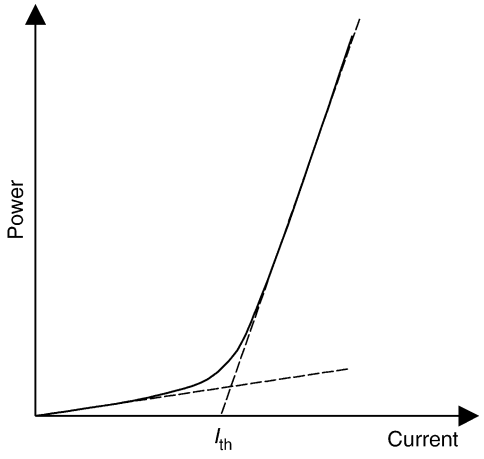

Figure 10 Power versus current (P–I) curve for a typical edge emitting laser diode.

from zero, the injected carrier densities increase and spontaneous recombination is observed. At some point the gain equals the internal absorption losses, and the material is transparent. Then, as the drive current is further increased, additional gain eventually equals the total losses, including mirror losses, and laser threshold is reached. Above threshold, nearly all additional injected carriers contribute to stimulated emission (laser output). The power generated internally is given by

$$P = wL(J - J_{th})\eta_i \frac{h\nu}{q} \qquad [12]$$

where wL is the area and $h\nu$ is the photon energy. Only a fraction of the power generated internally is extracted from the device

$$P_o = wL(J - J_{th})\eta_i \frac{h\nu}{q} \frac{\alpha_m}{\alpha_i + \alpha_m} \qquad [13]$$

Clearly a useful design goal is to minimize the internal optical loss α_i. The slope of the P–I curve of Figure 10 above threshold is described by an external differential quantum efficiency η_d, which is related to the internal quantum efficiency by

$$\eta_d = \eta_i \left[\frac{\alpha_m}{\alpha_i + \alpha_m} \right] \qquad [14]$$

Other common parameters used to characterize the efficiency of laser diodes include the power conversion efficiency η_p

$$\eta_p = \frac{P_o}{V_F I} \qquad [15]$$

and the wall plug efficiency η_w

$$\eta_w = \frac{P_o}{I} \qquad [16]$$

The power conversion efficiency η_p, recognizes that the forward bias voltage V_F is larger than the photon energy by an amount associated with the series resistance of the laser diode. The wall plug efficiency η_w, has the unusual units of WA^{-1} and is simply a shorthand term that relates the common input unit of current to the common output unit of power. In high performance low power applications, the ideal device has minimum threshold current since the current used to reach threshold contributes little to light emission. In high power applications, the threshold current becomes insignificant and the critical parameter is external quantum efficiency.

Temperature effects may be important for edge emitting lasers, depending on a particular application. Usually, concerns related to temperature arise under conditions of high temperature operation ($T > 50\,^{\circ}C$), where laser thresholds rise and efficiencies fall. It became common early in the development of laser diodes to define a characteristic temperature T_o for laser threshold, which is given by

$$I_{th} = I_{th_o} \exp\left(\frac{T}{T_o}\right) \qquad [17]$$

where a high T_o is desirable. Unfortunately, this simple expression does not describe the temperature dependence very well over a wide range of temperatures, so the appropriate temperature range must also be specified. For applications where the emission wavelength of the laser is important, the change in wavelength with temperature $d\lambda/dT$ may also be specified. For conventional Fabry–Perot cavity lasers, $d\lambda/dT$ is typically 3–5 $\text{Å}C^{-1}$.

In order for a diode laser to carry information, some form of modulation is required. One method for obtaining this is direct modulation of the drive current in a semiconductor laser. The transient and temporal behavior of lasers is governed by rate equations for carriers and photons which are necessarily coupled equations. The rate equation for carriers is given by

$$\frac{dn}{dt} = \frac{J}{qL_z} - \frac{n}{\tau_{sp}} - (c/n)\beta(n - n_o)\varphi(E) \qquad [18]$$

where J/qL_z is the supply, n/τ_{sp} is the spontaneous emission rate, and the third term is the stimulated emission rate $(c/n)\beta(n - n_o)\varphi(E)$ where β is the gain coefficient and $\varphi(E)$ is the photon density.

The rate equation for photons is given by

$$\frac{d\varphi}{dt} = (c/n)\beta(n - n_o)\varphi + \frac{\theta n}{\tau_{sp}} - \frac{\varphi}{\tau_p} \qquad [19]$$

where θ is the fraction of the spontaneous emission that couples into the mode (a small number), and τ_p is the photon lifetime (~1 psec) in the cavity. These rate equations can be solved for specific diode laser materials and structures to yield a modulation frequency response. A typical small signal frequency response, at two output power levels, is shown in Figure 11. The response is typically flat to frequencies above 1 GHz, rises to a peak value at some characteristic resonant frequency, and quickly rolls off. The characteristic small signal resonant frequency ω_r, is given by

$$\omega_r^2 = \frac{(c/n)\beta\bar{\varphi}}{\tau_p} \qquad [20]$$

where $\bar{\varphi}$ is the average photon density. Direct modulation of edge emitting laser diodes is limited by practicality to less than 10 GHz. This is in part because of the limits imposed by the resonant frequency and in part by chirp. Chirp is the frequency modulation that arises indirectly from direct current modulation. Modulation of the current modulates the carrier densities which, in turn, results in modulation of the quasi-Fermi levels. The separation of the quasi-Fermi levels is the emission energy (wavelength). Most higher-speed lasers make use of external modulation schemes.

The discussion thus far has addressed aspects of semiconductor diode edge emitting lasers that are common to all types of diode lasers irrespective of the choice of materials or the details of the active layer structure. The materials of choice for efficient laser devices include a wide variety of III–V binary compounds and ternary or quaternary alloys. The particular choice is based on such issues as emission wavelength, a suitable heterostructure lattice match, and availability of high-quality substrates. For example, common low-power lasers for CD players ($\lambda \sim 820$ nm) are likely to be made on a GaAs substrate using a GaAs–$Al_xGa_{1-x}As$ heterostructure. Lasers for fiberoptic telecommunications systems ($\lambda \sim 1.3$–1.5 μm) are likely to be made on an InP substrate using an InP–$In_xGa_{1-x}As_yP_{1-y}$ heterostructure. Red laser diodes ($\lambda \sim 650$ nm) are likely to be made on a GaAs substrate using a GaAs–$In_xGa_{1-x}As_yP_{1-y}$ heterostructure. Blue and ultraviolet lasers, a relatively new technology compared to the others, make use of $Al_xGa_{1-x}N$–GaN–$In_yGa_{1-y}N$ heterostructures formed on sapphire or silicon carbide substrates.

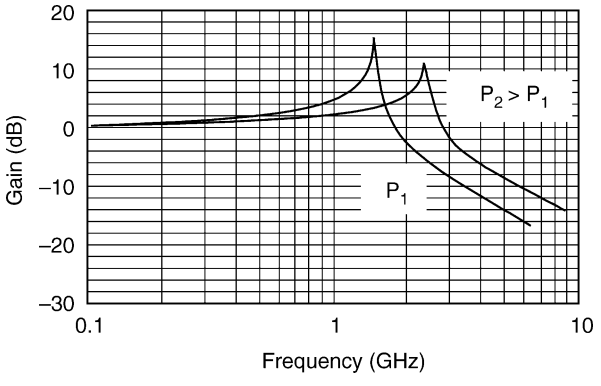

Figure 11 Direct current modulation frequency response for an edge emitting diode laser at two output power levels.

An important part of many diode laser structures is a strained layer. If a layer is thin enough, the strain arising from a modest amount of lattice mismatch can be accommodated elastically. In thicker layers, lattice mismatch results in an unacceptable number of dislocations that affect quantum efficiency, optical absorption losses, and, ultimately, long-term failure rates. Strained layer GaAs–$In_xGa_{1-x}As$ lasers are a critical component in rare-earth doped fiber amplifiers.

The structure of the active layer in edge emitting laser diodes was originally a simple double heterostructure configuration with a single active layer of 500–1000 Å in thickness. In the 1970s however, advances in the art of growing semiconductor heterostructure materials led to growth of high-quality quantum well active layers. These structures, having thicknesses that are comparable to the electron wavelength in a semiconductor (<200 Å), revolutionized semiconductor lasers, resulting in much lower threshold current densities, higher efficiencies, and a broader range of available emission wavelengths. The energy band diagram for a quantum well laser active region is shown in Figure 12.

This structure is a physical realization of the particle-in-a-box problem in elementary quantum mechanics. The quantum well yields quantum states in the conduction band at discrete energy levels, with odd and even electron wavefunctions, and breaks the degeneracy in the valence band, resulting in separate energy states for light holes and heavy holes. The primary transition for recombination is from the $n = 1$ electron state to the $h = 1$ heavy hole state and takes place at a higher energy than the bulk bandgap energy. In addition, the density of states for quantum wells becomes a step-like function and optical gain is enhanced. The advantages in practical edge

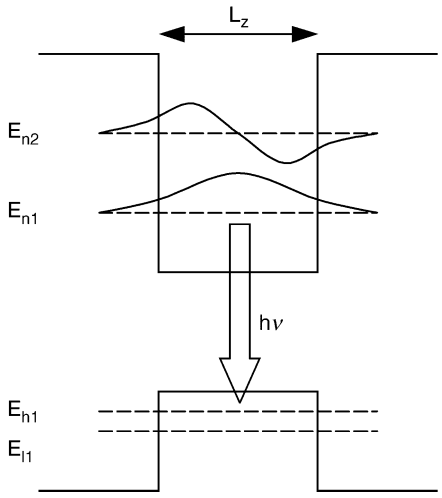

Figure 12 Energy band diagram for a quantum well heterostructure.

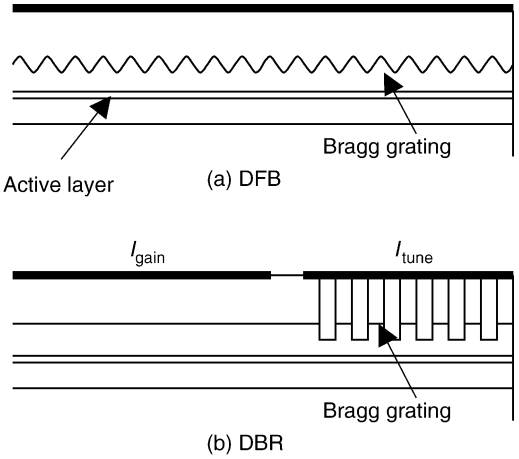

Figure 13 Schematic diagram of distributed feedback (DFB) and distributed Bragg reflector (DBR) edge emitting laser diodes.

emitting lasers that are the result of one-dimensional quantization are such that virtually all present commercial laser diodes are quantum well lasers. These kinds of advantages are driving development of laser diodes with additional degrees of quantization, including two dimensions (quantum wires) and three dimensions (quantum dots).

The Fabry–Perot cavity resonator described here is remarkably efficient and relatively easy to fabricate, which makes it the cavity of choice for many applications. There are many applications, however, where the requirements for linewidth of the laser emission or the temperature sensitivity of the emission wavelength make the Fabry–Perot resonator less desirable. An important laser technology that addresses both of these concerns involves the use of a wavelength selective grating as an integral part of the laser cavity. A notable example of a grating coupled laser is distributed feedback laser shown schematically in Figure 13a. This is similar to the SCH cross-section of Figure 4 with the addition of a Bragg grating above the active layer.

The period Λ, of the grating is chosen to fulfill the Bragg condition for mth-order coupling between forward- and backward-propagating waves, which is

$$\Lambda = \frac{m\lambda}{2n} \qquad [21]$$

where λ/n is the wavelength in the medium. The index step between the materials on either side of the grating is small and the amount of reflection is also small. Since the grating extends throughout the length of the cavity, however, the overall effective reflectivity can be large. Another variant is the distributed Bragg reflector (DBR) laser resonator, shown in Figure 13b. This DBR laser has a higher index contrast, deeply etched surface grating located at one or both ends of the otherwise conventional SCH laser heterostructure. One of the advantages of this structure is the opportunity to add a contact for tuning the Bragg grating by current injection.

Both the DBR and DFB laser structures are particularly well suited for telecommunications or other applications where a very narrow single laser emission line is required. In addition, the emission wavelength temperature dependence for this type of laser is much smaller, typically 0.5 $\text{Å}C^{-1}$.

Excimer Lasers

Introduction

We present a summary of the fundamental operating principles of ultraviolet, excimer lasers. After a brief discussion of the economics and application motivation, the underlying physics and technology of these devices is described. Key issues and limitations in the scaling of these lasers are presented.

Background: Why Excimer Lasers?

Excimer lasers have become the most widely used source of moderate power pulsed ultraviolet sources in laser applications. The range of manufacturing applications is also large. Production of computer chips, using excimer lasers as the illumination source for lithography, has by far the largest commercial manufacturing impact. In the medical arena, excimer lasers are used extensively in what is becoming one of the world's most common surgical procedures, the reshaping of the lens to correct vision problems. Taken together, the annual production rate for these lasers is a relatively modest number compared to the production of semiconductor lasers. Current markets are in the range of \$0.4 billion per year (Figure 1). More importantly, the unique wavelength, power, and pulse energy properties of the excimer laser enable a systems and medical procedure market, based on the excimer laser, to exceed \$3 billion per year. The current average sales price for these lasers is in the range of \$250 000 per unit, driven primarily by the production costs and reliability requirements of the lasers for lithography for chip manufacture. Relative to semiconductor diode lasers, excimer lasers have always been, and will continue to be, more expensive per unit device by a factor of order 10^4. UV power and pulse energy, however, are considerably higher.

The fundamental properties of these lasers enable the photochemical and photophysical processes used in manufacturing and medicine. Short pulses of UV light can photo-ablate materials, being of use in medicine and micromachining. Short wavelengths enable photochemical processes. The ability to provide a narrow linewidth using appropriate resonators enables precise optical processes, such as lithography. We trace out some of the core underlying properties of these lasers that lead to the core utility. We also discuss the technological problems and

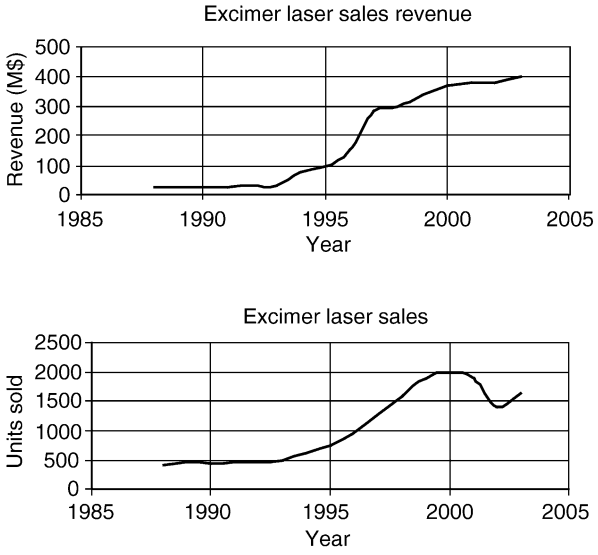

Figure 1 The sales of excimer lasers have always been measured in small numbers relative to other, less-expensive lasers. For many years since their commercial release in 1976 the sales were to R&D workers in chemistry, physics and ultimately biology and medicine. The market for these specialty but most useful R&D lasers was set to fit within a typical researcher's annual capital budget, i.e., less than \$100K. As applications and procedures were developed and certified or approved, sales and average unit sales price increased considerably. Reliance on cyclical markets like semiconductor fabrication led to significant variations in production rates and annual revenues as can be seen.

solutions that have evolved to make these lasers so useful.

The data in Figure 1 provide a current answer to the question of 'why excimer lasers?' At the dawn of the excimer era, the answer to this question was quite different. In the early 1970s, there were no powerful short wavelength lasers, although IR lasers were being scaled up to significant power levels. However, visible or UV lasers could in principle provide better propagation and focus to a very small spot size at large distances. Solid state lasers of the time offered very limited pulse repetition frequency and low efficiency. Diode pumping of solid state lasers, and diode arrays to excite such lasers, was a far removed development effort. As such, short-wavelength lasers were researched over a wide range of potential media and lasing wavelengths. The excimer concept was one of those candidates.

We provide, in Figure 2, a 'positioning' map showing the range of laser parameters that can be obtained with commercial or developmental excimer lasers. The map has coordinates of pulse energy and pulse rate, with diagonal lines expressing average power. We show where both development goals and current markets lay in a map. Current applications are shown by the boxes in the lower right-hand corner. Excimer lasers have been built with clear apertures in the range of a fraction of 0.1 to 10^4 cm^2, with single pulse energies covering a range of 10^7. Lasers with large apertures require electron beam excitation. Discharge lasers correspond to the more modest pulse energy used for current applications. In general, for energies lower than ~5 J, the excitation method of choice is a self-sustained discharge, clearly providing growth potential for future uses, if required.

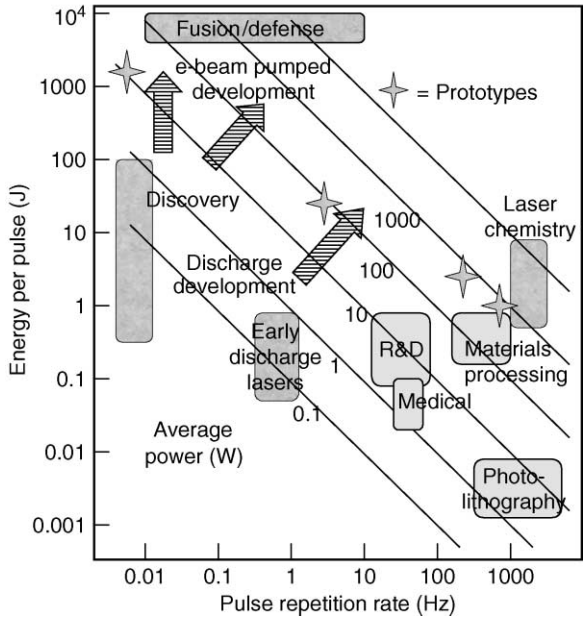

Figure 2 The typical energy and pulse rate for certain applications and technologies using excimer lasers. For energy under a few J, a discharge laser is used. The earliest excimer discharge lasers were derivatives of CO_2 TEA (transversely excited atmospheric pressure) and produced pulse energy in the range of 100 mJ per pulse. Pulse rates of order 30 Hz were all that the early pulsed power technology could provide. Early research focused on generating high energy. Current markets are at modest UV pulse energy and high pulse rates for lithography and low pulse rates for medical applications.

The applications envisaged in the early R&D days were in much higher energy uses, such as in laser weapons, laser fusion, and laser isotope separation. The perceived need for lasers for isotope separation, laser-induced chemistry, and blue-green laser-based communications from satellites, drove research in high pulse rate technology and reliability extension for discharge lasers. This research resulted in prototypes, with typical performance ranges as noted on the positioning map that well exceed current market requirements. However, the technology and underlying media physics developed in these early years made possible advances needed to serve the ultimate real market applications.

The very important application of UV lithography requires high pulse rates and high reliability. These two features differentiate the excimer laser used for lithography from the one used in the research laboratory. High pulse rates, over 2000 Hz in current practice, and the cost of stopping a computer chip production line for servicing, drive the reliability requirements toward 10^{10} shots per service interval. In contrast, the typical laboratory experiments are more often in the range of 100 Hz and, unlike a lithography production line, do not run 24 hours a day, 7 days a week. The other large market currently is in laser correction of myopia and other imperfections in the human eye. For this use the lasers are more akin to the commercial R&D style laser in terms of pulse rate and single pulse energy. Not that many shots are needed to ablate tissue to make the needed correction, and shot life is a straightforward requirement. However, the integration of these lasers into a certified and accepted medical procedure and an overall medical instrument drove the growth of this market.

The excimer concept, and the core technology used to excite these lasers, is applicable over a broad range of UV wavelengths, with utility at specific wavelength ranges from 351 nm in the near UV to 157 nm in the vacuum UV (VUV). There were many potential excimer candidates in the early R&D phase (Table 1). Some of these

Table 1 Key excimer wavelengths

Excimer emitter	*λ (nm)*	*Comment*
Ar_2	126	Very short emission wavelength, deep in the Vacuum UV; inefficient as laser due to absorption, see Xe_2.
Kr_2	146	Broad band emitter and early excimer laser with low laser efficiency. Very efficient converter of electric power into Vacuum UV light.
F_2	157	Molecule itself is not an excimer, but uses lower level dissociation; candidate for next generation lithography.
Xe_2	172	The first demonstrated excimer laser. Very efficient formation and emission but excited state absorption limits laser efficiency. Highly efficient as a lamp.
ArF	193	Workhorse for corneal surgery and lithography.
KrCl	222	Too weak compared to KrF and not as short a wavelength as ArF.
KrF	248	Best intrinsic laser efficiency; numerous early applications but found major market in lithography. Significant use in other materials processing.
XeI	254	Never a laser, but high formation efficiency and excellent for a lamp. Historically the first rare gas halide excimer whose emission was studied at high pressure.
XeBr	282	First rare gas halide to be shown as a laser; inefficient laser due to excited state absorption, but excellent fluorescent emitter; a choice for lamps.
Br_2	292	Another halogen molecule with excimer like transitions that has lased but had no practical use.
XeCl	308	Optimum medium for laser discharge excitation.
Hg_2	335	Hg vapor is very efficiently excited in discharges and forms excimers at high pressure. Subject of much early research, but as in the case of the rare gas excimers such as Xe_2 suffer from excited state absorption. Despite the high formation efficiency, this excimer was never made to lase.
I_2	342	Iodine UV molecular emission and lasing was first of the pure halogen excimer-like lasers demonstrated. This species served as kinetic prototype for the F_2 'honorary' excimer that has important use as a practical VUV source.
XeF	351, 353	This excimer laser transition terminates on a weakly bound lower level that dissociates rapidly, especially when heated. The focus for early defense-related laser development; as this wavelength propagates best of this class in the atmosphere.
XeF	480	This very broadband emission of XeF terminates on a different lower level than the UV band. Not as easily excited in a practical system, so has not had significant usage.
HgBr	502	A very efficient green laser that has many of the same kinetic features of the rare gas halide excimer lasers. But the need for moderately high temperature for the needed vapor pressure made this laser less than attractive for UV operation.
XeO	540	This is an excimer-like molecular transition on the side of the auroral lines of the O atom. The optical cross-section is quite low and as a result the laser never matured in practice.

candidates can be highly efficient, >50% relative to deposited energy, at converting electrical power into UV or visible emission, and have found a parallel utility as sources for lamps, though with differing power deposition rates and configurations. The key point in the table is that these lasers are powerful and useful sources at very short wavelengths. For lithography, the wavelength of interest has consistently shifted to shorter and shorter wavelengths as the printed feature size decreased. Though numerous candidates were pursued, as shown in Table 1, the most useful lasers are those using rare gas halide molecules. These lasers are augmented by dye laser and Raman shifting to provide a wealth of useful wavelengths in the visible and UV.

All excimer lasers utilize molecular dissociation to remove the lower laser level population. This lower level dissociation is typically from an unbound or very weakly bound ground-state molecule. However, halogen molecules also provide laser action on excimer-like transitions, that terminate on a molecular excited state that dissociates quickly. The vacuum UV transition in F_2 is the most practical method for making very short wavelength laser light at significant power. Historically, the rare gas dimer molecules, such as Xe_2, were the first to show excimer laser action, although self absorption, low gain, and poor optics in the VUV limited their utility. Other excimer-like species, such as metal halides, metal rare gas continua on the edge of metal atom resonance lines, and rare gas oxides were also studied. The key differentiators of rare gas halides from other excimer-like candidates are strong binding in the excited state, lack of self absorption, and relatively high optical cross-section for the laser transition.

Excimer Laser Fundamentals

Excimer lasers utilize lower-level dissociation to create and sustain a population inversion. For example, in the first excimer laser demonstrated, Xe_2, the lasing species is one which is comprised of two atoms that do not form a stable molecule in the ground state, as xenon dimers in the ground state are not a stable molecule. In the lowest energy state, that with neither of the atoms electronically excited, the interaction between the atoms in a collision is primarily one of repulsion, save for a very weak 'van der Waals' attraction at larger internuclear separations. This is shown in the potential energy diagram of Figure 3. If one of the atoms is excited, for example by an electric discharge, there can be a chemical binding in the electronically excited state of the molecule relative to the energy of one atom with an electron excited and one atom in the ground state. We use the shorthand notation * to denote an electronically excited atomic molecular species, e.g., Xe^*. The excited dimer, excimer for short, will recombine rapidly at high pressure from atoms into the Xe_2^* electronically excited molecule. Radiative lifetimes of the order 10 nsec to 1 μsec are typical before photon emission returns the molecule to the lower level. Collisional quenching often reduces the lifetime below the radiative rate. For Xe_2^* excimers, the emission is in the vacuum ultraviolet (VUV).

There are a number of variations on this theme, as noted in Table 1. Species, other than rare gas pairs, can exhibit broadband emission. The excited state binding energy can vary significantly, changing the fraction of excited states that will form molecules. The shape of the lower potential energy curve can vary as well. From a semantic point of view heteronuclear, diatomic molecules, such as XeO, are not excimers, as they are not made of two of the same atoms. However, the more formal name 'exciplex' did not stick in the laser world; excimer laser being preferred. Large binding energy is more efficient for capturing excited atoms into excited excimer-type molecules in the limited time they have before emission. Early measurements of the efficiency of converting electrical energy deposited into fluorescent radiation showed that up to 50% of the energy input could result in VUV light emission. Lasers were not this efficient due to absorption.

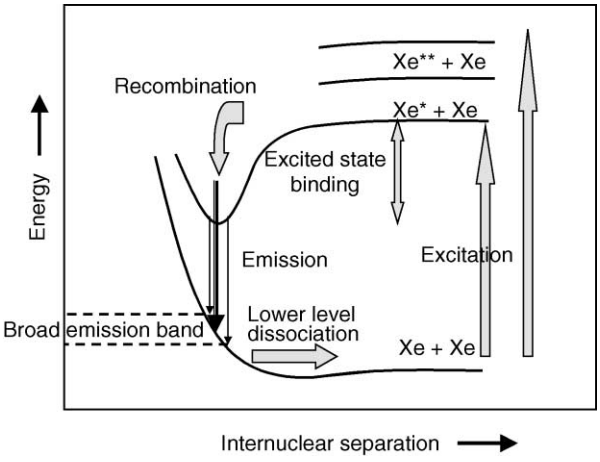

Figure 3 A schematic of the potential energy curves for an excimer species such as Xe_2. The excited molecule is bound relative to an excited atom and can radiate to a lower level that rapidly dissociates on psec timescales since the ground state is not bound, save for weak binding due to van der Waals forces. The emission band is intrinsically broad.

The diagram shown in Figure 3 is simplified because it does not show all of the excited states that exist for the excited molecule. There can be closely lying excited states that share the population and radiate at a lower rate, or perhaps absorb to higher levels, also not shown in Figure 3. Such excited state absorption may terminate on states derived from higher atomic excited states, noted as Xe^{**} in the figure, or yield photo-ionization, producing the diatomic ion-molecule plus an electron, such as:

$$Xe_2^* + h\nu \rightarrow Xe_2^+ + e \qquad [1]$$

Such excited state absorption limited the efficiency for the VUV rare gas excimers, even though they have very high formation and fluorescence efficiency.

Rare gas halide excimer lasers evolved from 'chemi-luminescence' chemical kinetics studies which were looking at the reactive quenching of rare gas metastable excited states in flowing after glow experiments. Broadband emission in reactions with halogen molecules was observed in these experiments, via reactions such as:

$$Xe^* + Cl_2 \rightarrow XeCl^* + Cl \qquad [2]$$

At low pressure the emissions from molecules, such as $XeCl^*$, are broad in the emissions bandwidth. Shortly after these initial observations, the laser community began examination of these species in high-pressure, electron-beam excited mixtures. The results differed remarkably from the low-pressure experiments and those for the earlier excimers such as Xe_2^*. The spectrum was shifted well away from the VUV emission. Moreover, the emission was much sharper at high pressure, though still a continuum with a bandwidth of the order of 4 nm. A basis for understanding is sketched in the potential energy curves of Figure 4. In this schematic we identify the rare gas atoms by Rg, excited rare gas atoms by

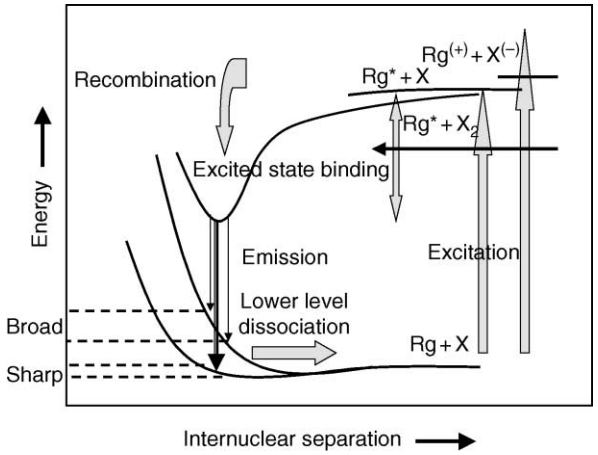

Figure 4 The potential energy curves for rare gas halides are sketched here. Both relatively sharp continuum emission is observed along with broad bands corresponding to different lower levels. The excited ion pair states consist of 3 distinct levels, two that are very close in energy and one that is shifted up from the upper laser level (the B state) by the spin orbit splitting of the rare gas ion.

Rg^*, and halogen atoms by X. Ions play a very important role in the binding and reaction chemistry, leading to excited laser molecules.

The large shift in wavelength from the VUV of rare gas dimer excimers, ~308 nm in $XeCl^*$ versus 172 nm in Xe_2^*, is due to the fact that the binding in the excited state of the rare gas halide is considerably stronger. The sharp and intense continuum at high pressure (> ~100 torr total pressure) is due to the fact that the 'sharp' transition terminates on a 'flat' portion of the lower-level potential energy curve. Indeed, in XeCl and XeF, the sharp band laser transition terminates on a slightly bound portion of the lower-level potential energy curve. Both the sharp emissions and broad bands are observed, due to the fact that some transitions from the excited levels terminate on a second, more repulsive potential energy curve.

An understanding of the spectroscopy and kinetic processes in rare gas plus halogen mixtures is based on the recognition that the excited state of a rare gas halide molecule is very similar to the ground state of the virtually isoelectronic alkali halide. The binding energy and mechanism of the excited state is very close to that of the ground state of the most similar alkali halide. Reactions of excited state rare gases are very similar to those of alkali atoms. For example, Xe^* and Cs are remarkably similar, from a chemistry and molecular physics point of view, as they have the same outer shell electron configuration and similar ionization potentials. The ionization potential of Xe^* is similar to that of cesium (Cs). Cs, and all the other alkali atoms, react rapidly with halogen molecules. Xenon metastable excited atoms react rapidly with halogen molecules. The alkali atoms all form ionically bonded ground states with halogens. The rare gas halides are effectively strongly bonded ion pairs, $Xe^{(+)}X^{(-)}$, that are very strongly bonded relative to the excited states that yield them. The difference between, for example, $XeCl^*$ and CsCl, is that $XeCl^*$ radiates in a few nanoseconds while CsCl is a stable ground-state molecule. The binding energy for these ionic bonded molecules is much greater than the more covalent type of bonding that is found in the rare gas excimer excited states. Thus XeI^*, which is only one electron different (in the I) than Xe_2^*, emits at 254 nm instead of 172 nm.

The first observed and most obvious connection to alkali atoms is in formation chemistry. Mostly, rare gas excited states react with halogen molecules rapidly. The rare gas halide laser analog reaction sequence is shown below, where some form of electric discharge excitation kicks the rare gas atom up to an excited state, so that it can react like an alkali atom, eqn [3]:

$$e_{fast} + Kr \rightarrow Kr^* + e_{slow} \qquad [3]$$

$$Kr^* + F_2 \rightarrow KrF^*(v, J)_{high} + F \qquad [4]$$

There are subtle and important cases where the neutral reaction, such as that shown in eqn [2] or [4], is not relevant as it is too slow compared to other processes. Note that the initial reaction does not yield the specific upper levels for the laser but states that are much higher up in the potential well of the excited rare gas halide excimer molecule. Further collisions with a buffer gas are needed to relax the states to the vibrational levels that are the upper levels for the laser transition. Such relaxation at high pressure can be fast, which leads the high-pressure spectrum to be much sharper than those first observed in flowing after-glow experiments.

The excited states of the rare gas halides are ion pairs bound together for their brief radiative lifetime. This opens up a totally different formation channel, indeed the one that often dominates the mechanism, ion–ion recombination. Long before excimer lasers were studied, it was well known that halogen molecules would react with 'cold' electrons (those with an effective temperature less than a few eV) in a process called attachment. The sequence leading to the upper laser level is shown below for the Kr/F_2 system, but the process is generically identical in other rare gas halide mixtures.

KrF^* formation kinetics via ion channel:

Ionization: $$e + Kr \rightarrow Kr^+ + 2e \quad [5]$$

Attachment: $$e + F_2 \rightarrow F^{(-)} + F \quad [6]$$

Ion–ion recombination:

$$Kr^+ + F^{(-)} + M \rightarrow KrF^*(v, J)_{high} + M \quad [7]$$

Relaxation:

$$KrF^*(v, J)_{high} + M \rightarrow KrF^*(v, J)_{low} + M \quad [8]$$

Finally, there is one other formation mechanism, displacement, that is unique to the rare gas halides. In this process, a heavier rare gas will displace a lighter rare gas ion in an excited state to form a lower-energy excited state:

$$ArF^* + Kr \rightarrow KrF^*(v, J)_{high} + Ar \quad [9]$$

In general, the most important excimer lasers tend to have all of these channels contributing to excited state formation for optimized mixtures.

These kinetic formation sequences express some important points regarding rare gas halide lasers. The source of the halogen atoms for the upper laser level disappears via both attachment reactions with electrons and by the reaction with excited states. The halogen atoms eventually recombine to make molecules, but at a rate too slow for sufficient continuous wave (cw) laser gain. For excimer-based lamps, however, laser gain is not a criterion and very efficient excimer lamps can be made. Another point to note is that forming the inversion requires transient species (and in some cases halogen fuels) that absorb the laser light. Net gain and extraction efficiency are a trade-off between pumping rate, an increase in which often forms more absorbers and absorption itself. Table 2 provides a listing of some of the key absorbers. Finally, the rare gas halide excited states can be rapidly quenched in a variety of processes. More often than not, the halogen molecule and the electrons in the discharge react with the excited states of the rare gas halide, removing the contributors to gain. We show, in Table 3, a sampling of some of the types of formation and quenching reactions with their kinetic rate constant parameters. Note that one category of reaction, three-body quenching, is unique to excimer lasers. Note also that the three-body recombination of ions has a rate coefficient that is effectively pressure dependent. At pressures above ~3 atm, the diffusion of ions toward each other is slowed and the effective recombination rate constant decreases.

Though the rare gas halide excited states can be made with near-unity quantum yield from the primary excitation, the intrinsic laser efficiency is not this high. The quantum efficiency is only ~25% (recall rare gas halides all emit at much longer wavelengths than rare gas excimers); there is inefficient extraction due to losses in the gas and windows. In practice there are also losses in coupling the power into the laser, and wasted excitation during the finite start-up time. The effect of losses is shown in Table 4 and Figure 5 where the pathways are charted and losses identified. In KrF, it takes ~20 eV to make a rare gas ion in an electron beam excited mixture,

Table 2 Absorbers in rare gas halide lasers

Species	*XeF*	*XeCl*	*KrF*	*ArF*
Laser λ (nm)	351, 353	308	248	193
F_2 absorption σ (cm^2)	8×10^{-21}	NA	1.5×10^{-20}	
Cl_2 absorption σ (cm^2)	NA	1.7×10^{-19}	NA	NA
HCl absorption σ (cm^2)	NA	Nil	NA	NA
$F^{(-)}$ absorption σ (cm^2)	2×10^{-18}	NA	5×10^{-18}	5×10^{-18}
$Cl^{(-)}$ absorption σ (cm^2)	NA	2×10^{-17}	NA	NA
$Rg_2^{(+)}$ diatomic ion absorption σ (cm^2)[a]	Ne: $\sim 10^{-18}$ Ar: $\sim 3 \times 10^{-17}$ Xe: $\sim 3 \times 10^{-17}$	Ne: $\sim 10^{-17}$ Ar: $\sim 4 \times 10^{-17}$ Xe: $\sim 3 \times 10^{-18}$	Ne: $\sim 2.5 \times 10^{-17}$ Ar: $\sim 2 \times 10^{-18}$ Kr $< 10^{-18}$	Ne: $\sim 10^{-18}$ Ar: NIL
Other transient absorbers	Excited states of rare gas atoms and rare gas dimer molecules $\sigma \sim 10^{-19}$–10^{-17}	Excited states of rare gas atoms and rare gas dimer molecules $\sigma \sim 10^{-19}$–10^{-17}	Excited states of rare gas atoms and rare gas dimer molecules $\sigma \sim 10^{-19}$–10^{-17}	Excited states of rare gas atoms and rare gas dimer molecules $\sigma \sim 10^{-19}$–10^{-17}
Other	Lower laser level absorbs unless heated	Weak lower level absorption $\sigma \sim 4 \times 10^{-16}$	Windows and dust can be an issue	Windows and dust can be an issue

[a]Note that the triatomic rare gas halides of the form Rg_2X will exhibit similar absorption as the diatomic rare gas ions as the triatomic rare gas halides of this form are essentially ion pairs of an $Rg_2^{(+)}$ ion and the halide ion.

Table 3 Typical formation and quenching reactions and rate coefficients

Formation	
Rare gas plus halogen molecule	$Kr^* + F_2 \rightarrow KrF^*(v, J)+F$ $k \sim 7\times10^{-10}$ cm^3/sec; Branching ratio to $KrF^* \sim 1$ $Ar^* + F_2 \rightarrow ArF^*(v, J)+F$ $k \sim 6\times10^{-10}$ cm^3/sec; Branching ratio to $ArF^* \sim 60\%$ $Xe^* + F_2 \rightarrow XeF^*(v, J)+F$ $k \sim 7\times10^{-10}$ cm^3/sec; Branching ratio to $XeF^* \sim 1$ $Xe^* + HCl(v = 0) \rightarrow Xe + H + Cl$ $k \sim 6\times10^{-10}$ cm^3/sec; Branching ratio to $XeCl^* \sim 0$ $Xe^* + HCl(v = 1) \rightarrow XeCl^* + H$ $k \sim 2\times10^{-10}$ cm^3/sec; Branching ratio to $XeCl^* \sim 1$
Ion–ion recombination	$Ar^{(+)} + F^{(-)} + Ar \rightarrow ArF^*(v,J)$ $k \sim 1\times10^{-25}$ cm^6/sec at 1 atm and below $k \sim 7.5\times10^{-26}$ cm^6/sec at 2 atm; Note effective 3-body rate constant decreases further as pressure goes over ~2 atm $Kr^{(+)} + F^{(-)} + Kr \rightarrow KrF^*(v, J)$ $k \sim 7\times10^{-26}$ cm^6/sec at 1 atm and below; rolls over at higher pressure
Displacement	$ArF^*(v, J)+Kr \rightarrow KrF^*(v, J)+Ar$ $k \sim 2\times10^{-10}$ cm^3/sec; Branching ratio to $KrF^* \sim 1$
Quenching	
Halogen molecule	$XeCl^* + HCl \rightarrow Xe + Cl + HCl$ $k \sim 5.6\times10^{-10}$ cm^3/sec; $KrF^* + F_2 \rightarrow Kr + F + F$ $k \sim 6\times10^{-10}$ cm^3/sec; All halogen molecule quenching have very high reaction rate constants
3-body inert gas	$ArF^* + Ar + Ar \rightarrow Ar_2F^* + Ar$ $k \sim 4\times10^{-31}$ cm^6/sec $KrF^* + Kr + Ar \rightarrow Kr_2F^* + Ar$ $k \sim 6\times10^{-31}$ cm^6/sec $XeCl^* + Xe + Ne \rightarrow Xe_2Cl^* + Ne$ $k \sim 1\times10^{-33}$ cm^6/sec; 4×10^{-31} cm^6/sec with Xe as 3rd body These reactions yield a triatomic excimer at lower energy that can not be recycled back to the desired laser states
Electrons	$XeCl^* + e \rightarrow Xe + Cl + e$ $k \sim 2\times10^{-7}$ cm^3/sec In 2-body quenching by electrons, the charge of the electron interacts with the dipole of the rare gas halide ion pair at long range; above value is typical of others
2-body inert gas	$KrF^* + Ar \rightarrow Ar + Kr + F$ $k \sim 2\times10^{-12}$ cm^3/sec $XeCl^* + Ne \rightarrow Ne + Xe + Cl$ $k \sim 3\times10^{-13}$ cm^3/sec 2-body quenching by rare gases is typically slow and less important than the reactions noted above

somewhat less in an electric discharge. The photon release is ~5 eV; the quantum efficiency is only 25%. Early laser efficiency measurements (using electron beam excitation) showed laser efficiency in the best cases slightly in excess of 10%, relative to the deposited energy. The discrepancy relative to the quantum efficiency is due to losses in the medium. For the sample estimate in Table 4 and Figure 5 we show approximate density of key species in the absorption chain, estimated on a steady-state approximation of the losses in a KrF laser for an excitation rate of order 1 MW/cc, typical of fast discharge lasers. The net small signal gain is of the order of 5%/cm. The key absorbers are the parent halogen molecule, F_2, the fluoride ion $F^{(-)}$, and the rare gas excited state atoms. A detailed pulsed kinetics code will provide slightly different results due to transient kinetic effects and the intimate coupling of laser extraction to quenching and absorber dynamics. The ratio of gain to loss is usually in the range of 7 to 20, depending on the actual mixture used and the rare gas halide wavelength. The corresponding extraction efficiency is then limited to the range of ~50%. The small signal gain, g_o, is related to the power deposition

Table 4 Typical ground and excited state densities shown for KrF at $P_{in} \sim 1$ MW/cm^3

Species	*Amount particles/cm^3*	*Absorption σ (cm)^2*	*Loss %/cm*
F_2	$\sim 1.2 \times 10^{17}$	1.5×10^{-20}	0.18
Kr	$\sim 3 \times 10^{18}$	–	–
Buffer	4×10^{19}	–	–
$F^{(-)}$	$\sim 10^{14}$	5×10^{-18}	0.05
Rg^*, Rg^{**}	1×10^{15}	$\langle 10^{-18} \rangle$ depends on ratio of Rg^{**}/Rg^*	0.1
KrF (before dissociating)	$\sim 10^{12}$	2×10^{-16}	0.02
Rg_2F^*	8×10^{14}, Note this species density decreases as flux grows	1×10^{-18}	0.08
KrF^* (B)	2.5×10^{14}	2×10^{-16}	5 (gain)

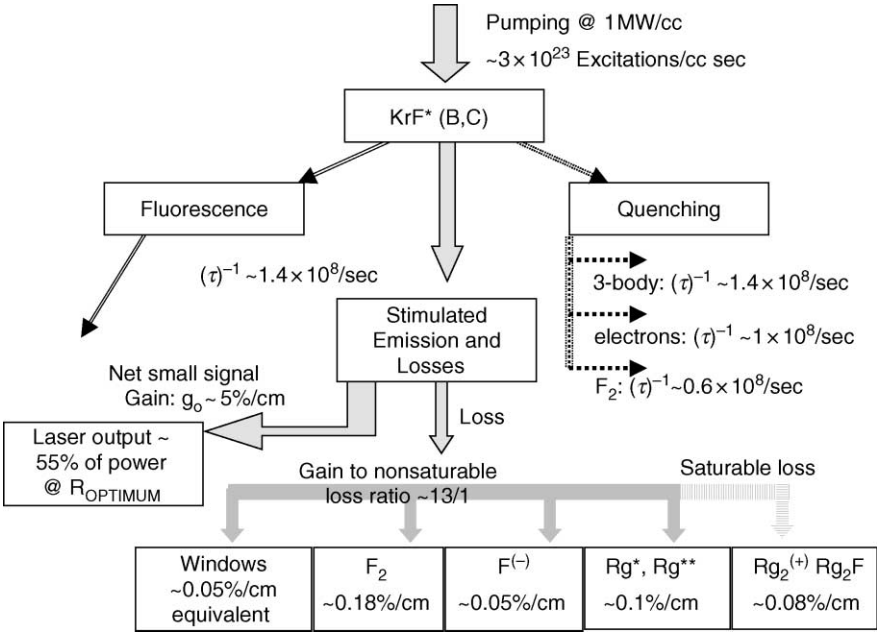

Figure 5 The major decay paths and absorbers that impact the extraction of excited states of rare gas halide excimers. Formation is via the ion–ion recombination, excited atom reaction with halogens and displacement reactions, not shown. We note for a specific mixture of KrF the approximate values of the absorption by the transient and other species along with the decay rates for the major quenching processes. Extraction efficiency greater than 50% is quite rare.

rate per unit volume, $P_{\text{deposited}}$, by eqn [10].

$$P_{\text{deposited}} = g_0 E^* (\tau_{\text{upper}} \eta_{\text{pumping}} \eta_{\text{branching}} f \sigma)^{-1} \qquad [10]$$

E^* is the energy per excitation, ~20 eV or 3.2×10^{-18} J/excitation, f is the fraction of excited molecules in the upper laser level, ~40% due to KrF^* in higher vibrational states and the slowly radiating 'C' state. The laser cross-section is σ, and the η terms are efficiencies for getting from the primary excitation down to the upper laser level. The upper state lifetime, τ_{upper}, is the sum of the inverses of radiative and quenching lifetimes. When the laser cavity flux is sufficiently high, stimulated emission decreases the flow of power into the quenching processes.

The example shown here gives a ratio of net gain to the nonsaturating component of loss of 13/1. Of the excitations that become KrF^*, only ~55% or so will be extracted in the best of cases. For other less ideal rare gas halide lasers, the gain to loss ratio, the extraction efficiency, and the intrinsic efficiency are all lower. Practical discharge lasers have lower practical wall plug efficiency due to a variety of factors, discussed below.

Discharge Technology

Practical discharge lasers use fast-pulse discharge excitation. In this scheme, an outgrowth of the CO_2 TEA laser, the gas is subjected to a rapid high-voltage pulse from a low-inductance pulse forming line or network, PFL or PFN. The rapid pulse serves to break down the gas, rendering it conductive with an electron density of $> \sim 10^{14}$ electrons/cm^3. As the

gas becomes conductive, the voltage drops and power is coupled into the medium for a short duration, typically less than 50 nsec. The discharge laser also requires some form of 'pre-ionization', usually provided by sparks or a corona-style discharge on the side of the discharge electrodes. The overall discharge process is intrinsically unstable, and pump pulse duration needs to be limited to avoid the discharge becoming an arc.

Moreover, problems with impedance matching of the PFN or PFL with the conductive gas lead to both inefficiency and extra energy that can go into post-discharge arcs, which both cause component failure and produce metal dust which can give rise to window losses. A typical discharge laser has an aperture of a few cm^2 and a gain length of order 80 cm and produces outputs in the range of 100 mJ to 1 J. The optical pulse duration tends to be ~20 nsec, though the electrical pulse is longer due to the finite time needed for the gain to build up and the stimulated emission process to turn spontaneously emitted photons into photons in the laser cavity.

The pre-ionizer provides an initial electron density on the order of 10^8 electrons/cm^3. With spark pre-ionization or corona pre-ionization, it is difficult to make a uniform discharge over an aperture greater than a few cm^2. For larger apertures, one uses X-rays for pre-ionization. X-ray pre-ionized discharge excimer lasers have been scaled to energy well over 10 J per pulse and can yield pulse durations over 100 nsec. The complexity and expense of the X-ray approach, along with the lack of market for lasers in this size range, resulted in the X-ray approach remaining in the laboratory.

Aside from the kinetic issues of the finite time needed for excitation to channel into the excimer upper levels and the time needed for the laser to 'start up' from fluorescent photons, these lasers have reduced efficiency due to poor matching of the pump source to the discharge. Ideally, one would like to have a discharge such that when it is conductive the voltage needed to sustain the discharge is less than half of that needed to break the gas down. Regrettably for the rare gas halides (and in marked distinction to the CO_2 TEA laser) the voltage that the discharge sustains in a quasi-stable mode is ~20% of the breakdown voltage, perhaps even less, depending on the specific gases and electrode shapes.

Novel circuits, which separate the breakdown phase from the fully conductive phase, can readily double the efficiency of an excimer discharge laser, though this approach is not necessary in many applications. The extra energy that is not dissipated in the useful laser discharge often results in arcing or 'hot' discharge areas after the main laser pulse, leading to electrode sputtering, dust that finds its way to windows, and the need to service the laser after ~10^8 pulses. When one considers the efficiency of the power conditioning system, along with the finite kinetics of the laser start-up process in short pulses, and the mismatch of the laser impedance to the PFN/PFL impedance, lasers that may have 10% intrinsic efficiency in the medium in e-beam excitation may only have 2% to 3% wall plug efficiency in a practical discharge laser.

A key aspect of excimer technology is the need for fast electrical circuits to drive the power into the discharge. This puts a significant strain on the switch that is used to start the process. While spark gaps, or multichannel spark gaps, can handle the required current and current rate of rise, they do not present a practical alternative for high-pulse rate operation. Thyratrons and other switching systems, such as solid state switches, are more desirable than a spark gap, but do not offer the desired needed current rate of rise. To provide the pumping rate of order 1 MW/cm^3 needed for enough gain to turn the laser on before the discharge becomes unstable, the current needs to rise to a value of the order of 20 kA in a time of ~20 nsec; the current rate of rise is ~10^{12} A/sec. This rate of rise will limit the lifetime of the switch that drives the power into the laser gas. As a response to this need, magnetic switching and magnetic compression circuits were developed so that the lifetime of the switch can be radically increased. In the simplest cases, one stage of magnetic compression is used to make the current rate of rise to be within the range of a conventional thyratron switch as used in radar systems. Improved thyratrons and a simple magnetic assist also work. For truly long operating lifetimes, multiple stages of magnetic switching and compression are used, and with a transformer one can use a solid state diode as the start switch for the discharge circuit. A schematic of an excimer pulsed power circuit, that uses a magnetic assist with a thyratron and one stage of magnetic compression, is shown in Figure 6. The magnetic switching approach can also be used to provide two separate circuits to gain high efficiency by having one circuit to break down the gas (the spiker) and a second, low-impedance 'sustainer' circuit, to provide the main power flow. In this approach, the laser itself can act as part of the circuit by holding off the sustaining voltage for a μ-sec or so during the charge cycle and before the spiker breaks down the gas. A schematic of such a circuit is shown in Figure 7. Using this type of circuit, the efficiency of a XeCl laser can be over 4% relative to the wall plug. A wide variety of technological twists on this approach have been researched.

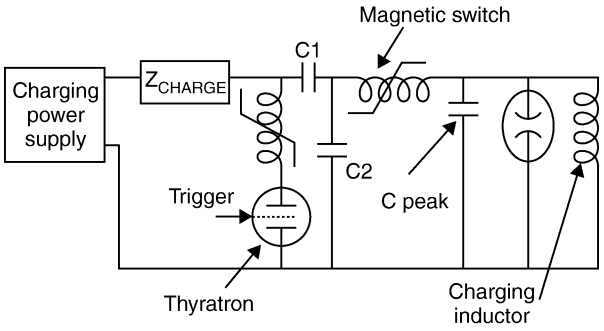

Figure 6 One of the variants on magnetic switching circuits that have been used to enhance the lifetime of the primary start switch. A magnetic switch in the form of a simple 1 turn inductor with a saturable core magnetic material such as a ferrite allows the thyratron to turn on before major current flows. Other magnetic switches may be used in addition to peak up the voltage rate of rise on the laser head or to provide significant compression. For example one may have the major current flow in the thyratron taking place on the 500 nsec time scale while the voltage pulse on the discharge is in the 50 nsec duration. A small current leaks through and is accommodated by the charging inductor.

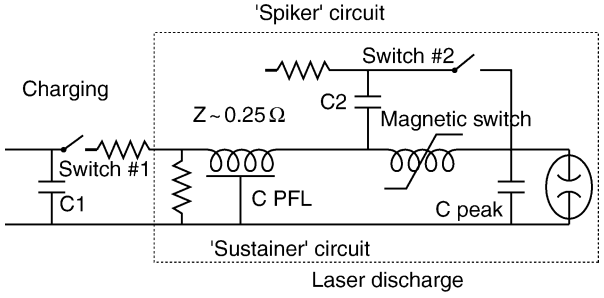

Figure 7 For the ultimate in efficiency the circuit can be arranged to provide a leading edge spike that breaks the gas down using a high impedance 'spiker' and a separate circuit that is matched to the discharge impedance when it is fully conductive. High coupling efficiency reduces waste energy that can erode circuit and laser head components via late pulse arcs. The figure shows a magnetic switch as the isolation but the scheme can be implemented with a second laser head as the isolation switch, a rail gap (not appropriate for long life) or a diode at low voltage.

Excimer lasers present some clear differences in resonator design compared to other lasers. The apertures are relatively large, so one does not build a TEM_{oo} style cavity for good beam quality and expect to extract any major portion of the energy available. The typical output is divergent and multimode. When excimer lasers are excited by a short pulse discharge, ~30 nsec, the resulting gain duration is also short, ~20 nsec, limiting the number of passes a photon in a resonator can have in the gain. The gain duration of ~20 nsec only provides ~3.5 round trips of a photon in the cavity during the laser lifetime, resulting in the typical high-order multimode beam. Even with an unstable resonator, the gain duration is not long enough to collapse the beam into the lowest-order diffraction-limited output. If line narrowing is needed, and reasonable efficiency is required, an oscillator amplifier configuration is often used with the oscillator having an appropriate tuning resonator in the cavity. If both narrow spectral linewidth and excellent beam quality are needed one uses a seeded oscillator approach where the narrowband oscillator is used to seed an unstable resonator on the main amplifier. By injecting the seed into the unstable resonator cavity, a few nsec before the gain is turned on, the output of the seeded resonator can be locked in wavelength, bandwidth, and provide good beam quality. Long pulse excimer lasers, such as e-beam excited lasers or long pulse X-ray pre-ionized discharge devices can use conventional unstable resonator technology with good results.

Excimer lasers are gas lasers that run at both high pressure and high instantaneous power deposition rates. During a discharge pulse, much of the halogen bearing 'fuel' is burned out by the attachment and reactive processes. The large energy deposition per pulse means that pressure waves are generated. All of these combine with the characteristic device dimensions to require gas flow to recharge the laser mixture between pulses. For low pulse rates, less than ~200 Hz, the flow system need not be very sophisticated. One simply needs to flush the gas from the discharge region with a flow having a velocity of the order of 5 m/sec for a typical discharge device. The flow is transverse to the optical and discharge directions. At high pulse rates, the laser designer needs to consider flow in much more detail to minimize the power required to push the gas through the laser head. Circulating pressure waves need to be damped out so that the density in the discharge region is controlled at the time of the next pulse. Devices called acoustic dampers are placed in the sides of the flow loop to remove pressure pulses. A final subtlety occurs in providing gas flow over the windows. The discharge, post pulse arcs, and reactions of the halogen source with the metal walls and impurities creates dust. When the dust coats the windows, the losses in the cavity increase, lowering efficiency. By providing a simple gas flow over the window, the dust problem can be ameliorated. For truly long life, high-reliability lasers, one needs to take special care in the selection of materials for electrodes and insulators and avoid contamination, by assembling in clean environments.

Free Electron Lasers

Introduction

The Free Electron Laser (FEL) is an exceptional kind of laser. Its active medium is not matter, but charged particles (electrons) accelerated to high energies, passing in vacuum through a periodic undulating magnetic field. This distinction is the main reason for the exceptional properties of FEL: operating at a wide range of wavelengths – from mm-wave to X-rays with tunability, high power, and high efficiency.

In this article we explain the physical principles of FEL operation, the underlying theory and technology of the device and various operating schemes, which have been developed to enhance performance of this device.

The term 'Free Electron Laser' was coined by John Madey in 1971, pointing out that the radiative transitions of the electrons in this device are between free space (more correctly – unbound) electron quantum states, which are therefore states of continuous energy. This is in contrast to conventional atomic and molecular lasers, in which the electron performs radiative transition between bound (and therefore of distinct energy) quantum states. Based on these theoretical observations, Madey and his colleagues in Stanford University demonstrated FEL operation first as an amplifier (at $\lambda = 10.6\ \mu m$) in 1976, and subsequently as an oscillator (at $\lambda = 3.4\ \mu m$) in 1980.

From the historical point of view, it turned out that Madey's invention was essentially an extension of a former invention in the field of microwave-tubes technology – the Ubitron. The Ubitron, a mm-wave electron tube amplifier based on a magnetic undulator, was invented and developed by Philips and Enderbry who operated it at high power levels in 1960. The early Ubitron development activity was not noticed by the FEL developers because of the disciplinary gap, and largely because its research was classified at the time. Renewed interest in high-power mm-wave radiation emission started in the 1970s, triggered by the development of pulsed-line generators of 'Intense Relativistic Beams' (IRB). This activity, led primarily by plasma physicists in the defense establishment laboratories of Russia (mostly IAP in Gorky – Nizhny Novgorod) and the US (mostly N.R.L. – DC) led to development of high-gain high-power mm-wave sources independently of the development of the optical FEL. The connection between these devices and between them to conventional microwave tubes (as Traveling Wave Tubes – TWT) and other electron beam radiation schemes, like Cenenkov and Smith-Purcell radiation that may also be considered FELs, was revealed in the mid-1970s, starting with the theoretical works of P. Spangle, A. Gover and A. Yariv who identified that all these devices satisfy the same dispersion equation as the TWT derived by John Pierce in the 1940s. Thus, the optical FEL could be conceived as a kind of immense electron tube, operating with a high-energy electron beam in the low gain regime of the Pierce TWT dispersion equation.

The extension of the low-gain FEL theory to the general 'electron-tube' theory is important because it led to development of new radiation schemes and new operating regimes of the optical FEL. This was exploited by physicists in the discipline of accelerator physics and synchrotron radiation, who identified, starting with the theoretical works of C. Pellegrini and R. Bonifacio in the early 1980s, that high-current, high-quality electron beams, attainable with further development of accelerators technology, could make it possible to operate FELs in the high-gain regime, even at short wavelengths (vacuum ultra-violet – VUV and soft X-ray) and that the high-gain FEL theory can be extended to include amplification of the incoherent synchrotron spontaneous emission (shot noise) emitted by the electrons in the undulator. These led to the important development of the 'self (synchrotron) amplified spontaneous emission (SASE) FEL', which promised to be an extremely high brightness radiation source, overcoming the fundamental obstacles of X-ray lasers development: lack of mirrors (for oscillators) and lack of high brightness radiation sources (for amplifiers).

A big boost to the development of FEL technology was given during the period of the American 'strategic defense initiative – SDI' (Star-Wars) program in the mid-1980s. The FEL was considered one of the main candidates for use in a ground-based or space-based 'directed energy weapon – DEW', that can deliver megawatts of optical power to hit attacking missiles. The program led to heavy involvement of major American defense establishment laboratories (Lawrence–Livermore National Lab, Los-Alamos National Lab) and contracting companies (TRW, Boeing). Some of the outstanding results of this effort were demonstration of the high-gain operation of an FEL amplifier in the mm-wavelength regime, utilizing an Induction Linac (Livermore, 1985), and demonstration of enhanced radiative energy extraction efficiency in FEL oscillator, using a 'tapered wiggler' in an RF-Linac driven FEL oscillator (Los-Alamos, 1983). The program has not been successful in demonstrating the potential of FELs to operate at the high average power levels needed for DEW applications. But after the cold-war period, a small part of the program continues to support research and development of medical FEL application.

Principles of FEL Operation

Figure 1 displays schematically an FEL oscillator. It is composed of three main parts: an electron accelerator, a magnetic wiggler (or undulator), and an optical resonator.

Without the mirrors, the system is simply a synchrotron undulator radiation source. The electrons in the injected beam oscillate transversely to their propagation direction z, because of the transverse magnetic Lorenz force:

$$\mathbf{F}_{\perp} = -ev_z\hat{\mathbf{e}}_z \times \mathbf{B}_{\perp} \qquad [1]$$

In a planar (linear) wiggler, the magnetic field on axis is approximately sinusoidal:

$$\mathbf{B}_{\perp} = B_{\mathrm{w}}\hat{e}_y \cos k_{\mathrm{w}}z \qquad [2]$$

In a helical wiggler:

$$\mathbf{B}_{\perp} = B_{\mathrm{w}}(\hat{\mathbf{e}}_y \cos k_{\mathrm{w}}z + \hat{\mathbf{e}}_x \sin k_{\mathrm{w}}z) \qquad [3]$$

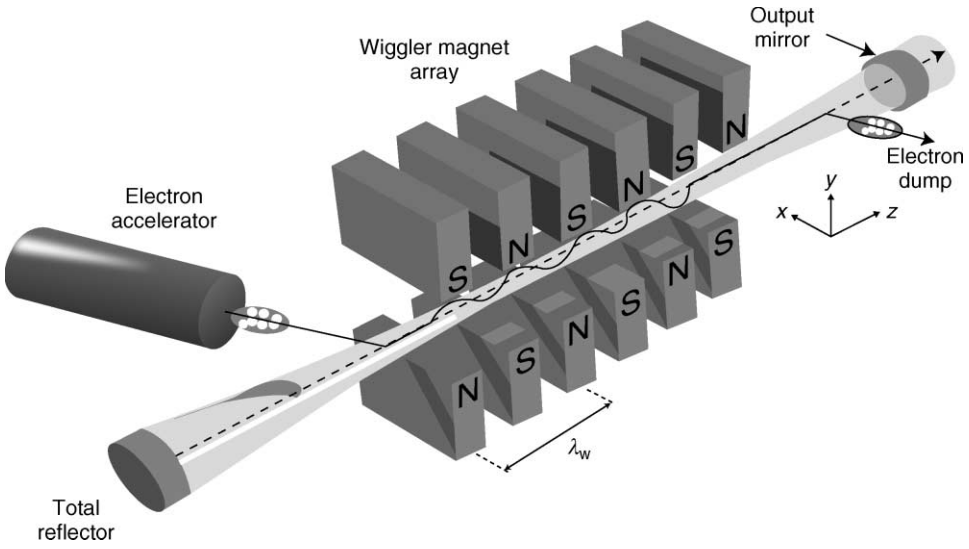

Figure 1 Components of a FEL-oscillator. (Reproduced from Benson SV (2003) Free electron lasers push into new frontiers. *Optics and Photonics News* 14: 20–25. Illustration by Jaynie Martz.)

In either case, if we assume constant (for the planar wiggler – only on the average) axial velocity, then $z = v_z t$. The frequency of the transverse force and the mechanical oscillation of the electrons, as viewed transversely in the laboratory frame of reference, is:

$$\omega_{0s} = k_w v_z = 2\pi \frac{v_z}{\lambda_w} \qquad [4]$$

where $\lambda_w = 2\pi/k_w$ is the wiggler period.

The oscillating charge emits an electromagentic radiation wavepacket. In a reference frame moving with the electrons, the angular radiation pattern looks exactly like dipole radiation, monochromatic in all directions (except for the frequency-line-broadening due to the finite oscillation time, i.e., the wiggler transit time). In the laboratory reference-frame the radiation pattern concentrates in the propagation ($+z$) direction, and the Doppler up-shifted radiation frequency depends on the observation angle Θ relative to the z-axis:

$$\omega_0 = \frac{\omega_{0s}}{1 - \beta_z \cos\Theta} \qquad [5]$$

On axis ($\Theta = 0$), the radiation frequency is:

$$\omega_0 = \frac{ck_w\beta_z}{1-\beta_z} = (1+\beta_z)\beta_z\gamma_z^2 ck_w \cong 2\gamma_z^2 ck_w \qquad [6]$$

where $\beta_z \equiv v_z/c$, $\gamma_z \equiv (1-\beta_z^2)^{-1/2}$ are the axial (average) velocity and the axial Lorenz factor, respectively, and the last part of the equation is valid only in the (common) highly relativistic limit $\gamma_z \gg 1$.

Using the relations $\beta_z^2 + \beta_\perp^2 = \beta^2$, $\beta_\perp = a_w/\gamma$, one can express γ_z:

$$\gamma_z = \frac{\gamma}{1 + a_w^2/2} \qquad [7]$$

(this is for a linear wiggler, in the case of a helical wiggler the denoninator is $1 + a_w^2$):

$$\gamma \equiv (1-\beta^2)^{-1/2} = 1 + \frac{\varepsilon_k}{mc^2} = 1 + \varepsilon_k\,[\text{MeV}]/0.511 \qquad [8]$$

and a_w – (also termed K) 'the wiggler parameter' is the normalized transverse momentum:

$$a_w = \frac{eB_w}{k_w mc} = 0.093 B_w\,[\text{KGauss}]\lambda_w\,[\text{cm}] \qquad [9]$$

Typical values of B_w in FEL wigglers (undulators) are of the order of Kgauss', and λ_w of the order of CMs, and consequently $a_w < 1$. Considering that electron beam accelerator energies are in the range of MeV to GeV, one can appreciate from eqns [6]–[8], that a significant relativistic Doppler shift factor $2\gamma_z^2$, in the range of tens to millions, is possible. It, therefore, provides incoherent synchrotron undulator radiation in the frequency range of microwave to hard X-rays.

Synchrotron undulator radiation was studied in 1951 and since then has been a common source of VUV radiation in synchrotron facilities. From the point of view of laser physics theory, this radiation can be viewed as 'spontaneous synchrotron radiation emission' in analogy to spontaneous radiation emission by electrons excited to higher bound-electron quantum levels in atoms or molecules. Alternatively, it can be regarded as the classical shot noise radiation, associated with the current fluctuations of the randomly injected discrete charges comprising the electron beam. Evidently this radiation is incoherent, and the fields it produces average in time to zero, because the wavepackets emitted by the randomly injected electrons interfere at the observation point with random phase. However, their energies sum up and can produce substantial power.

Based on fundamental quantum-electrodynamical principles or Einstein's relations, one would expect that any spontaneous emission scheme can be stimulated. This principle lies behind the concept of the FEL, which is nothing but stimulated undulator synchrotron radiation. By stimulating the electron beam to emit radiation, it is possible, as with any laser, to generate a coherent radiation wave and extract more power from the gain medium, which in this case is an electron beam, that carries an immense amount of power. There are two kinds of laser schemes which utilize stimulation of synchrotron undulator radiation:

(i) *A laser amplifier*. In this case the mirrors in the schematic configuration of **Figure 1** are not present, and an external radiation wave at frequencies within the emission range of the undulator is injected at the wiggler entrance. This requires, of course, an appropriate radiation source to be amplified and availability of sufficiently high gain in the FEL amplifier.

(ii) *A laser oscillator*. In this case an open cavity (as shown in **Figure 1**) or another (waveguide) cavity is included in the FEL configuration. As in any laser, the FEL oscillator starts building up its radiation from the spontaneous (synchrotron undulator) radiation which gets trapped in the resonator and amplified by stimulated emission along the wiggler. If the threshold condition is satisfied (having single path gain higher than the round trip losses), the oscillator arrives to saturation and steady state coherent operation after a short transient period of oscillation build-up.

Because the FEL can operate as a high-gain amplifier (with a long enough wiggler and an electron beam of high current and high quality), also a third mode of operation exists: self amplified spontaneous emission (SASE). In this case, the resonator mirrors in Figure 1 are not present and the undulator radiation generated spontaneously in the first sections of the long undulator is amplified along the wiggler and emitted at the wiggler exit at high power and high spatial coherence.

The Quantum-Theory Picture

A free electron, propagating in unlimited free space, can never emit a single photon. This can be proven by examining the conservation of energy and momentum conditions:

$$\varepsilon_{k_i} - \varepsilon_{k_f} = \hbar\omega \qquad [10]$$

$$\mathbf{k}_i - \mathbf{k}_f = \mathbf{q} \qquad [11]$$

that must be satisfied, when an electron in an initial free-space energy and momentum state $(\varepsilon_{k_i}, \hbar k_i)$ makes a transition to a final state $(\varepsilon_{k_f}, \hbar k_f)$, emitting a single photon of energy and momentum $(\hbar\omega, q)$. In free space:

$$\varepsilon_k = c\sqrt{(\hbar\mathbf{k})^2 + (mc^2)^2} \qquad [12]$$

$$\mathbf{q} = \frac{\omega}{c}\hat{\mathbf{e}}_q \qquad [13]$$

and eqns [10]–[13] have only one solution, $\omega = 0$, $\mathbf{q} = 0$. This observation is illustrated graphically in the energy–momentum diagram of Figure 2a in the framework of a one-dimensional model. It appears that if both eqns [10] and [11] can be satisfied, then the phase velocity of the emitted radiation wave $v_{ph} = \omega/q$ (the slope of the chord) will equal the electron wavepacket group velocity $v_g = v_z$ at some intermediate point $k^* = p^*/\hbar$:

$$v_{ph} = \frac{\omega}{q} = \frac{\varepsilon_{ki} - \varepsilon_{kf}}{\hbar(k_i - k_f)} = \left.\frac{\partial\varepsilon}{\partial p}\right|_{p^*} = v_g \qquad [14]$$

For a radiation wave in free space (eqn [13]), this results in $c = v_g$, which contradicts special relativity.

The reason for the failure to conserve both energy and momentum in the transition is that the photon momentum $\hbar q$ it too small to absorb the large momentum shift of the electron, as it recoils while releasing radiative energy $\hbar\omega$. This observation leads to ideas on how to make a radiative transition possible:

(i) *Limit the interaction length*. If the interaction length is L, the momentum conservation

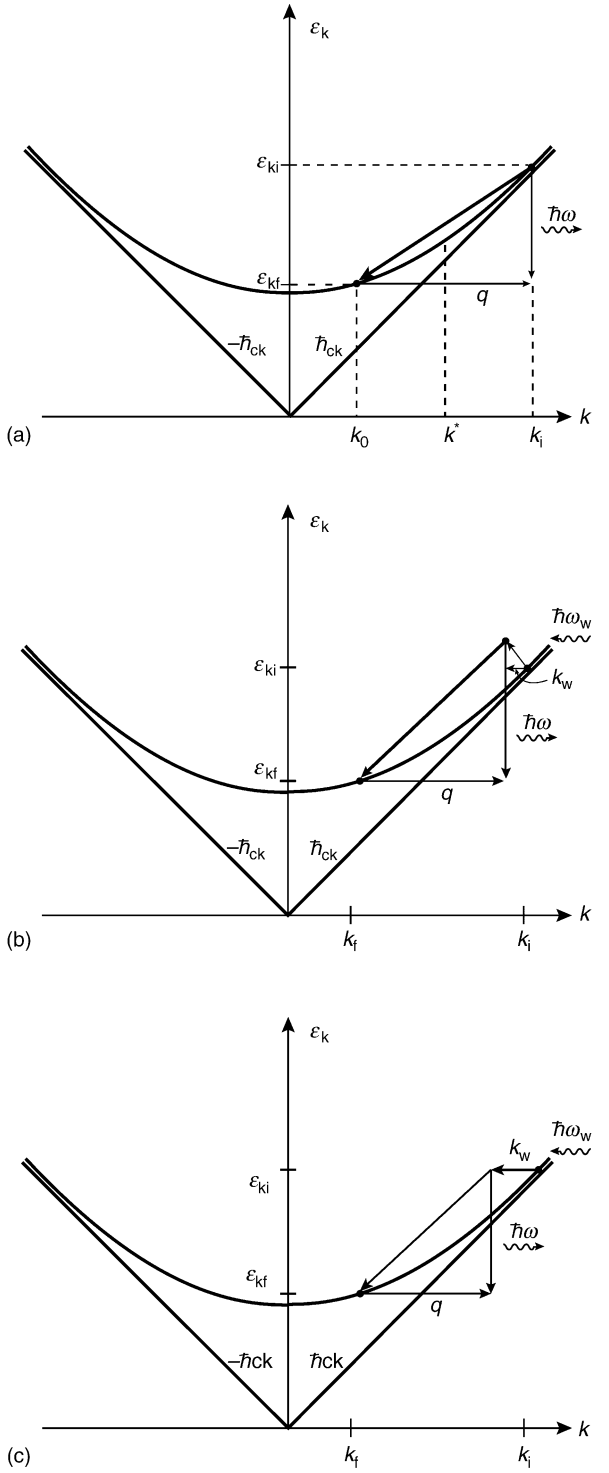

Figure 2 Conservation of energy and momentum in forward photon emission of a free electron: (a) The slope of the tangent to the curve at intermediate point k^*, $\partial\varepsilon_k(k^*)/\partial k$ may be equal to the slope of the chord $\hbar\omega/q$ which is impossible in free space. (b) electron radiative transition made possible with an electromagnetic pump (Compton Scattering). (c) The wiggler wavenumber – k_w conserves the momentum in electron radiative transition of FEL.

condition in eqn [11] must be satisfied only within an uncertainty range $\pm\pi/L$. This makes it possible to obtain radiative emission in free electron radiation effects like 'Transition Radiation' and in microwave tubes like the Klystron.

(ii) *Propagate the radiation wave* in a 'slow wave' structure, where the phase velocity of the radiation wave is smaller than the speed of light, and satisfaction of eqn [14] is possible. For example, in the Cerenkov effect, charged particles pass through a medium (gas) with index of refraction $n > 1$. Instead of eqn [13], $\mathbf{q} = n(\omega)(\omega/c)\hat{\mathbf{e}}_q$, and consequently $q_z = n(\omega)(\omega/c)\cos\Theta_q$, where we assume radiative emission at an angle Θ_q relative to the electron propagation axis z. Substitution in eqn [14] results in the Cerenkov radiation condition $v_g n(\omega)\cos\Theta_q = 1$.

Another example for radiation emission in a slow-wave structure is the Traveling Wave Tube (TWT). In this device, a periodic waveguide of periodicity λ_w permits (via the Floquet theorem) propagation of slow partial waves (space harmonics) with increased wavenumber $q_z + mk_w$ ($m = 1, 2, \ldots$), and again eqn [14] can be satisfied.

(iii) *Rely on a 'two-photon' radiative transition.* This can be 'real photon' Compton scattering of an intense radiation beam (electromagnetic pump) off an electron beam, or 'virtual photon' scattering of a static potential, as is the case in bremsstrahlung radiation and in synchrotron–undulator radiation. The latter radiation scheme may be considered as a 'magnetic brehmsstrahlung' effect or as 'zero frequency pump' Compton scattering, in which the wiggler contributes only 'crystal momentum' $\hbar k_w$, to help satisfy the momentum conservation condition in eqn [11]. The Compton scattering scheme is described schematically for the one-dimensional (back scattering) case in Figure 3, and its conservation of energy and momentum diagram is depicted in Figure 2b (a 'real photon' (ω_w, k_w) free-space pump wave is assumed with $k_w = \omega_w/c$). The analogous diagram of a static wiggler ($\omega_w = 0$, $k_w = 2\pi/\lambda_w$) is shown in Figure 2c. It is worth noting that the effect of the incident scattered wave or the wiggler is not necessarily a small perturbation. It may modify substantially the electron energy-dispersion diagram of the free electron and a more complete 'Brillouin diagram' should be used in Figure 2c. In this sense, the wiggler may be viewed as the analogue of a one-dimensional crystal, and its period λ_w analogous to the crystal lattice constant. The momentum conservation during a radiation transition, with the aid of the wiggler 'crystal momentum' $\hbar k_w$ is quite analogous to the occurrence of vertical radiative transitions in direct bandgap semiconductors, and thus the FEL has, curiously enough, some analogy to microscopic semiconductor lasers.

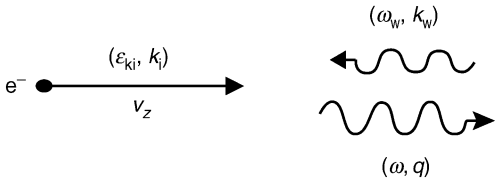

Figure 3 The scheme of backward scattering of an electromagnetic wave off an electron beam (Doppler shifted Compton scattering).

All the e-beam radiation schemes already mentioned can be turned into stimulated emission devices, and thus may be termed 'free electron lasers' in the wide sense. The theory of all of these devices is closely related, but most of the technological development was carried out on undulator radiation (Magnetic brehmsstrahlung) FELs, and the term FEL is usually reserved for this kind (though some developments of Cerenkov and Smith–Purcell FELs are still carried out).

When considering a stimulated emission device, namely enhanced generation of radiation in the presence of an external input radiation wave, one should be aware, that in addition to the emission process described by eqns [10] and [11] and made possible by one of the radiation schemes described above, there is also a stimulated absorption process. Also, this electronic transition process is governed by the conservation of energy and momentum conditions, and is described by eqns [10] and [11] with k_i and k_f exchanged.

Focusing on undulator-radiation FEL and assuming momentum conservation in the axial (z) dimension by means of the wiggler wavenumber k_w, the emission and absorption quantum transition levels and radiation frequencies are found from the solution of equations:

$$\varepsilon_{k_{zi}} - \varepsilon_{k_{zf}} = \hbar\omega_e \qquad [15a]$$

$$k_{zi} - k_{zf} = q_{ze} + k_w \qquad [15b]$$

$$\varepsilon_{k_{za}} - \varepsilon_{k_{zi}} = \hbar\omega_a \qquad [16a]$$

$$k_{za} - k_{zi} = q_{za} + k_w \qquad [16b]$$

For fixed k_w, fixed transverse momentum and given e-beam energy $\varepsilon_{k_{zi}}$ and radiation emission angle Θ_q ($q_z = (\omega/c)\cos\Theta_q$), eqns [15] and [16] have separately

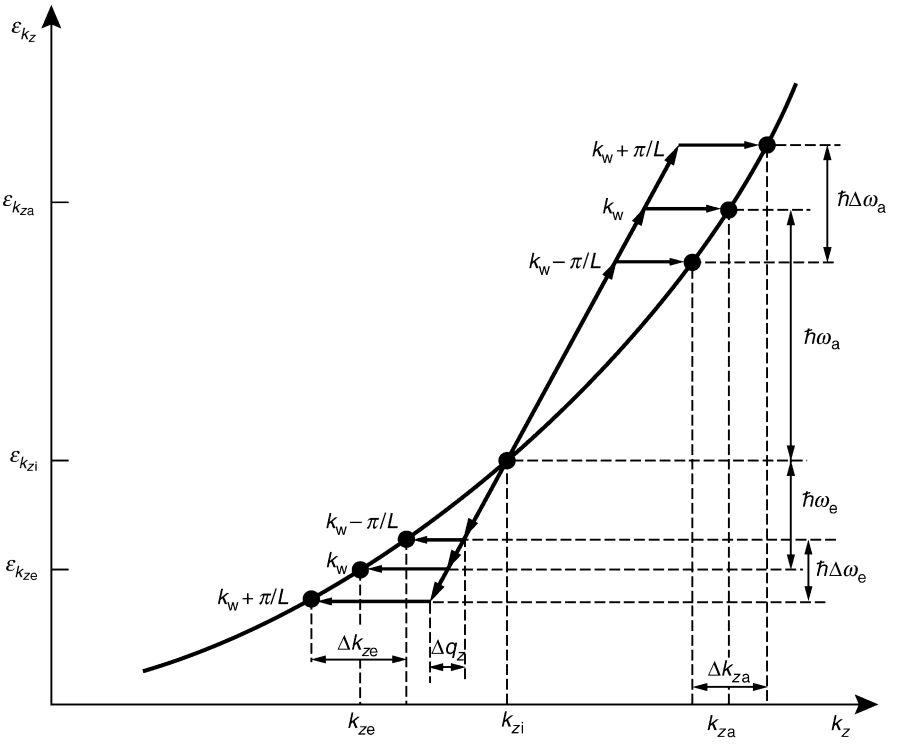

Figure 4 The figure illustrates that the origin of difference between the emission and absorption frequencies is the curvature of the energy dispersion line, and the origin of the homogeneous line broadening is momentum conservation uncertainty $\pm\pi/L$ in a finite interaction length. (Reproduced with permission from Friedman A, Gover A, Ruschin S, Kurizki G and Yariv A (1988) Spontaneous and stimulated emission from quasi-free electrons. *Reviews of Modern Physics* 60: 471–535. Copyright (1988) by the American Physical Society.)

distinct solutions, defining the electron upper and lower quantum levels for radiative emission and absorption respectively. The graphical solutions of these two set of equations are shown in Figure 4, which depicts also the 'homogeneous' frequency-line broadening $\hbar\Delta\omega_e$, $\hbar\Delta\omega_a$ of the emission and absorption lines due to the uncertainty in the momentum conservation $\pm\pi/L$ in a finite interaction length. In the quantum limit of a cold (monoenergetic) e-beam and a long interaction length L, the absorption line center ω_a is larger than the emission line center ω_e, and the linewidths $\Delta\omega_e \cong \Delta\omega_a = \Delta\omega_L$ are narrower than the emission and absorption lines spacing $\omega_a - \omega_e$, as shown in Figure 5a. The FEL then behaves as a 3-level quantum system, with electrons occupying only the central level, and the upper level is spaced apart from it more than the lower level (Figure 4).

In the classical limit $\hbar \to 0$, one can Taylor-expand ε_{kz} around k_{zi}. Using:

$$v_z = \frac{1}{\hbar}\frac{\partial\varepsilon_{kz}}{\partial k_z}, \qquad \frac{1}{\gamma_z^2\gamma m} = \frac{1}{\hbar^2}\frac{\partial^2\varepsilon_{kz}}{\partial k_z^2}$$

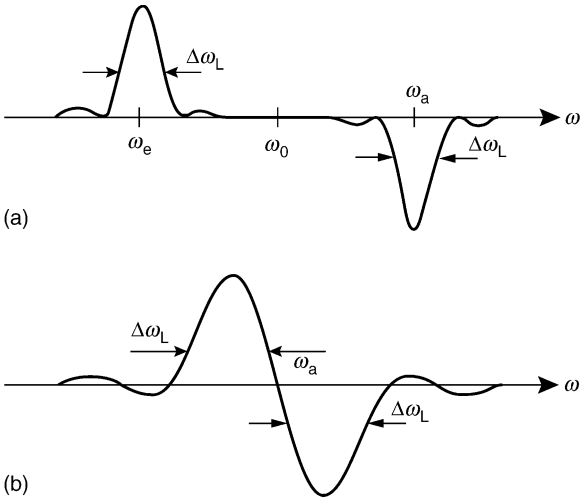

Figure 5 Net gain emission/absorption frequency lines of FEL: (a) in the quantum limit: $\omega_a - \omega_e \gg \Delta\omega_L$, (b) in the classical limit: $\omega_a - \omega_e \ll \Delta\omega_L$.

one obtains:

$$\omega_e \cong \omega_a \cong \omega_0 = v_z(q_{z0} + k_w) \qquad [17]$$

which for $q_{z0} = (\omega/c)\cos\Theta_q$ reproduces the classical synchronism condition in eqn [5]. The homogeneous

broadening linewidth is found to be:

$$\frac{\Delta\omega_L}{\omega_0} = \frac{1}{N_w} \qquad [18]$$

where $N_w = L/\lambda_w$ is the number of wiggler periods.

The classical limit condition requires that the difference between the emission and absorption line centers will be smaller than their width. This is expressed in terms of the 'recoil parameter ε' (for $\Theta_q = 0$):

$$\varepsilon = \frac{\omega_a - \omega_e}{\Delta\omega_L} = \frac{1+\beta}{\beta_z^2}\frac{\hbar\omega_0}{\gamma mc^2}N_w \ll 1 \qquad [19]$$

This condition is satisfied in all practical cases of realizable FELs. When this happens, the homogeneous line broadening dominates over the quantum-recoil effect, and the emission and absorption lines are nearly degenerate (Figure 5b). The total quantum-electrodynamic photonic emission rate expression:

$$\frac{d\nu_q}{dt} = \Gamma_{sp}[(\nu_q+1)F(\omega-\omega_e) - \nu_q F(\omega-\omega_a)] \qquad [20]$$

reduces then into:

$$\frac{d\nu_q}{dt} = \nu_q\Gamma_{sp}\varepsilon\Delta\omega_L\frac{d}{d\omega}F(\omega-\omega_e) + \Gamma_{sp}F(\omega-\omega_0) \qquad [21]$$

Here ν_q is the number of photons in radiation mode q, Γ_{sp} – the spontaneous emission rate, and $F(\omega-\omega_0)$ is the emission (absorption) lineshape function. Figure 5b depicts the transition of the net radiative emission/absorption rate into a gain curve which is proportional to the derivative of the spontaneous emission lineshape function (first term in eqn [21]). Equation [21] presents a fundamental relation between the spontaneous and stimulated emission of FELs, which was observed first by John Madey (Madey's theorem). It can be viewed as an extension of Einstein's relations to a classical radiation source.

The Classical Picture

The spontaneous emission process of FEL (synchrotron undulator radiation) is nothing but dipole radiation of the undulating electrons, which in the laboratory frame of reference is Doppler shifted to high frequency. The understanding of the stimulated emission process requires a different approach.

Consider a single electron, following a sinusoidal trajectory under the effect of a planar undulator magnetic field in eqn [2] (Figure 1):

$$v_x = v_w \cos k_w z_e(t) \qquad [22]$$

$$x = x_w \sin k_w z_e(t) \qquad [23]$$

where $v_w = ca_w/\gamma$ and $x_w = v_w/(v_z k_w)$. An electromagnetic wave $E_x(z,t) = E_0\cos(\omega t - k_z z)$ propagates collinearly with the electron. Figure 6 displays the electron and wave 'snap-shot' positions as they propagate along one wiggler period λ_w.

If the electron, moving at average axial velocity v_z, enters the interaction region $z = 0$ at $t = 0$, its axial position is $z_e(t) = v_z t$, and the electric force it experiences is $-eE_x(z_e(t),t) = -eE_0\cos(\omega - k_z v_z)t$. Clearly, this force is (at least initially at $t = 0$) opposite to the transverse velocity of the electron $v_x = v_w\cos(k_w v_z)t$ (imply in deceleration) and the power exchange rate $-ev_e\cdot E = -ev_x E_x$ corresponds to transfer of energy into the radiation field on account of the electron kinetic energy. Because the phase velocity of the radiation mode is larger than the electron velocity, $v_{ph} = \omega/k_z > v_z$, the electron phase $\varphi_e = (\omega - k_z v_z)t$ grows, and the power exchange rate $-ev_x E_x$ changes. However, if one synchronizes the electron velocity, so that while the electron traverses one wiggler period ($t = \lambda_w/v_z$), the electron phase advances by $2\pi: (\omega - k_z v_z)\cdot\lambda_w/v_z = 2\pi$, then the power exchange rate from the electron to the wave remains non-negative through the entire interaction length, because then the electron transverse velocity

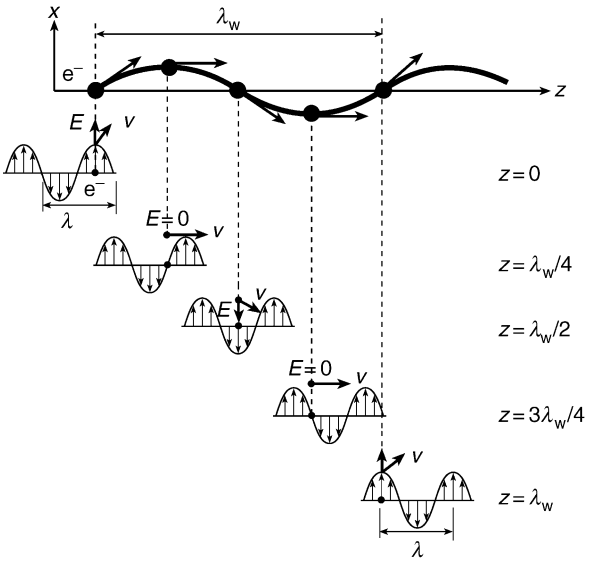

Figure 6 'Snapshots' of an electromagnetic wave period slipping relative to an undulating electron along one wiggler period λ_w. The energy transfer to the wave – $e\mathbf{v}\cdot\mathbf{E}$ remains non-negative all along.

v_x and the wave electric field E_x reverse sign, at each period exactly at the same points $(\lambda_w/4, 3\lambda_w/4)$. This situation is depicted in Figure 6, which shows the slippage of the wave crests relative to the electron at five points along one wiggler period. The figure describes the synchronism condition, in which the radiation wave slips one optical period ahead of the electron, while the electron goes through one wiggle motion. In all positions along this period, $v \cdot E \geq 0$ (in a helical wiggler and a circularly polarized wave this product is constant and positive $v \cdot E > 0$ along the entire period). Substituting $\lambda_w = 2\pi/k_w$, this phase synchronism condition may be written as:

$$\frac{\omega}{v_z} = k_z + k_w \qquad [24]$$

which is the same as eqns [17] and [5].

Figure 6 shows that a single electron (or a bunch of electrons of duration smaller than an optical period) would amplify a co-propagating radiation wave, along the entire wiggler, if it satisfies the synchronism condition in eqn [24] and enters the interaction region ($z = 0$) at the right (decelerating) phase relative to the radiation field. If the electron enters at the opposite phase it accelerates (on account of the radiation field energy which is then attenuated by 'stimulated absorption'). Thus, when an electron beam is injected into a wiggler at the synchronism condition with electrons entering at random times, no net amplification or absorption of the wave is expected on the averages. Hence, some more elaboration is required, in order to understand how stimulated emission gain is possible then.

Before proceeding, it is useful to define the 'pondermotive force' wave. This force originates from the nonlinearity of the Lorenz force equation:

$$\frac{d}{dt}(\gamma m \mathbf{v}) = -e(\mathbf{E} \times \mathbf{v} \times \mathbf{B}) \qquad [25]$$

At zero order (in terms of the radiation fields), the only field force on the right-hand side of eqn [25] is due to the strong wiggler field (eqns [2] and [3]), which results in the transverse wiggling velocity (eqn [22] for a linear wiggler). When solving next eqn [25] to first order in terms of the radiation fields:

$$\begin{aligned} \mathbf{E}_s(r, \mathbf{t}) &= \mathrm{Re}\left[\tilde{\mathbf{E}}_s \, e^{i(k_z z - \omega t)}\right] \\ \mathbf{B}_s(r, \mathbf{t}) &= \mathrm{Re}\left[\tilde{\mathbf{B}}_s \, e^{i(k_z z - \omega t)}\right] \end{aligned} \qquad [26]$$

the cross product $\mathbf{v} \times \mathbf{B}$ between the transverse components of the velocity and the magnetic field generates a longitudinal force component:

$$\mathbf{F}_{pm}(z, t) = \mathrm{Re}\left[\hat{\mathbf{e}}_z \tilde{F}_{pm} e^{i(k_z + k_w)z - i\omega t}\right] \qquad [27]$$

that varies with the beat wavenumber $k_s + k_w$ at slow phase velocity $(v_{ph} = \omega/(k_z + k_w) < c)$. This slow force-wave is called the pomdermotive (PM) wave. Assuming the signal radiation wave in eqn [26] is polarization-matched to the wiggler (linearly polarized or circularly polarized for a linear or helical wiggler respectively), the PM force amplitude is given by:

$$|\tilde{F}_{pm}| = e|\tilde{E}_{s\perp}|a_w/\gamma\beta_z \qquad [28]$$

With large enough k_w, it is always possible to slow down the phase velocity of the pondermotive wave until it is synchronized with the electron velocity:

$$v_{ph} = \frac{\omega}{k_z + k_w} = v_z \qquad [29]$$

and can apply along the interaction length a decelerating axial force, that will cause properly phased electrons to transfer energy to the wave on account of their longitudinal kinetic energy.

This observation is of great importance. It reveals that even though the main components of the wiggler and radiation fields are transverse, the interaction is basically longitudinal. This puts the FEL on an equal footing with the slow-wave structure devices as the TWT and the Cerenkov–Smith–Purcell FELs, in which the longitudinal interaction takes place with the longitudinal electric field component of a slow TM radiation mode. The synchronism condition in eqn [29] between the pondermotive wave and the electron, which is identical with the phase-matching condition in eqn [24], is also similar to the synchronism condition between an electron and a slow electromagnetic wave (eqn [14]).

Using the pondermotive wave concept, we can now explain the achievement of gain in the FEL with a random electron beam. Figure 7 illustrates the interaction between the pondermotive wave and electrons, distributed at the entrance ($z = 0$) randomly within the wave period. Figure 7a shows 'snap-shots' of the electrons in one period of the pondermotive wave $\lambda_{pm} = 2\pi/(k_z + k_w)$ at different points along the wiggler, when it is assumed that the electron beam is perfectly synchronous with the pondermotive wave $v_{ph} = v_0$. As explained before, some electrons are slowed down, acquiring negative velocity increment Δv. However, for each such electron, there is another one, entering the wiggler at an accelerating phase of the wave, acquiring the same positive velocity increment Δv. There is then no net change in the energy of the e-beam or the wave, however, there is clearly an effect of 'velocity-bunching' (modulation), which turns along the wiggler into 'density-bunching' at the same

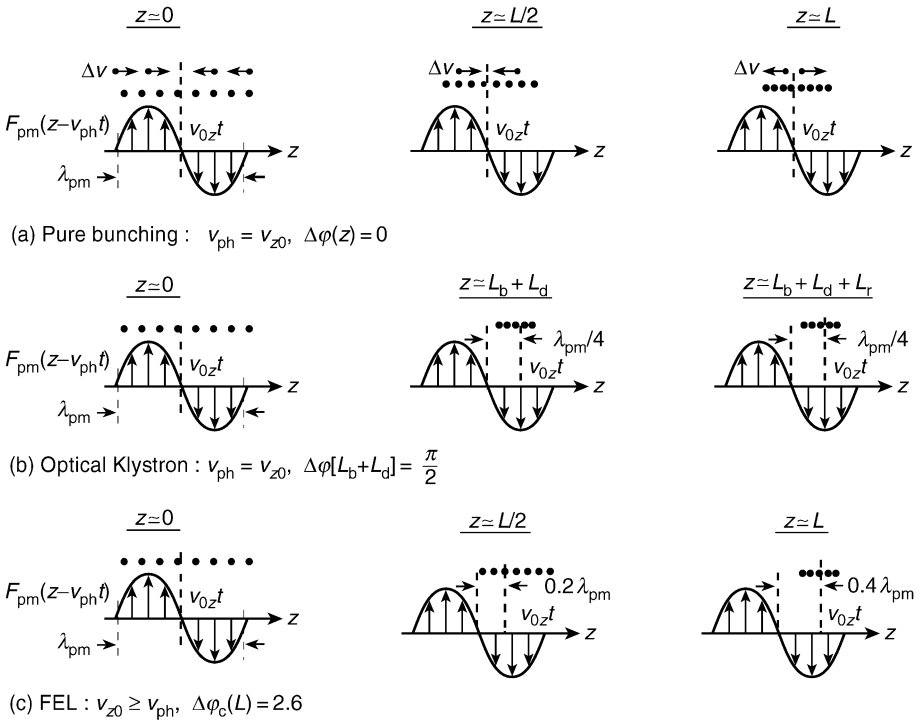

Figure 7 'Snapshots' of a pondermotive wave period interacting L with an initially uniformly distributed electron beam taking place respectively along the interaction length $0 < z < L_b$. (a) Exact synchronism in a uniform wiggler (bunching). (b) Energy bunching, density bunching and radiation are in the energy buncher, dispersive magnet $L_b < z < L_b + L_d$ and radiating wiggler $L_b + L_d < z < L_b + L_d + L_r$ sections of an Optical–Klystron. (c) Slippage from bunching phase to radiating phase at optimum detuning off synchronism in a uniform wiggler FEL.

frequency ω and wavenumber $k_z + k_w$ as the modulating pondermotive wave. The degree of density-bunching depends on the amplitude of the wave and the interaction length L. In the nonlinear limit the counter propagating (in the beam reference frame) velocity modulated electrons may over-bunch namely cross over, and debunch again.

Bunching is the principle of classical stimulated emission in electron beam radiation devices. If the e-beam had been prebunched in the first place, we would have injected it at a decelerating phase relative to the wave and obtained net radiation gain right away (super radiant emission). This is indeed the principle behind the 'Optical-Klystron' (OK) demonstrated in Figure 7b. The structure of the OK is described ahead in Figure 19. The electron beam is velocity (energy) modulated by an input electromagnetic radiation wave in the first 'bunching-wiggler section' of length L_b. It then passes through a drift-free 'energy-dispersive magnet section' (chicane) of length L_d, in which the velocity modulation turns into density bunching. The bunched electron beam is then injected back into a second 'radiating-wiggler section', where it co-propagates with the same electromagnetic wave but with a phase advance of $\pi/2 - m2\pi$, $m = 1, 2, \ldots$ (spatial lag of $\lambda_{pm}/4 - m\lambda_{pm}$ in real space) which places the entire bunch at a decelerating phase relative to the PM-wave and so amplifies the radiation wave.

The principle of stimulated-emission gain in FEL, illustrated in Figure 7c, is quite similar. Here the wiggler is uniform along the entire length L, and the displacement of the electron bunches into a decelerating phase position relative to the PM-wave is obtained by injecting the electron beam at a velocity v_{z0}, slightly higher than the wave v_{ph} (velocity detuning). The detailed calculation shows that detuning corresponding to a phase shift of $\Delta\Psi(L) = [(\omega/v_{z0}) - (k_z + k_w)]L = -2.6$ (corresponding to spatial bunch advance of $0.4\lambda_{pm}$ along the wiggler length), provides sufficient synchronism with the PM-wave in the first half of the wiggler to obtain bunching, and sufficient deceleration-phasing of the created bunches in the second part of the wiggler to obtain maximum gain.

Principles of FEL Theory

The 3D radiation field in the interaction region can be expanded in general in terms of a complete set of

free-space or waveguide modes $\{\varepsilon_q(x,y)\mathcal{H}_q(x,y)\}$:

$$E(\boldsymbol{r},t) = \mathrm{Re}\Big[\sum_q c_q(z)\varepsilon_q(x,y)\mathrm{e}^{\mathrm{i}(k_{zq}z-\omega t)}\Big] \qquad [30]$$

The mode amplitudes $C_q(z)$ may grow along the wiggler interaction length $0 < z < L$, according to the mode excitation equation:

$$\frac{\mathrm{d}}{\mathrm{d}z}C_q(z) = -\frac{1}{4\mathcal{P}}\mathrm{e}^{-\mathrm{i}k_{zq}}\int\int \mathbf{J}(x,y,z)\cdot\boldsymbol{\varepsilon}_q^*(x,y)\mathrm{d}x\,\mathrm{d}y \qquad [31]$$

where $\mathcal{P} = -\frac{1}{2}\mathrm{Re}\int\int \boldsymbol{\varepsilon}_q \times \mathcal{H}_q\cdot\hat{e}_z\,\mathrm{d}x\,\mathrm{d}y$ is the mode normalization power, and $\tilde{\mathbf{J}}$ is the bunching current component at frequency ω, that is phase matched to the radiation waves, and needs to be calculated consistently from the electron force equations.

The FEL Small Signal Regime

We first present the basic formulation of FEL gain in the linear (small signal) regime, namely the amplified radiation field is assumed to be proportional to the input signal radiation field, and the beam energy loss is negligible. This is done in the framework of a one-dimensional (single transverse radiation mode) model.

The electron beam charge density, current density, and velocity modulation are solved in the framework of a one-dimensional plasma equations model (kinetic or fluid equations). The longitudinal PM-force in eqn [27] modulates the electron beam velocity via the longitudinal part of the force eqn [25]. This brings about charge modulation $\rho(z,t) = \mathrm{Re}[\tilde{\rho}(k_z+k_\mathrm{w},\omega)\mathrm{e}^{\mathrm{i}(k_z+k_\mathrm{w})z-\mathrm{i}\omega t}]$ and consequently, also longitudinal space-charge field $\tilde{E}_\mathrm{sc}(k_{zq}+k_\mathrm{w},\omega)$ and longitudinal current density modulation $\tilde{J}_z(k_z+k_\mathrm{w},\omega)$, related through the Poison and continuity equations:

$$\mathrm{i}(k_z+k_\mathrm{w})\tilde{E}_\mathrm{sc}(k_z+k_\mathrm{w},\omega) = \tilde{\rho}(k_z+k_\mathrm{w},\omega)/\varepsilon \qquad [32]$$

$$(k_z+k_\mathrm{w})\tilde{J}_z(k_z+k_\mathrm{w},\omega) = \omega\tilde{\rho}(k_z+k_\mathrm{w},\omega) \qquad [33]$$

Solving the force eqn [25] for a general longitudinal force $F_z(z,t) = \mathrm{Re}[\tilde{F}_z(k_z,\omega)\mathrm{e}^{\mathrm{i}(k_z z-\omega t)}]$ results in a linear longitudinal current response relation:

$$\tilde{J}_z(k_z,\omega) = -\mathrm{i}\omega\chi_\mathrm{p}(k_z,\omega)\tilde{F}_z(k_z,\omega)/(-e) \qquad [34]$$

where $\chi_\mathrm{p}(k_z,\omega)$ is the longitudinal susceptibility of the electron beam 'plasma'.The beam charge density in the FEL may be quite high, and consequently the space charge field $\tilde{E}_\mathrm{sc}$, arising from the Poison eqn [32], may not be negligible. One should take into consideration then that the total longitudinal force $\tilde{F}_z$ is composed of both the PM-force of eqn [27] and an arising longitudinal space-charge electric force $-e\tilde{E}_\mathrm{sc}$. Thus, one should substitute in eqn [34]:

$$\tilde{F}_z(k_z+k_\mathrm{w},\omega) = -e[\tilde{E}_\mathrm{pm}(k_z+k_\mathrm{w},\omega) + \tilde{E}_\mathrm{sc}(k_z+k_\mathrm{w},\omega)] \qquad [35]$$

and solve it self-consistently with eqns [32] and [33] to obtain the 'external-force' response relation:

$$\tilde{J}_z(k_z+k_\mathrm{w},\omega) = \frac{-\mathrm{i}\omega\chi_\mathrm{p}(k_z+k_\mathrm{w},\omega)}{1+\chi_\mathrm{p}(k_z+k_\mathrm{w},\omega)/\varepsilon}\tilde{E}_\mathrm{pm}(k_z+k_\mathrm{w},\omega) \qquad [36]$$

where we defined the PM 'field': $\tilde{E}_\mathrm{pm} = \tilde{F}_\mathrm{pm}/(-e)$.

In the framework of a single-mode interaction model, we keep in the summation of eqn [30] only one mode q (usually the fundamental mode, and in free space – a Gaussian mode). The transverse current density components in eqn [31] $\tilde{\boldsymbol{J}}_\perp = \frac{1}{2}\tilde{\rho}\,\tilde{\boldsymbol{v}}_w$ are found using eqns [22], [33], and [36]. Finally, substituting $C_q(z) = \tilde{C}_q\,\mathrm{e}^{\mathrm{i}\delta k z}$ (where $\delta k \equiv k_z - k_{qz}$ and $k_z \cong k_{qz}$ is the wavenumber of the radiation wave modified by the interaction with the electrons) results in the general FEL dispersion relation:

$$(k_z - k_{zq})[1+\chi_\mathrm{p}(k_z+k_\mathrm{w},\omega)/\varepsilon] = \kappa\chi_\mathrm{p}(k_z+k_\mathrm{w},\omega)/\varepsilon_0 \qquad [37]$$

Equation [37] is a general expression, valid for a wide variety of FELs, including Cerenkov–Smith–Purcell and TWT. They differ only in the expression for κ. For the conventional (magnetic wiggler) FEL:

$$\kappa = \frac{1}{4}\frac{A_\mathrm{e}}{A_\mathrm{em}}\frac{a_\mathrm{w}^2}{\gamma^2\beta_z^2}\frac{\omega}{c}A_\mathrm{JJ}^2 \qquad [38]$$

where A_e is the cross-section area of the electron beam, and $A_\mathrm{em} \equiv \mathcal{P}_q/[\frac{1}{2}\sqrt{\varepsilon_0/\mu_0}|\varepsilon_{q\perp}(0,0)|^2]$ is the effective area of the interacting radiation-mode q, and it is assumed that the electron beam, passing on axis $(x_\mathrm{e},y_\mathrm{e}) = (0,0)$, is narrow relative to the transverse mode variation $A_\mathrm{e}/A_\mathrm{em} \ll 1$. The 'Bessel-functions coefficient' A_JJ is defined for a linear wiggler only, and is given by:

$$A_\mathrm{JJ} = J_0\left[\frac{a_\mathrm{w}^2}{2(a_\mathrm{w}^2+2)}\right] - J_1\left[\frac{a_\mathrm{w}^2}{2(a_\mathrm{w}^2+2)}\right] \qquad [39]$$

In a helical wiggler, $A_\mathrm{JJ} \equiv 1$. Usually $a_\mathrm{w} \ll 1$, and therefore $A_\mathrm{JJ} \cong 1$.

The Pierce Dispersion Equation

The longitudinal plasma response susceptibility function $\chi_\mathrm{p}(k_z,\omega)$ has been calculated, in any plasma formulation, including fluid model, kinetic model, or

even quantum-mechanical theory. If the electron beam axial velocity spread is small enough (cold beam), then the fluid plasma equations can be used. The small signal longitudinal force equation derived from eqn [25], together with eqn [33] and the small signal current modulation expression:

$$\tilde{J}_z \cong \rho_0 \tilde{v}_z + v_z \tilde{\rho} \qquad [40]$$

result in:

$$\chi_p(k_z, \omega) = -\frac{\omega_p'^2}{(\omega - k_z v_z)^2}\varepsilon \qquad [41]$$

where $\omega_p' = (e^2 n_0/\gamma\gamma_z^2 \varepsilon m)^{1/2}$ is the longitudinal plasma frequency, n_0 is the beam electrons density ($\rho_0 = -en_0$), v_z is the average axial velocity of the beam.

In this 'cold-beam' limit, the FEL dispersion eqn [37] reduces into the well-known 'cubic dispersion equation' derived first by John Pierce in the late 1940s for the TWT:

$$\delta k(\delta k - \theta - \theta_{pr})(\delta k - \theta + \theta_{pr}) = Q \qquad [42]$$

where $\delta k = k_z - k_{zq}$, θ is the detuning parameter (off the synchronism condition of eqn [24]):

$$\theta \equiv \frac{\omega}{v_z} - k_{zq} - k_w \qquad [43]$$

$$\theta_p = \frac{\omega_p}{v_z} \qquad [44]$$

$$Q = \kappa\theta_p^2 \qquad [45]$$

Here $\theta_{pr} = r_p\theta_p$, where $r_p < 1$ is the plasma reduction factor. It results from the reduction of the longitudinal space-charge field $\tilde{E}_{sp}$ in a beam of finite radius r_b due to the fringe field effect ($r_p \to 1$ when the beam is wide relative to the longitudinal modulation wavelength: $r_b \gg \lambda_{pm} = 2\pi/(k_{zq} + k_w)$).

The cubic equation has, of course, three solutions δk_i ($i = 1, 2, 3$), and the general solution for the radiation field amplitude and power is thus:

$$C_q(z) = \sum_{j=1}^{3} A_j\, e^{i\delta k_j z} \qquad [46]$$

$$P(z) = |C_q(z)|^2 \mathcal{P}_q \qquad [47]$$

The coefficients A_i can be determined from three initial conditions of the radiation and e-beam parameters $C_q(0)$, $\tilde{v}(0)$, $\tilde{i}(0)$, and can be given as a linear combination of them (here $\tilde{i} = A_e\tilde{J}_z$ is the longitudinal modulation current):

$$A_j = A_j^E(\omega)C_q^\omega(0) + A_j^v(\omega)\tilde{v}^\omega(0) + A_j^i(\omega)\tilde{i}^\omega(0) \qquad [48]$$

Alternatively stated, the exit amplitude of the electromagnetic mode can in general be expressed in terms of the initial conditions:

$$C_q(L) = H^E(\omega)C_q(\omega, 0) + H^v(\omega)\tilde{v}_q(\omega, 0) + H^i(\omega)\tilde{i}(\omega, 0) \qquad [49]$$

where

$$H^{(E,v,i)}(\omega) = \sum_{j=1}^{3} A_j^{(E,v,i)}(\omega)e^{i\delta k_j L} \qquad [50]$$

In the conventional FEL, electrons are injected in randomly, and there is no velocity prebunching ($\tilde{v}(\omega, 0) = 0$) or current prebunching ($\tilde{i}(\omega, 0) = 0$) (or equivalently $\tilde{n}(\omega, 0) = 0$). Consequently, $C_q(z)$ is proportional to $C_q(0)$ and one can define and calculate the FEL small-signal single-path gain parameter:

$$G(\omega) \equiv \frac{P(L)}{P(0)} = \frac{|C_q(\omega, L)|^2}{|C_q(\omega, 0)|^2} = |H^E(\omega)|^2 \qquad [51]$$

The FEL Gain Regimes

At different physically meaningful operating regimes, some parameters in eqn [42] can be neglected relative to others, and simple analytic expressions can be found for δk_i, A_i, and consequently $G(\omega)$. It is convenient to normalize the FEL parameters to the wiggler length: $\bar{\theta} = \theta L$, $\bar{\theta}_{pr} = \theta_{pr}L$, $\bar{Q} = QL^3$. An additional figure of merit parameter is the 'thermal' spread parameter:

$$\bar{\theta}_{th} = \frac{v_{zth}}{v_z}\frac{\omega}{v_z}L \qquad [52]$$

where v_{zth} is the axial velocity spread of the e-beam (in a Gaussian velocity distribution model: $f(v_z) = \exp[(v_z - v_{z0})/v_{zth}]/\sqrt{\pi}v_{zth}$). The axial velocity spread can result out of beam energy spread or angular spread (finite 'emittance'). It should be small enough, so that the general dispersion relation of eqn [37] reduces to eqn [42] (the practical 'cold beam' regime).

Assuming now a conventional FEL ($\tilde{v}_z(0) = 0$, $\tilde{i}(0) = 0$), the single path gain in eqn [51] can be calculated. We present next this gain expression in the different regimes. The maximum values of the gain expression in the different regimes are listed in Table 1.

Low gain

This is the regime where the differential gain in a single path satisfies $G - 1 = [P(L) - P(0)]/P(0) \ll 1$. It is not useful for FEL amplifiers but most FEL oscillators operate in this regime.

Table 1 The gain regimes maximum gain expressions

	Gain regime	*Parameters domain*	*Max. gain expression*
I	Tenuous beam low-gain	$\bar{Q},\ \bar{\theta}_{pr},\ \bar{\theta}_{th} < \pi$	$\frac{P(L)}{P(0)} = 1 + 0.27\bar{Q}$
II	Collective low-gain	$\bar{\theta}_{pr} > \frac{\bar{Q}}{2},\ \bar{\theta}_{th},\ \pi$	$\frac{P(L)}{P(0)} = 1 + \bar{Q}/2\bar{\theta}_{pr}$
III	Collective high-gain	$\bar{Q}/2 > \bar{\theta}_{pr} > \bar{Q}^{1/3},\ \bar{\theta}_{th},\ \bar{Q} > \pi$	$\frac{P(L)}{P(0)} = \frac{1}{4}\exp(\sqrt{2\bar{Q}/\bar{\theta}_{pr}})$
IV	Strong coupling high-gain	$\bar{Q}^{1/3} > \bar{\theta}_{pr},\ \bar{\theta}_{th},\ \bar{Q} > \pi$	$\frac{P(L)}{P(0)} = \frac{1}{9}\exp(\sqrt{3}\bar{Q}^{1/3})$
V	Warm beam	$\bar{\theta}_{th} > \bar{\theta}_{pr},\ \bar{Q}^{1/3},\ \pi$	$\frac{P(L)}{P(0)} = \exp(3\bar{Q}/\bar{\theta}_{th}^2)$

The three solutions of eqn [42] – namely the terms of eqn [46] – are reminiscent of the three eigenwaves of the uncoupled system ($\kappa = Q = 0$) : the radiation mode and the two plasma (space-charge) waves of the e-beam (the slow and fast waves, corresponding respectively to the forward and backward propagating plasma-waves in the beam rest reference-frame). In the low-gain regime, all three terms in eqn [46] are significant. Calculating them to first order in κ, results in analytical gain expressions in the collective ($\bar{\theta}_{pr} \gg \pi$) and tenuous-beam ($\bar{\theta}_{pr} \ll \pi$) regimes (note that $\bar{\theta}_{pr}/2\pi = f'_{pr}L/v_z$ is the number of plasma oscillations within the wiggler transit time L/v_z).

In most practical situations the beam current density is small enough, and its energy high enough, to limit operation to the tenuous-beam regime. The gain curve function is then:

$$G(\omega) - 1 = \bar{Q}F(\bar{\theta}(\omega)) = \bar{Q}\frac{d}{d\bar{\theta}}\mathrm{sinc}^2(\bar{\theta}/2) \qquad [53]$$

$$\bar{\theta}(\omega) \equiv \theta(\omega)L = 2\pi\frac{\omega - \omega_0}{\Delta\omega_L} \qquad [54]$$

where $\mathrm{sinc}(u) \equiv (\sin u)/u$, and in free space (no waveguide) propagation ($k_{zq} = \omega/c$), the FWHM frequency bandwidth of the $\mathrm{sinc}^2(\bar{\theta}/2)$ function is:

$$\frac{\Delta\omega_L}{\omega_0} = \frac{1}{N_w} \qquad [55]$$

The small signal gain curve is shown in Figure 8. There is no gain at synchronism – $\omega = \omega_0$. Maximum gain – $G - 1 = 0.27\bar{Q}$, is attained at a frequency slightly smaller than ω_0, corresponding to $\bar{\theta} = -2.6$. The small gain curve bandwidth is $\Delta\omega_{SG} \cong \Delta\omega_L/2$,

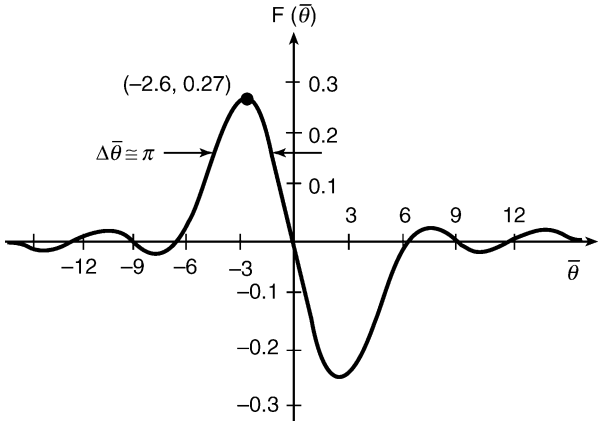

Figure 8 The low-gain cold-beam small-signal gain curve of FEL as a function of the detuning parameter $\bar{\theta}(\omega)$.

namely:

$$\frac{\Delta\omega_{SG}}{\omega_0} = \frac{1}{2N_w} \qquad [56]$$

High gain

This is the regime where the FEL gain in a single path satisfies $G = P(L)/P(0) \gg 1$. It is useful, of course, when the FEL is used as an amplifier.

Since the coefficients of the cubic eqn [42] are all real, the solutions δk_i ($i = 1, 2, 3$) must be either all real, or composed of one real solution δk_3 and two complex solutions, which are complex conjugate of each other: $\delta k_1 = \delta k_2^*$. In the first case, all terms in eqn [46] are purely oscillatory, there is no exponential growth, and the FEL operates in the low gain regime. In the second case, assuming $\mathrm{Im}(\delta k_1) < 0$, $\mathrm{Im}(\delta k_2) > 0$, the first term grows exponentially, and if L is long enough it will dominate over the other decaying ($j = 2$) and oscillatory ($j = 3$) terms, and

result in an exponential gain expression:

$$G(\omega) = \left(\frac{A_1}{A_1 + A_2 + A_3}\right)^2 \mathrm{e}^{2(\mathrm{Im}\ \delta k_1)L} \qquad [57]$$

If we focus on the tenuous-beam strong coupling (high–gain) regime $\theta_{\mathrm{pr}} \ll |\delta k|$, then the cubic eqn [42] gets the simple form:

$$\delta k\lfloor(\delta k)^2 - \theta^2\rfloor = \Gamma^3 \qquad [58]$$

where

$$\Gamma = Q^{1/3} = \left(\pi \frac{a_{\mathrm{w}}^2}{\gamma^3 \gamma_z^2 \beta_z^5} \frac{\omega/c}{A_{\mathrm{em}}} \frac{I_{\mathrm{b}}}{I_{\mathrm{A}}} A_{\mathrm{JJ}}^2\right)^{1/3} \qquad [59]$$

and $I_{\mathrm{A}} = 4\pi\varepsilon_0 m_{\mathrm{e}} c^3/e \cong 17\ \mathrm{kA}$ is the Alfven current. The solution of eqn [58] near synchronism ($\theta \cong 0$) is:

$$\delta k_1 = \frac{1 - \sqrt{3}\mathrm{i}}{2}\Gamma, \qquad \delta k_2 = \frac{1 + \sqrt{3}\mathrm{i}}{2}\Gamma, \qquad \delta k_3 = -\Gamma \qquad [60]$$

resulting in:

$$H^{\mathrm{E}}(\omega) = \frac{C_q(z)}{C_q(0)} = \frac{1}{3}\left[\mathrm{e}^{\frac{\sqrt{3}+\mathrm{i}}{2}\Gamma z} + \mathrm{e}^{\frac{-\sqrt{3}+\mathrm{i}}{2}\Gamma z} + \mathrm{e}^{-\mathrm{i}\Gamma z}\right] \qquad [61]$$

and for $\Gamma L \gg 1$:

$$G \cong \frac{1}{9}\mathrm{e}^{\sqrt{3}\Gamma L} \qquad [62]$$

The FEL gain is then exponential and can be very high. The gain exponential coefficient is characterized then by its third-order root scaling with the current, $\alpha I_{\mathrm{b}}^{1/3}$. The high-gain frequency detuning curve (found by solving eqn [58] to second order in θ) is:

$$G \cong \frac{1}{9}\mathrm{e}^{\sqrt{3}\Gamma L} \exp(-\theta^2/\Gamma L 3^{3/2}) \equiv \frac{1}{9}\mathrm{e}^{\sqrt{3}\Gamma L} \exp\left[-\frac{(\omega - \omega_0)^2}{\Delta\omega_{\mathrm{HG}}^2}\right] \qquad [63]$$

where $\Delta\omega_{\mathrm{HG}}$ is the 1/e half-width of the gain curve:

$$\frac{\Delta\omega_{\mathrm{HG}}}{\omega_0} = \frac{3^{3/4}}{2\pi} \frac{\lambda_{\mathrm{w}}}{(L/\Gamma)^{1/2}} \qquad [64]$$

Super-Radiance, Spontaneous-Emission and Self Amplified Spontaneous Emission (SASE)

Intense coherent radiation power can be generated in a wiggler or any other radiation scheme without any input radiation signal ($C_q(\omega, 0) = 0$) if the electron beam velocity or current (density) are prebunched. Namely, the injected e-beam has a frequency component $\tilde{v}(\omega)$ or $\tilde{i}(\omega)$ in the frequency range where the radiation device emits. In the case of pure density bunching ($\tilde{v}(\omega) = 0$), the coherent power emitted is found from eqns [46, 47, 49]:

$$(P_q)_{\mathrm{SR}} = P_q |H^i(\omega)|^2 |\tilde{i}(\omega, 0)|^2 \qquad [65]$$

A 'prebunched-beam FEL' emits coherent radiation based on the process of Super-radiant Emission (in the sense of Dike). Because all electrons emit in phase radiation wavepackets into the radiation mode, the resultant field amplitude is proportional in this case to the beam current I_{b} and the radiation. By contrast, spontaneous emission from a random electron beam (no bunching) is the result of incoherent superposition of the wavepackets emitted by the electrons and its power is expected to be proportional to the current I_{b}.

When the current to radiation field transfer function $H^i(\omega)$ is known, eqn [65] can be used to calculate the superradiant power, and in the high-gain regime also the amplified-superradiant power. The latter is the amplification of the superradiant radiation in the downstream sections of a long wiggler. Such unsaturated gain is possible only when the beam is partly bunched $\tilde{i}(\omega)(I_{\mathrm{b}})$ (because the FEL gain process requires enhanced bunching).

The expressions for the current to field transfer function, in the superradiant gain and the high-gain amplified superradiance limits respectively, are:

$$|H^i(\omega)| = \frac{(P_{\mathrm{pb}}/P_q)^{1/2}}{I_{\mathrm{b}}} \mathrm{sinc}(\theta L/2) \qquad [66]$$

$$\left|H^i(\omega)\right| = \frac{(P_{\mathrm{pb}}/P_q)^{1/2}}{3\Gamma L I_{\mathrm{b}}} \mathrm{e}^{(\sqrt{3}/2)\Gamma L}\ \mathrm{e}^{-(\omega-\omega_0)^2/2(\Delta\omega)_{\mathrm{HG}}^2} \qquad [67]$$

where

$$P_{\mathrm{pb}} = \frac{I_{\mathrm{b}}^2 Z_q}{32}\left(\frac{a_{\mathrm{w}}}{\gamma\beta_z}\right)^2 \frac{L^2}{A_{\mathrm{em}}} \qquad [68]$$

Z_q is the radiation mode impedance (in free-space $Z_q = \sqrt{\mu_0/\varepsilon_0}$). From these expressions one can calculate the power and spectral power of both coherent (superradiant) and partially coherent (spontaneous emission) radiation of FEL in the negligible gain and high gain regimes. The corresponding super-radiant power is in the negligible superradiance gain limit:

$$P_{\mathrm{SR}} = P_{\mathrm{pb}}\left|\frac{\tilde{i}(\omega)}{I_{\mathrm{b}}}\right|^2 \mathrm{sinc}^2(\theta L/2) \qquad [69]$$

(proportional, as expected, to the modulation current squared) and in the high-gain amplified superradiance limit (assuming initial partial bunching $|i(\omega)/I\mathrm{b}| \ll 1$):

$$P_{\mathrm{SR}} = P_{\mathrm{pb}}\left|\frac{\tilde{i}(\omega)}{I_{\mathrm{b}}}\right|^2 \frac{1}{9(\Gamma L)^2}\mathrm{e}^{\sqrt{3}\Gamma L}\,\mathrm{e}^{-(\omega-\omega_0)^2/(\Delta\omega)^2_{\mathrm{HG}}} \qquad [70]$$

The discussion is now extended to incoherent (or partially coherent) spontaneous emission. Due to its particulate nature, every electron beam has random frequency components in the entire spectrum (shot noise). Consequently, incoherent radiation power is always emitted from an electron-beam passing through a wiggler, and its spectral-power can be calculated through the relation:

$$\frac{\mathrm{d}P_q}{\mathrm{d}\omega} = \frac{2}{\pi}\mathcal{P}_q|H^i(\omega)|^2\frac{\langle|\tilde{i}(\omega)|^2\rangle}{T} \qquad [71]$$

Here $\tilde{i}(\omega)$ is the Fourier transform of the current of randomly injected electrons $i(t) = -e\sum_{j=1}^{N_T}\delta(t - t_{oj})$, where N_T is the average number of electrons in a time period T, namely, the average (DC) current is $I_{\mathrm{b}} = -eN_T/T$. For a randomly distributed beam, the shot noise current is simply $\langle|i(\omega)|^2\rangle/T = eI_{\mathrm{b}}$, and therefore the spontaneous emission power of the FEL, which is nothing but the 'synchrotron-undulator radiation', is given by (see eqn [66]):

$$\frac{\mathrm{d}P_q}{\mathrm{d}\omega} = \frac{1}{16\pi}eI_{\mathrm{b}}Z_q\frac{L^2}{A_{\mathrm{em}}}\left(\frac{a_{\mathrm{w}}}{\gamma\beta_z}\right)^2\mathrm{sinc}^2(\theta L/2) \qquad [72]$$

If the wiggler is long enough, the spontaneous emission emitted in the first part of the wiggler can be amplified by the rest of it (SASE). In the high-gain limit (see eqn [67]), the amplified spontaneous emission power within the gain bandwidth of eqn [64] is given by:

$$P_q = \frac{2}{\pi}\mathcal{P}_q eI_{\mathrm{b}}\int_0^\infty |H^i(\omega)|^2\mathrm{d}\omega = \frac{1}{9}P_{\mathrm{sh}}\,\mathrm{e}^{\sqrt{3}\Gamma L} \qquad [73]$$

where P_{sh} is an 'effective shot-noise input power':

$$P_{\mathrm{sh}} = \frac{2}{\sqrt{\pi}}\frac{eP_{\mathrm{pb}}}{I_0(\Gamma L)^2}(\Delta\omega)_{\mathrm{HG}} \qquad [74]$$

Saturation Regime

The FEL interaction of an electron with an harmonic electromagnetic (EM) wave is essentially described by the longitudinal component of the force in eqn [25], driven by the pondermotive force of eqns [27] and [28]:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\gamma_i m v_{zi}) = |\tilde{F}_{\mathrm{pm}}|\cos[\omega t - (k_z + k_{\mathrm{w}})z_i] \qquad [75]$$

$$\mathrm{d}z_i/\mathrm{d}t = v_{zi} \qquad [76]$$

As long as the interaction is weak enough (small signal regime), the change in the electron velocity is negligible – $v_{zi} \cong v_{z0}$, and the phase of the force-wave, experienced by the electron, is linear in time $\Psi_i(t) = [\omega - (k_z + k_{\mathrm{w}})v_{z0}](t - t_{0i}) + \omega t_{0i}$. Near synchronism condition $\theta \cong 0$ (eqn [24]), eqn [75] results in bunching of the beam, because different acceleration/deceleration forces are applied on each electron, depending on their initial phase $\Psi_i(0) = \omega t_{0i}(-\pi < \Psi_i(0) < \pi)$ within each optical period $2\pi/\omega$ (see Figure 7). Taylor expansion of v_{zi} around v_{z0} in eqns [75] and [76], and use of conservation of energy between the e-beam and the radiation field, would lead again to the small signal gain expression eqn [53] in the low gain regime.

When the interaction is strong enough (the nonlinear or saturation regime), the electron velocities change enough to invalidate the assumption of linear time dependence of Ψ_i and the nonlinear set of eqns [75] and [76] needs to be solved exactly.

It is convenient to invert the dependence on time $z_i(t) = \int_{t_{0i}}^{t} v_{zi}(t')\mathrm{d}t'$, and turn the coordinate z to the independent variable $t_i(z) = \int_0^z \mathrm{d}z'/v_{zi}(z') + t_{0i}$. This, and direct differentiation of $\gamma_i(v_{zi})$, reduces eqns [75] and [76] into the well-known pendulum equation:

$$\frac{\mathrm{d}\theta_i}{\mathrm{d}z} = K_{\mathrm{s}}^2\sin\Psi_i \qquad [77]$$

$$\frac{\mathrm{d}\Psi_i}{\mathrm{d}z} = \theta_i \qquad [78]$$

where

$$\Psi_i = \int_0^z(\omega/v_{zi}(z') - k_z - k_{\mathrm{w}})\,\mathrm{d}z' \qquad [79]$$

$$\theta_i = \frac{\omega}{v_{zi}} - k_z - k_{\mathrm{w}} \qquad [80]$$

are respectively the pondermotive potential phase and the detuning value of electron i at position z.

$$K_{\mathrm{s}} = \frac{k\sqrt{a_{\mathrm{w}}a_{\mathrm{s}}A_{\mathrm{JJ}}}}{\gamma_0\gamma_{z0}\beta_{z0}^2} \qquad [81]$$

is the synchrotron oscillation wavenumber, where a_{w} is given in eqn [9], $a_{\mathrm{s}} = e|\tilde{E}|\omega/mc$, and $\gamma_0 = \gamma(0)$, $\gamma_{z0} = \gamma_z(0)$, and $\beta_{z0} = \beta_z(0)$ are the initial parameters of the assumed cold beam.

The pendulum eqns [77] and [78] can be integrated once, resulting in:

$$\tfrac{1}{2}\theta_i^2(z) - K_{\mathrm{s}}^2\cos\Psi_i(z) = C_i \qquad [82]$$

and the integration constant is determined for each electron by its detuning and phase relative to the

pondermotive wave at the entrance point ($z = 0$): $C_i = \frac{1}{2}\theta_i^2(0) - K_s^2 \cos \Psi_i(0)$.

The $\theta(z)$, $\Psi(z)$ phase-space trajectories of eqn [82] are shown in **Figure 9** for various values of C_i (corresponding to the initial conditions $\theta_i(0)$, $\Psi_i(0)$). The trajectories corresponding to $|C_i| > K_s^2$ are open; namely electrons on these trajectories, while oscillating, can slip-off out of the pondermotive–potential wave period to adjacent periods, ahead or backward, depending on the value of their detuning parameter $\bar{\theta}$. The trajectories corresponding to $|C_i| < K_s^2$ are closed, namely the electrons occupying these trajectories are 'trapped', and their phase displacement is bound to a range $|\Psi_i(z) - n\pi| < \Psi_{im} \equiv \arccos(|C_i|/K_s^2) < \pi$ within one pondermotive-wave period. The trajectory $C_i = K_s^2$ defines the 'separatrix':

$$\theta_i(z) = \pm 2K_s \cos(\Psi_i/2) \qquad [83]$$

which is sometimes referred to as the 'trap' or 'bucket'. Every electron within the separatrix stays trapped, and the ones out of it are free (untrapped). The height of the separatrix (maximum detuning swing) is $\Delta\theta_{trap} = 4K_s$. The oscillation frequency of the trapped electrons can be estimated for deeply trapped electrons ($\Psi_m \ll 2\pi$). In this case the physical pendulum eqns [77] and [78] reduce to the mathematical pendulum equation with an oscillation frequency K_s, in the z coordinate. This longitudinal oscillation, called 'synchrotron oscillation', takes place as a function of time at the 'synchrotron frequency' $\Omega_s = K_s v_z$.

Differentiation of $\theta_i(v_{zi})$ and $v_{zi}(\gamma_i)$ permits to describe the phase-space dynamics in terms of the more physical parameters $\delta v_{zi} = v_{zi} - v_{ph}$ and

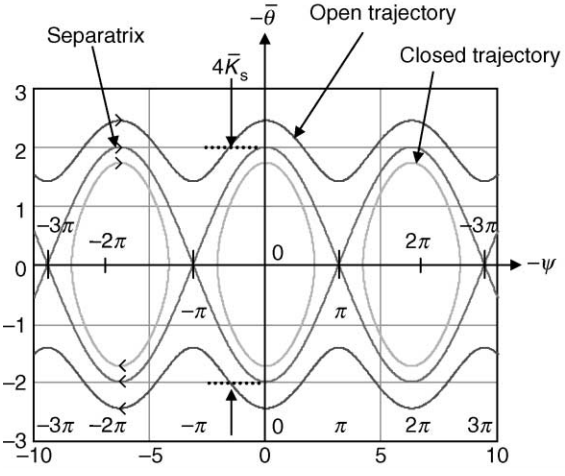

Figure 9 The (θ–Ψ) phase-space trajectories of the pendulum equation.

$\delta\gamma_i = \gamma_i - \gamma_{ph}$, where:

$$v_{ph} = \frac{\omega}{k_z + k_w} \qquad [84]$$

is the phase velocity of the pondermotive wave and $\gamma_{ph} \equiv (1 - \beta_{ph}^2)^{-1/2}$:

$$-\theta_i = \frac{\omega}{c^2\beta_{z0}^2}\delta v_{zi} = \frac{k}{\beta_{z0}^3\gamma_{z0}^2\gamma_0}\delta\gamma_i \qquad [85]$$

Figure 10 displays a typical dynamics of electron beam phase-space (γ, Ψ) evolution for the case of a cold beam of energy $\gamma(0)$ entering the interaction region at $z = 0$ with uniform phase distribution (random arrival times t_{0i}). The FEL is assumed to operate in the low-gain regime (typical situation in an FEL oscillator), and, therefore, the trap height (corresponding to $\Delta\theta_{trap} = 4k_s$):

$$\Delta\gamma_{trap} = 8\beta_z^2\gamma_z^2\gamma K_s/k \qquad [86]$$

remains constant along the interaction length. **Figure 10a** displays the e-beam phase-space evolution in the small signal regime. The uniform phase distribution evolves along the wiggler into a bunched distribution (compare to **Figure 7c**), and its average kinetic energy goes down $(\Delta E_k) = [\langle\gamma_i(L)\rangle - \gamma(0)]mc^2 < 0$, contributing this energy to the field of the interacting radiation mode, $\Delta P_q = (\Delta E_k)I_0/e$. In this case (corresponding in an FEL oscillator to the early stages of oscillation build-up), the electrons remain free (untrapped) along the entire length L.

Figure 10b displays the e-beam phase-space evolution in the large signal (saturation) regime (in the case of an oscillator – at the steady-state saturation stage). Part of the electrons are found inside the trap, immediately upon entering the interaction region ($z = 0$), and they lose energy of less than (but near) $mc^2\Delta\gamma_{trap}$ as they pass through the interaction region ($z = L$). A portion of the electrons remain outside the traps upon entrance. They follow open trajectories and lose less energy or may even become accelerated due to their interaction with the wave.

It can be appreciated from this discussion that a good design strategy in attempting to extract maximum power from the electron beam in the FEL interaction, is to set the parameters determining the synchrotron oscillation frequency K_s in eqn [81] so that only half a synchrotron oscillation period will be performed along the interaction length:

$$K_s L = \pi \qquad [87]$$

This is controlled in an amplifier by keeping the input radiation power $P_q(0)$ (and consequently a_s) small enough, so that K_s will not exceed the value set

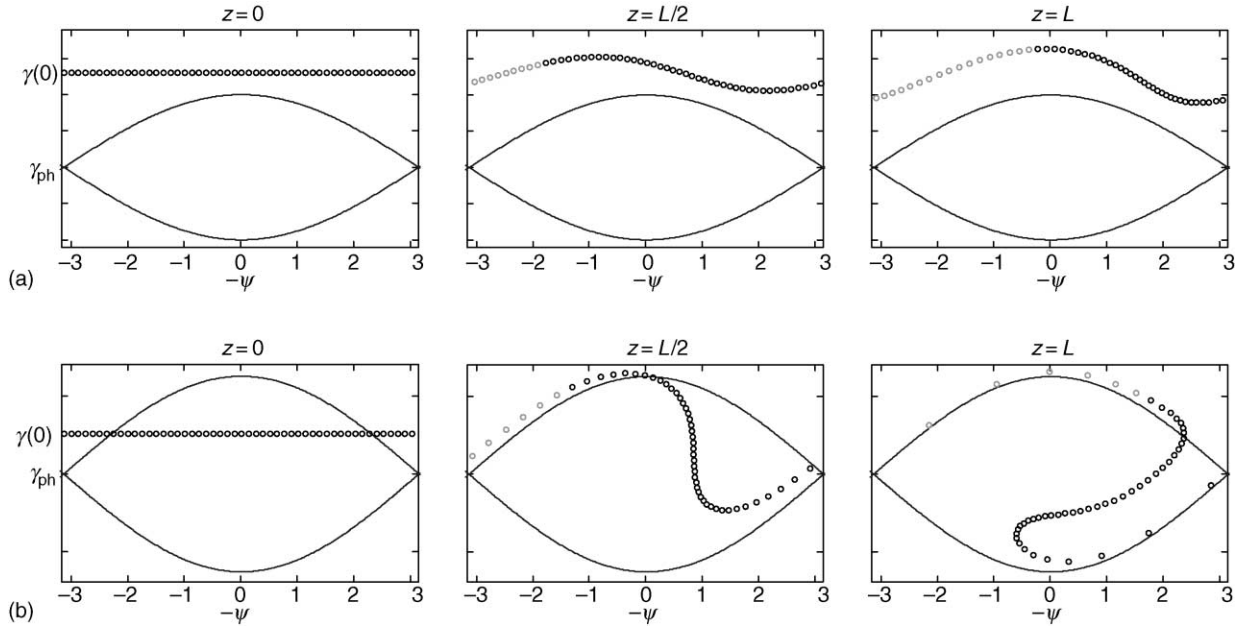

Figure 10 'Snapshots' of the ($\gamma-\Psi$) phase-space distribution of an initially uniformly distributed cold beam relative to the PM-wave trap at three points along the wiggler (a) Moderate bunching in the small-signal low gain regime. (b) Dynamics of electron beam trapping and synchrotron oscillation at steady state saturation stage of a FEL oscillator ($K_s L = \pi$).

by eqn [87]. In an oscillator, this is controlled by increasing the output mirror transmission sufficiently, so that the single path incremental small signal gain G-1 will not be much larger than the round trip loss, and the FEL will not get into deep saturation. When the FEL is over-saturated ($K_s L > \pi$), the trapped electrons begin to gain energy as they continue to rotate in their phase-space trajectories beyond the lowest energy point of the trap, and the radiative energy extraction efficiency drops down.

A practical estimate for the FEL saturation power emission and radiation extraction efficiency can be derived from the following consideration: the electron beam departs from most of its energy during the interaction with the wave, if a significant fraction of the electrons are within the trap and have positive velocity δv_{zi} relative to the wave velocity v_{ph} at $z = 0$, and if at the end of the interaction length ($z = L$), they complete half a pendulum swing and reverse their velocity relative to the wave $\delta v_{zi}(L) \cong -\delta v_{zi}(0)$. Correspondingly, in the energy phase-space diagram (Figure 10b) the electrons perform half a synchrotron oscillation swing and $\delta\gamma_i(L) = \gamma_i(L) - \gamma_{ph} = -\delta\gamma_i(0)$. In order to include in this discussion also the FEL amplifier (in the high gain regime), we note that in this case the phase velocity of the wave v_{ph} in eqn [84], and correspondingly γ_{ph}, are modified by the interaction contribution to the radiation wavenumber – $k_z = k_{z0} + \mathrm{Re}(\delta k)$, and also the electron detuning parameter (relative to the pondermotive wave) θ_i in eqn [80] differs from the beam detuning parameter θ in eqn [43]: $\theta_i = \theta - \mathrm{Re}(\delta k)$. Based on these considerations and eqn [85], the maximum energy extraction from the beam in the saturation process is:

$$\Delta\gamma = 2\delta\gamma_i(0) = 2\beta_{z0}^3\gamma_{z0}^2\gamma_0\frac{\mathrm{Re}\,\delta k - \theta}{k} \qquad [88]$$

where θ is the initial detuning parameter in eqn [43].

In an FEL oscillator, operating in general in the low-gain regime, $|\mathrm{Re}\,\delta k| \ll |\theta|$, oscillation will start usually at the resonator mode frequency, corresponding to the detuning parameter $\theta(\omega) = -2.6/L$, for which the small signal gain is maximal (see Figure 8). Then the maximum radiation extraction efficiency can be estimated directly from eqn [88]. It is, in the highly relativistic limit ($\beta_{z0} \cong 1$):

$$\eta_{ext} = \frac{\Delta\gamma}{\gamma_0} \cong \frac{1}{2N_w} \qquad [89]$$

In an FEL amplifier, in the high-gain regime $\mathrm{Re}\,\delta k = \Gamma/2 \gg |\theta|$, and consequently in the same limit:

$$\eta_{ext} \cong \frac{\Gamma\lambda_w}{4\pi} \qquad [90]$$

It may be interpreted that the effective wiggler length for saturation is $L_{eff} = 2\pi/\Gamma$.

Equation [90], derived here for a coherent wave, is considered valid also for estimating the saturation

efficiency also in SASE-FEL. In this context, it is also called 'the efficiency parameter' $-\rho$.

FEL Radiation Schemes and Technologies

Contrary to conventional atomic and molecular lasers, the FEL operating frequency is not determined by natural discrete quantum energy levels of the lasing matter, but by the synchronism condition of eqn [24] that can be predetermined by the choice of wiggler period, $\lambda_w = 2\pi/k_w$, the resonator dispersion characteristics $k_{zq}(\omega)$, and the beam axial velocity v_z.

Because the FEL design parameters can be chosen at will, its operating frequency can fit any requirement, and furthermore, it can be tuned over a wide range (primarily by varying v_z). This feature of FEL led to FEL development efforts in regimes where it is hard to attain high-power tunable conventional lasers or vacuum-tube radiation sources – namely in the sub-mm (far infrared or THz) regimes, and in the VUV down to soft X-ray wavelengths.

In practice, in an attempt to develop short wavelength FELs, the choice of wiggler period λ_w is limited by an inevitable transverse decay of the magnetic field away from the wiggler magnets surface (a decay range of $\approx k_w^{-1}$) dictated by the Maxwell equations. To avoid interception of electron beam current on the walls or on the wiggler surfaces, typical wiggler periods are made longer than $\lambda_w > 1$ cm. FELs (or FEMs – free electron masers) operating in the long wavelengths regime (mm and sub-mm wavelengths) must be based on waveguide resonators to avoid excessive diffraction of the radiation beam along the interaction length (the wiggler). This determines the dispersion relation $k_{zq}(\omega) = (\omega^2 - \omega_{coq}^2)^{1/2}/c$ where ω_{coq} is the waveguide cutoff frequency of the radiation mode q. The use of this dispersion relation in eqn [24] results in an equation for the FEL synchronism frequency ω_0. Usually the fundamental mode in an overmoded waveguide is used (the waveguide is overmoded because it has to be wide enough to avoid interception of electron beam current). In this case ($\omega_0 \gg \omega_{co}$) and certainly in the case of an open resonator (common in FELs operating in the optical regime) $k_{zq} = \omega/c$, and the synchronism condition in eqn [24] simplified to the well-known FEL radiation wavelength expression in eqn [6]:

$$\lambda = (1 + \beta_z)\beta_z\gamma_z^2\lambda_w \cong 2\gamma_z^2\lambda_w \qquad [91]$$

where γ_z, a_w are defined in eqns [7]–[9].

To attain strong interaction, it is desirable to keep the wiggler parameter a_w large (eqn [38]), however, if $a_w > 1$, this will cause reduction in the operating wavelength according to eqns [7] and [91]. For this reason, and also in order to avoid harmonic frequencies emission (in case of a linear wiggler), $a_w < 1$ in common FEL design. Consequently, considering the practical limitations on λ_w, the operating wavelength eqn [91] is determined primarily by the beam relativistic Lorentz factor γ (eqn [8]).

The conclusion is that for a short wavelength FEL, one should use an electron beam accelerated to high kinetic energy E_k. Also, tuning of the FEL operating-wavelength can be done by changing the beam energy. Small-range frequency tuning can be done also by changing the spacing between the magnet poles of a linear wiggler. This varies the magnetic field experienced by the e-beam, and effects the radiation wavelength through change of a_w (see eqns [7] and [91]).

Figure 11 displays the operating wavelengths of FEL projects all over the world versus their e-beam energy. FELs were operated or planned to operate over a wide range of frequencies, from the microwave to X-ray – eight orders of magnitude. The data points fall on the theoretical FEL radiation curve eqns [7], [8], and [91].

FEL Accelerator Technologies

The kind of accelerator used is the most important factor in determining the FEL characteristics. Evidently, the higher the acceleration energy, the shorter is the FEL radiation wavelength. However, not only the acceleration beam energy determines the shortest operating wavelength of the FEL, but also the e-beam quality. If the accelerated beam has large energy spread, energy instability, or large emittance (the product of the beamwidth with its angular spread), then it may have large axial velocity spread v_{zth}. At high frequencies, this may push the detuning spread parameter $\bar{\theta}_{th}$ (eqn [52]) to the warm beam regime (see Table 1), in which the FEL gain is diminished, and FELs are usually not operated.

Other parameters of the accelerator determine different characteristics of the FEL. High current in the electron beam enables higher gain and higher power operation. The e-beam pulse shape (or CW) characteristics, affect, of course, the emitted radiation waveform, and may also affect the FEL gain and saturation characteristics. The following are the main accelerator technologies used for FEL construction. Their wavelength operating-regimes (eqn [91]) (determined primarily by their beam acceleration energies), are displayed in Figure 12.

Modulators and pulse-line accelerators

These are usually single pulse accelerators, based on high voltage power supplies and fast discharge stored

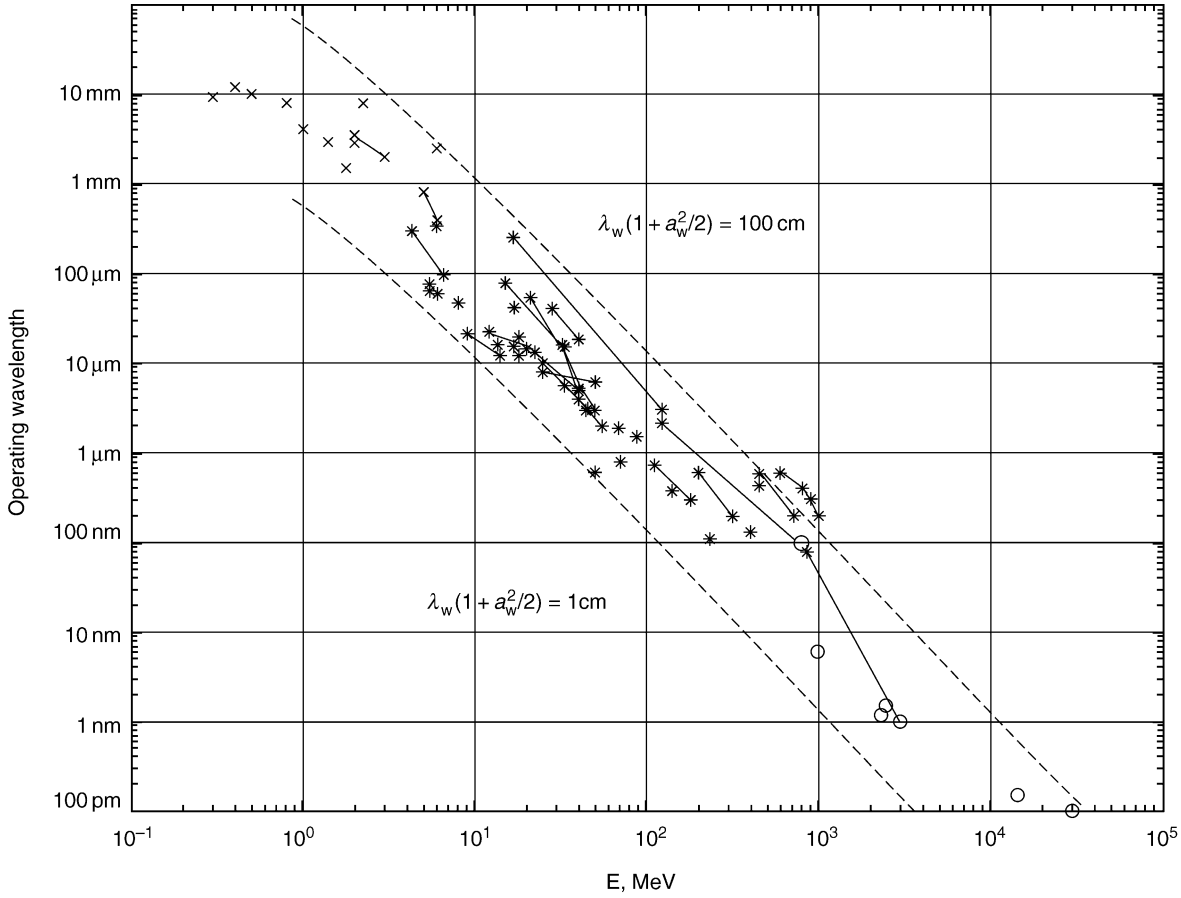

Figure 11 Operating wavelengths of FELs around the world vs. their accelerator beam energy. The data points correspond in ascending order of accelerator energy to the following experimental facilities: NRL (USA), IAP (Russia), KAERI (Korea), IAP (Russia), JINR/IAP (Russia), INP/IAP (Russia), TAU (Israel), FOM (Netherlands), KEK/JAERI (Japan/Korea), CESTA (France), ENEA (Italy), KAERI-FEL (Korea), LEENA (Japan), ENEA (Italy), FIR FEL (USA), mm Fel (USA), UCSB (USA), ILE/ILT (Japan), MIRFEL (USA), UCLA-Kurchatov (USA/Russia), FIREFLY (GB), JAERI-FEL (Japan), FELIX (Netherlands), RAFEL (USA), ISIR (Japan), UCLA-Kurchatov-LANL (USA/RU), ELSA (France), CLIO (France), SCAFEL (GB), FEL (Germany), BFEL (China), KHI-FEL (Japan), FELI4 (Japan), iFEL1 (Japan), HGHG (USA), FELI (USA), MARKIII (USA), ATF (USA), iFEL2 (Japan), VISA (USA), LEBRA (Japan), OK-4 (USA), UVFEL (USA), iFEL3 (Japan), TTF1 (Germany), NIJI-IV (Japan), APSFEL (USA), FELICITAI (Germany), FERMI (Italy), UVSOR (Japan), Super-ACO (France), TTF2 (Germany), ELETTRA (Italy), Soft X-ray (Germany), SPARX (Italy), LCLS (USA), TESLA (Germany). X, long wavelengths; $*$, short wavelengths; ○, planned short wavelengths SASE-FELs. Data based in part on H. P. Freund, V. L. Granatstein, Nucl. Inst. and Methods In Phys. Res. A249, 33 (1999), W. Colson, Proc. of the 24th Int. FEL conference, Argone, III. (ed. K. J. Kim, S. V. Milton, E. Gluskin). The data points fall close to the theoretical FEL radiation condition expression (91) drawn for two practical limits of wiggler parameters.

electric energy systems (e.g., Marx Generator), which produce short pulse (tens of nSec) Intense Relativistic Beam (IRB) of energy in the range of hundreds of keV to few MeV and high instantaneous current (order of kAmp), using explosive cathode (plasma field emission) electron guns. FELs (FEMs), based on such accelerators, operated mostly in the microwave and mm-wave regimes. Because of their poor beam quality and single pulse characteristic, these FELs were, in most cases, operated only as Self Amplified Spontaneous Emission (SASE) sources, producing intense radiation beams of low coherence at instantaneous power levels in the range of 1–100 MW. Because of the high e-beam current and low energy, these FEMs operated mostly in the collective high-gain regime (see Table 1).

Some of the early pioneering work on FEMs was done in the 1970s and 1980s in the US (NRL, Columbia Univ., MIT), Russia (IAP), and France (Echole Politechnique), based on this kind of accelerators.

Induction linacs

These too are single pulse (or low repetition rate) accelerators, based on induction of electromotive potential over an acceleration gap by means of an electric-transformer circuit. They can be cascaded to high energy, and produce short pulse (tens to hundreds

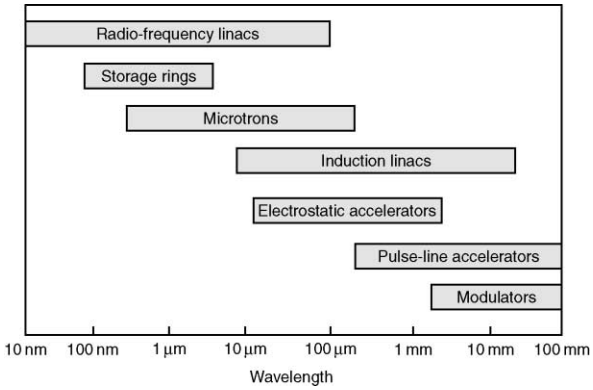

Figure 12 Approximate wavelength ranges accessible with FELs based on current accelerator and wiggler technologies.

of nSec), high current (up to 10 kA) electron beams, with relatively high energy (MeV to tens of MeV). The interest in FELs, based on this kind of accelerator technology, stemmed in the 1980s primarily from the SDI program, for the propose of development of a DEW FEL. The main development of this technology took place on a 50 MeV accelerator – ATA (for operating at 10 μm wavelength) and a 3.5 MeV accelerator – ETA (for operating at 8 mm wavelength). The latter experiment, operating in the high-gain regime, demonstrated record high power (1 GW) and energy extraction efficiency (35%).

Electrostatic accelerators

These accelerators are DC machines, in which an electron beam, generated by a thermionic electron-gun (typically 1–10 Amp) is accelerated electrostatically. The charging of the high voltage terminal can be done by mechanical charge transport (Van de Graaff) or electrodynamically (Crockford–Walton accelerator, Dynamitron). The first kind can be built at energies up to 25 MeV, and the charging current is less than mAmp. The second kind have terminal voltage less than 5 MeV, and the charging current can be hundreds of mAmps.

Because of their DC characteristics, FELs based on these kinds of accelerators can operate at arbitrary pulse shape structure and in principle – continuously (CW). However, because of the low charging current, the high electron beam current (1–10 Amp), required for FEL lasing must be transported without any interception along the entire way from the electron gun, through the acceleration tubes and the FEL wiggler, and then decelerated down to the voltage depressed beam-collector (multistage collector), closing the electric circuit back to the e-gun (current recirculation). The collector is situated at the e-gun potential, biased by moderate voltage high current power supplies, which deliver the current and power needed for circulating the e-beam and compensates for its kinetic energy loss in favor of the radiation field in the FEL cavity. This beam current recirculation is, therefore, also an 'Energy retrieval' scheme, and can make the overall energy transfer efficiency of the electrostatic-accelerator FEL very high.

In practice, high-beam transport efficiency in excess of 99.9% is needed for CW lasing, and has not been demonstrated yet. To avoid HV-terminal voltage drop during lasing, electrostatic-accelerator FELs are usually operated in a single pulse mode. Few FELs of this kind have been constructed. The first and main facility is the UCSB FEL shown in Figure 13. It operates in the wavelength range of 30 μm to 2.5 mm (with three switchable wigglers) in the framework of a dedicated radiation user facility. This FEL operates in the negatively charged terminal mode, in which the e-gun and collector are placed in the negatively charged HV-terminal inside the pressurized insulating gas tank, and the wigglers are situated externally at ground potential. An alternative operating mode of positively charged terminal internal cavity electrostatic-accelerator FEM was demonstrated in the Israeli Tandem–Accelerator FEM and the Dutch F.O.M. Fusion-FEM projects. This configuration enables operating with long pulse, high coherence, and very high average power. Linewidth of $\Delta\omega/\omega \cong 10^{-5}$ was demonstrated in the Israeli FEM and high power (730 kW over few microseconds) was demonstrated in the Dutch FEM, both at mm-wavelengths. The goal of the latter development project (which was not completed) was quasicontinuous operation at 1 MW average power for application in fusion plasma heating.

Radio-frequency (RF) accelerators

RF-accelerators are by far the most popular electron-beam sources for FELs. In RF accelerators, short electron beam bunches (bunch duration 1–10 pSec) are accelerated by the axial field of intense RF radiation (frequency about 1 GHz), which is applied in the acceleration cavities on the injected short e-beam bunches, entering with the accelerating-phase of the RF field. In microtrons, the electron bunches perform circular motion, and get incremental acceleration energy every time they re-enter the acceleration cavity. In RF-LINACs (linear accelerator), the electron bunches are accelerated in a sequence of RF cavities or a slow-wave structure, which keep an accelerating-phase synchronization of the traversing electron bunches with the RF field along a long linear acceleration length. The bunching of the electrons, prior to the acceleration step, is traditionally performed by bunching RF-cavities and a dispersive magnet (chicane) pulse compression system.

The FEL small signal gain, must be large enough to build-up the radiation field in the resonator from noise to saturation well within the macropulse duration.

RF-Linacs are essential facilities in synchrotron radiation centers, used to inject electron beam current into the synchrotron storage ring accelerator from time to time. Because of this reason, many FELs based on RF-LINACs were developed in synchrotron centers, and provide additional coherent radiation sources to the synchrotron radiation center users.

Figure 15 displays FELIX – a RF-LINAC FEL which is located in one of the most active FEL radiation user-centers in FOM – Holland.

Storage rings

Storage rings are circular accelerators in which a number of electron (or positron) beam bunches (typically of 50–500 pS pulse duration and hundreds of ampere peak current) are circulated continuously by means of a lattice of bending magnets and quadrupole lenses. Typical energies of storage ring accelerators are in the hundreds of MeV to GeVs range. As the electrons pass through the bending magnets, they lose a small amount of their energy due to emission of synchrotron radiation. This energy is replenished by a small RF acceleration cavity placed in one section of the ring. The electron beam bunch dimensions, energy spread, and emittance parameters are set in steady state by a balance between the electrons oscillations within the ring lattice and radiation damping due to the random synchrotron emission process. This produces high-quality (small emittance and energy spread) continuous train of electron beam bunches, that can be used to drive a FEL oscillator placed as an insertion device in one of the straight sections of the ring between two bending magnets.

Demonstrations of FEL oscillators, operating in a storage ring, were first reported by the French (LURE-Orsay) in 1987 (at visible wavelengths) and the Russians (VEPP-Novosibirsk) in 1988 (in the ultra-violet). The short wavelength operation of storage-ring FELs is facilitated by the high energy, low emittance and low energy spread parameters of the beam.

Since storage ring accelerators are at the heart of all synchrotron radiation centers, one could expect that FEL would be abundant in such facilities as insertion devices. There is, however, a problem of interference of the FEL operating as an insertion device in the normal operation of the ring itself. The energy spread increase, induced in the electron beam during the interaction in a saturated FEL oscillator, cannot be controlled by the synchrotron radiation damping process, if the FEL operating power is too high.

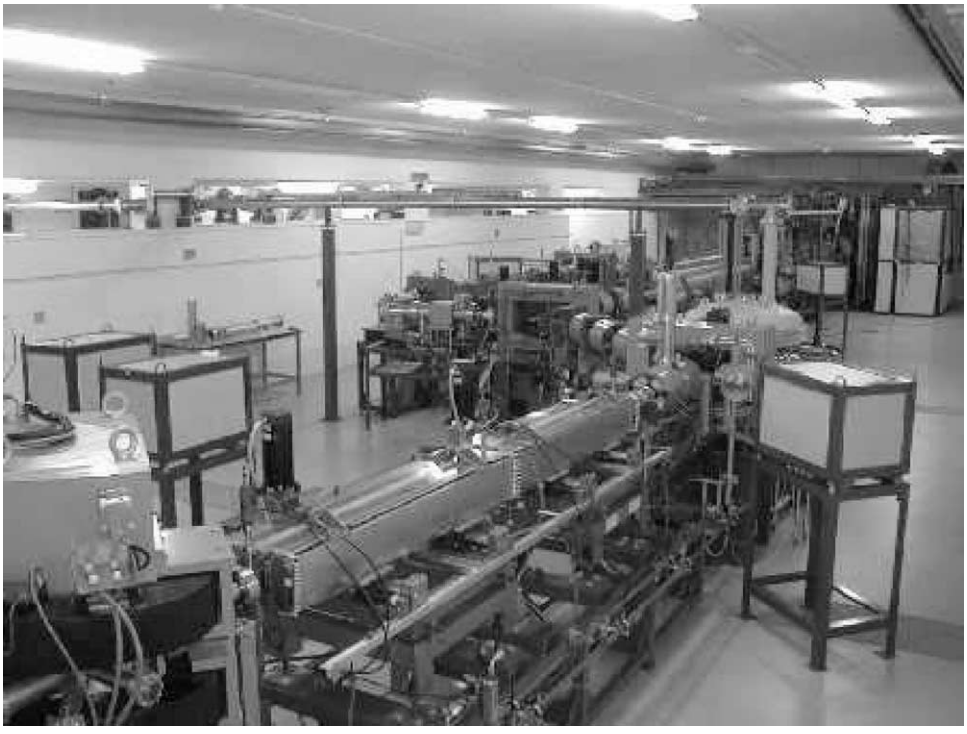

Figure 15 The FELIX RF-Linac FEL operating as a radiation users center in F.O.M. Netherlands. (Courtesy of L. van der Meer, F.O.M.)

This limits the FEL power to be kept as a fraction of the synchrotron radiation power dissipation all around the ring (the 'Renieri Limit'). The effect of the FEL on the e-beam quality, reduces the lifetime of the electrons in the storage ring, and so distrupts the normal operation of the ring in a synchrotron radiation user facility.

To avoid the interference problems, it is most desirable to operate FELs in a dedicated storage ring. This also provides the option to leave long enough straight sections in which long enough wigglers provide sufficient gain for FEL oscillation. Figure 16 displays the Duke storage ring FEL, which is used as a unique radiation user facility, providing intense coherent short wavelength radiation for applications in medicine, biology, material studies, etc.

Superconducting (SC) RF-LINACS

When the RF cavities of the accelerator are superconducting, there are very low RF power losses on the cavity walls, and it is possible to maintain continuous acceleration field in the RF accelerator with a moderate-power continuous RF source, which delivers all of its power to the electron beam kinetic energy. Combining the SC-RF-LINAC technology with an FEL oscillator, pioneered primarily by Stanford University and Thomas Jefferson Lab (TJL) in the US and JAERI Lab in Japan, gave rise to an important scheme of operating such a system in a current recirculating energy retrieval mode. This scheme revolutionized the development of FELs in the direction of high-power, high-efficiency operation, which is highly desirable, primarily for industrial applications (material processing, photochemical production, etc.).

In the recirculating SC-RF-LINAC FEL scheme the wasted beam emerging out of the wiggler after losing a fraction of only few percents (see eqn [89]) out of its kinetic energy, is not dumped into a beam-dump, as in normal cavity RF accelerators, but is re-injected, after circulation, into the SC-RF accelerator. The timing of the wasted electron bunches re-injection is such that they experience a deceleration phase along the entire length of the accelerating cavities. Usually, they are re-injected at the same cell with a fresh new electron bunch injected at an acceleration phase, and thus the accelerated fresh bunch receives its acceleration kinetic energy directly from the wasted beam bunch, that is at the same time decelerated. The decelerated wasted beam bunches are then dumped in the electron beam dump at much lower energy than without recirculation, at energies that are limited primarily just by the energy spread induced in the beam in the FEL laser-saturation process. This scheme, not only increases many folds the over-all energy transformation efficiency from wall-plug to radiation, but would solve significant heat dissipation and radioactivity activation problems in a high-power FEL design.

Figure 17 displays the TJL Infrared SC-RF-LINAC FEL oscillator, that demonstrated for the first time

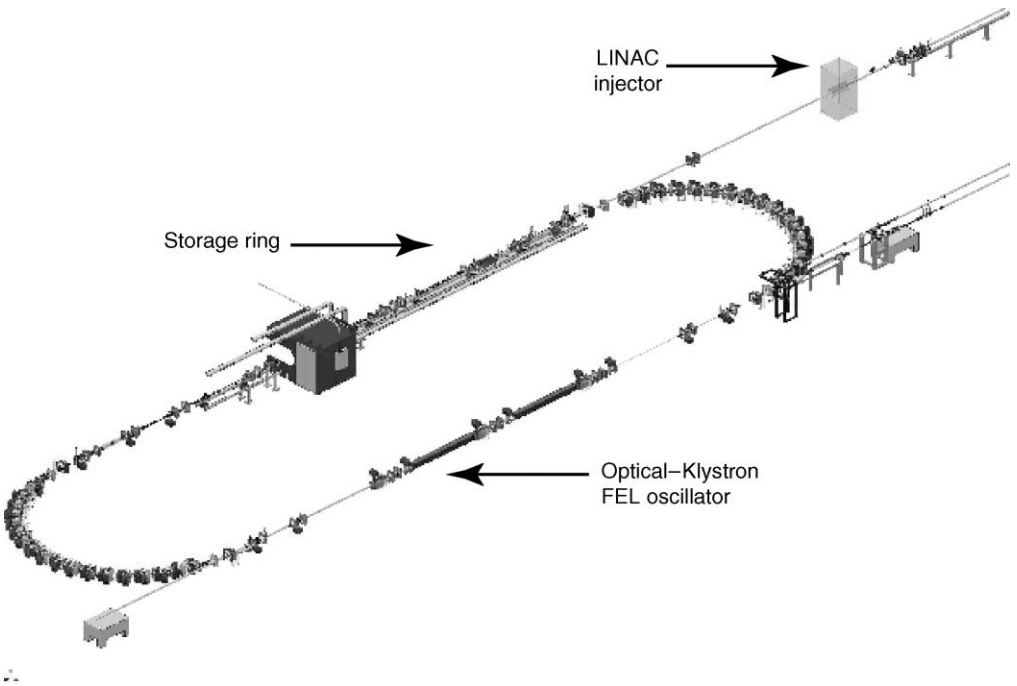

Figure 16 The Duke – University Storage Ring FEL operating as a radiation-users center in N. Carolina, USA. (Mendening: Matthew Busch, courtesy of Glenn Edwards, Duke FEL Lab.)

record high average power levels – nearly 10 kWatt at optical frequencies (1–14 μm). The facility is in upgrade development stages towards eventual operation at 100 kWatt in the IR and 1 kWatt in the UV. It operates in the framework of a laser material processing consortium and demonstrates important material processing applications, such as high-rate micromachining of hard materials (ceramics) with picoSecond laser pulses.

The e-beam current recirculation scheme of SC-RF-LINAC FEL has a significant advantage over the e-beam recirculation in a storage ring. As in electrostatic accelerators, the electrons entering the wiggler are 'fresh' cold-beam electrons from the injector, and not a wasted beam corrupted by the laser saturation process in a previous circulation through the FEL. This also makes it possible to sustain high average circulating current despite the disruptive effect of the FEL on the e-beam. This technological development has given rise to a new concept for a radiation-user facility light-source 4GLS (fourth-generation light source), which is presently in a pilot project development stage at Daresbury Lab in the UK (see Figure 18). In such a scheme, IR and UV FEL oscillators and XUV SASE-FEL can be operated together with synchrotron magnet dipole and wiggler insertion devices without disruptive interference. Such a scheme, if further developed, can give rise to new radiation-user, light-source facilities, that can provide a wider range of radiation parameters than synchrotron centers of previous generation.

Magnetic Wiggler Schemes

The optical klystron

The stimulated emission process in FEL (see Figure 7c) is based on velocity (energy) bunching of the e-beam in the first part of the wiggler, which turns into density bunching along the central part of the wiggler, and then the density-bunched electron beam performs 'negative work' on the radiation wave and emits radiative energy in the last part of the wiggler. In the OK, these steps are carried out in three separate parts of the wiggler: the energy bunching wiggler section, the dispersive magnet density buncher, and the radiating wiggler section (see Figure 7b).

A schematic of the OK is shown in Figure 19. The chicane magnetic structure in the dispersive section brings all electrons emerging from the bunching wiggler back onto the axis of the radiating wiggler, but provides variable delay $\Delta t_{di} = \int_{L_b}^{L_b+L_d} (v_{zi}^{-1} - v_{ph}^{-1})\, dz = [d(\Delta t_d)/d\gamma]\delta\gamma_i$ relative to the pondermotive wave phase to different electrons, which acquired different energy modulation increments $\delta\gamma_i = \gamma_i - \gamma_{ph}$ in the final section. The radiation condition is satisfied whenever the bunch-center phase satisfies $\Delta\varphi_d = \omega\Delta t_d = \pi/2 - 2m\pi$ (see Figure 7b). However, because the energy dispersion coefficient $d(\Delta t_d)/d\gamma$, is much larger in the chicane than in a wiggler of the same length, the density bunching amplitude, and consequently the OK gain, are much larger than in a uniform wiggler FEL of the same length.

The OK was invented by Vinokurov and Skrinsky in 1977 and first demonstrated in 1987 at visible wavelengths in the ACO storage ring of LURE in Orsay, France, and subsequently in 1988 at UV wavelengths, in the VEPP storage ring in Novosibirsk, Russia. The OK is an optimal FEL configuration, if used as an insertion device in a storage ring, because it can provide sufficient gain to exceed the high lasing threshold at the short operating wavelengths of a high-energy storage-ring FEL, and still conform with the rather short straight sections available for insertion devices in conventional synchrotron storage rings. It should be noted that the OK is equivalent to a long wiggler FEL of length L_{eff} of equal gain and therefore its axial velocity spread acceptance is small (this is determined from the cold beam limit $\bar{\theta}_{th} \ll \pi$ with L_{eff} used in eqn [52]). This too is consistent with storage ring accelerators, which are characterized by small energy spread and emittance of the electron beam.

Radiation emission at harmonic frequencies

In a linear wiggler (eqn [2]), the axial velocity:

$$\beta_z = [\beta^2 - (a_w/\gamma)^2 \cos^2 k_w z]^{1/2} \qquad [92]$$

is not constant. It varies with spatial periodicity $\lambda_w/2$, and in addition to its average value $\bar{\beta}_z = [\beta^2 - a_w^2/2\gamma^2]^{1/2}$, contains Fourier components of spatial frequencies $2mk_w$ $(m = 1, 2, \ldots)$. When $a_w \gg 1$, the axial oscillation deforms the sinusoidal trajectory of the electrons in the wiggler (eqns [22] and [23]), and in a frame of reference moving at the average velocity $\bar{\beta}_z$, the electron trajectories in the wiggling $(x-z)$ plane forms an figure 8 shape, rather than a pure transverse linear motion. In the laboratory frame this leads to synchrotron undulator emission in the forward direction at all odd harmonic frequencies of ω_0, corresponding to substitution of $k_w \to (2m+1)k_w$ $(m = 1, 2, 3, \ldots)$ in eqn [6]:

$$\omega_{2m+1} = (2m+1)\omega_0 \cong 2\gamma_z^2 c(2m+1)k_w \qquad [93]$$

All the stimulated emission gain expressions, presented earlier for the fundamental harmonic, are valid with appropriate substitution of

$$\theta_{2m+1} = \frac{\omega}{v_z} - k_z - (2m+1)k_w \qquad [94]$$

instead of eqn [43], and substitution of the harmonic-weight Bessel-function coefficient of

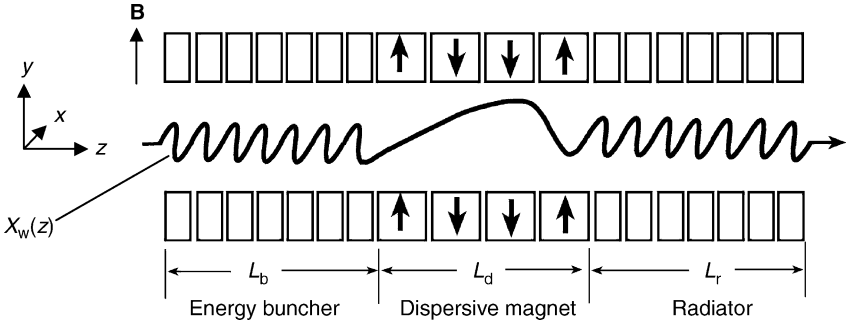

Figure 19 Schematics of the Optical–Klystron, including an energy bunching wiggler, a dispersive magnet bunching section and a radiating wiggler.

synchronism with the beam. Slowing down the PM wave can be done by the gradual increase of the wiggler wavenumber $k_w(z)$ (or decrease of its period $\lambda_w(z)$), so that eqns [29] or [91] keep being satisfied for a given frequency, even if v_z (or γ_z) goes down.

A more correct description of the nonlinear interaction dynamics of the electron beam in a saturated tapered-wiggler FEL is depicted in Figure 20: the electron trap synchronism energy $\gamma_{ph}(z)$ tapers down (by design) along the wiggler, while the trapped electrons are forced to slow down with it, releasing their excess energy by enhanced radiation. An upper limit estimate for the extraction efficiency of such a tapered wiggler FEL would be:

$$\eta_{ext} = \frac{\gamma_{ph}(0) - \gamma_{ph}(L)}{\gamma_{ph}(0)} \qquad [99]$$

and the corresponding radiative power generation would be: $\Delta P = \eta_{ext} I_b E_k / e$. In practice, the phase-space area of the tapered wiggler separatrix is reduced due to the tapering, and only a fraction of the electron beam can be trapped, which reduces correspondingly the practical enhancement in radiative extraction efficiency and power.

An alternative wiggler tapering scheme consists of tapering the wiggler field $B_w(z)$ (or wiggler parameter amplitude $a_w(z)$). If these are tapered down, the axial velocity and axial energy (eqn [7]) can still keep constant (and in synchronism with the PM wave) even if the beam energy γ goes down. Thus, in this scheme, the excess radiative energy extracted from the beam comes out of its transverse (wiggling) energy.

Efficiency and power enhancement of FEL by wiggler tapering have been demonstrated experimentally both in FEL amplifiers (first by Livermore, 1985) and oscillators (first by Los-Alamos, 1983). This elegant way to extract more power from the beam still has some limitations. It can operate efficiently only at a specified high radiation power level for which the tapering was designed. In an oscillator, a long enough untapered section must be left to permit sufficient small signal gain in the early stages of the laser oscillation build-up process.

FEL Oscillators

Most FEL devices are oscillators. As in any laser, in order to turn the FEL amplification process into an oscillation process, one provides a feedback mechanism by means of an optical resonator. In steady state saturation, $GR_{rt} = 1$, where R_{rt} is the round trip reflectivity factor of the resonator and $G = P(L)/P(0)$ is the saturated single-path gain coefficient of the FEL. To attain oscillation, the small signal (unsaturated) gain, usually given by the small gain expression in eqn [53], must satisfy the lasing threshold condition $G > 1/R_{rt}$, as in any laser.

When steady state oscillation is attained, the oscillator output power is:

$$P_{out} = \frac{T}{1 - R_{rt}} \Delta P_{ext} \qquad [100]$$

where $\Delta P_{ext} = \eta_{ext} I_0 (\gamma_0 - 1) mc^2/e$ and η_{ext} is the extraction efficiency, usually given by eqn [89] (low-gain limit).

Usually, FEL oscillators operate in the low-gain regime, in which case $1 - R_{rt} = L + T \ll 1$ (where L is the resonator internal loss factor). Consequently, then $P_{out} \cong \Delta P_{ext} T/(L + T)$, which would give a maximum value, depending on the saturation level of the oscillator. In the general case, one must solve the nonlinear force equations together with the resonator feedback relations of the oscillating radiation mode, in order to maximize the output power (eqn [100]) or efficiency by choice of optimal T for given L.

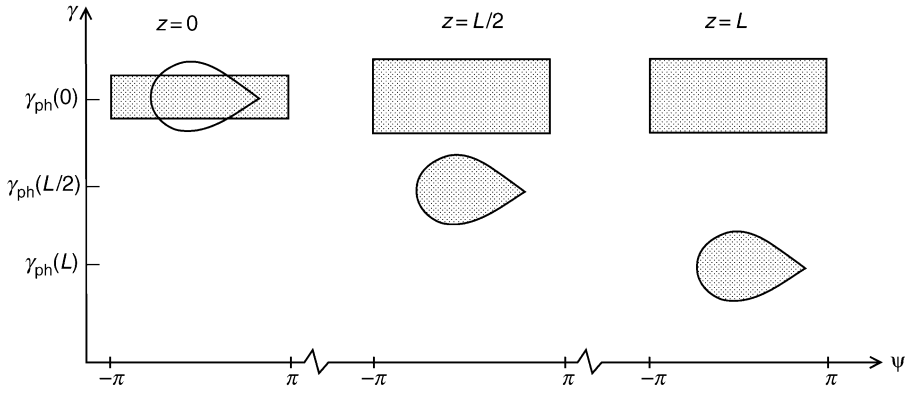

Figure 20 'Snapshots' of the trap at three locations along a tapered wiggler FEL.

In an FEL oscillator operating with periodic electron bunches (as in RF-acclerator based FEL), the solution for the FEL gain and saturation dynamics requires extension of the single frequency solution of the electron and electromagnetic field equations to the time domain. In principle, the situation is similar to that of a mode-locked laser, and the steady state laser pulse train waveform constitutes a superposition of the resonator longitudinal modes that produces a self-similar pulse shape with the highest gain (best overlap with the e-beam bunch along the interaction length). Because the e-beam velocity v_{z0} is always smaller (in an open resonator) than the group velocity of the circulating radiation wavepacket, the radiation wavepacket slips ahead of the electron bunch one optical period λ in each wiggling period (Slippage effect). This reduces the overlap between the radiation pulse and the e-beam bunch along the wiggler (see **Figure 14**) and consequently decreases the gain. Fine adjustment of the resonator mirrors (as shown in **Figure 14**) is needed to attain maximal power and optimal radiation pulse shape. The pulse-slippage gain reduction effect is negligible only if the bunch length is much longer than the slippage length $N_w\lambda$, which can be expressed as:

$$\tau_p \gg 2\pi/\Delta\omega_L \qquad [101]$$

where $\Delta\omega_L$ is the synchrotron undulator radiation frequency bandwidth (eqn [55]). This condition is usually not satisfied in RF-accelerator FELs operating in the IR or lower frequencies, and the

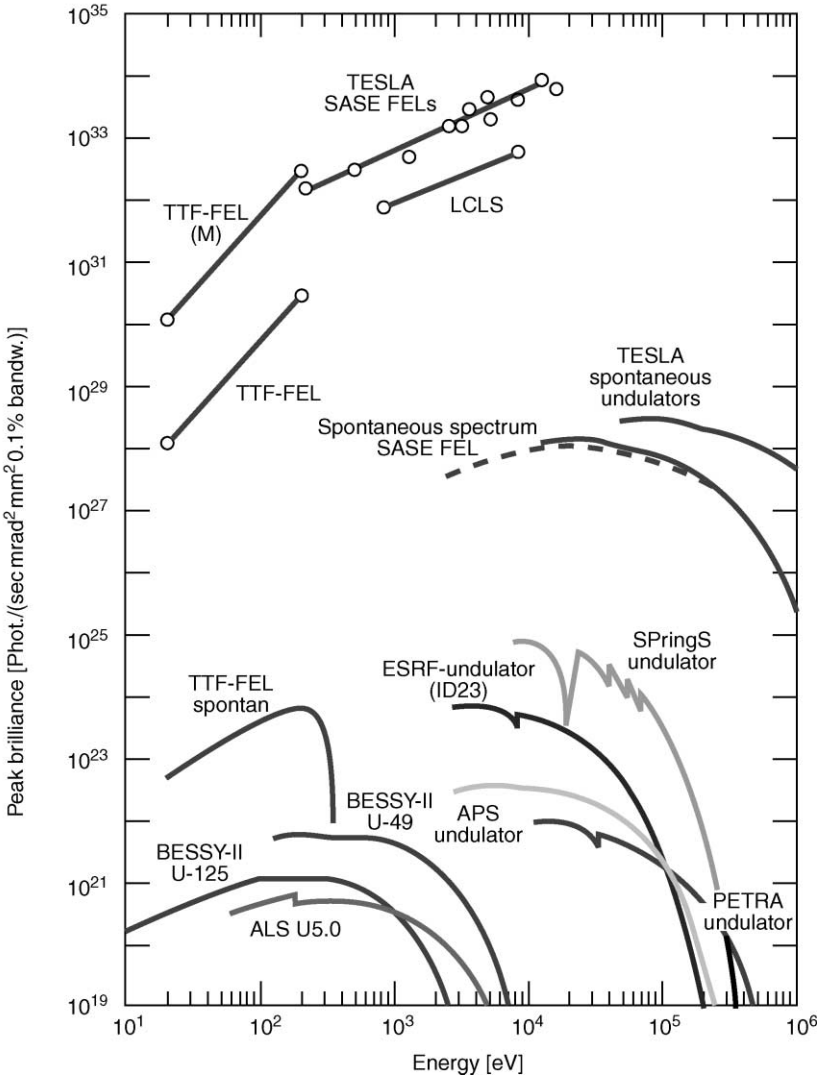

Figure 21 Anticipated peak brightness of SASE FELs (TTF-DESY, LCLS-SLAC) in comparison to the undulators in present third generation Synchrotron Radiation sources. Figure courtesy of DESY, Hamburg, Germany.

slippage effect gain reduction must be then taken into account.

An FEL operating in the cold-beam regime constitutes an 'homogeneous broadening' gain medium in the sense of conventional laser theory. Consequently, the longitudinal mode competition process that would develop in a CW FEL oscillator, leads to single-mode operation and high spectral purity (temporal coherence) of the laser radiation. The minimal (intrinsic) laser linewidth would be determined by an expression analogous to the Schawlow–Towns limit of atomic laser:

$$(\Delta f)_{\text{int}} = \frac{(\Delta f_{1/2})^2}{I_b/e} \qquad [102]$$

where $\Delta f_{1/2}$ is the spectral width of the cold resonator mode. Expression [102] predicts extremely narrow linewidth. In practice, CW operation of FEL was not yet attained, but Fourier transform limited linewidths in the range of $\Delta f/f_0 \cong 10^{-6}$ were measured in long-pulse electrostatic accelerator FELs. In an FEL oscillator, based on a train of e-beam bunches (e.g., an R.F. accelerator beam), the linewidth is very wide and is equal to the entire gain bandwidth (eqn [56]) in the slippage dominated limit, and to the Fourier transform limit $\Delta\omega \cong 2\pi/\tau_p$ in the opposite negligible-slippage limit (eqn [101]). Despite this slippage, it was observed in RF-LINAC FEL that the radiation pulses emitted by the FEL oscillator are phase corrected with each other, and therefore their total temporal coherence length may be as long as the

Metal Vapor Lasers

D W Coutts, University of Oxford, Oxford, UK

Introduction

Metal vapor lasers form a class of laser in which the active medium is a neutral or ionized metal vapor usually excited by an electric discharge. These lasers fall into two main subclasses, namely cyclic pulsed metal vapor lasers and continuous-wave metal ion lasers. Both types will be considered in this article, including basic design and construction, power supplies, operating characteristics (including principal wavelengths), and brief reference to their applications.

Self-Terminating Resonance-Metastable Pulsed Metal Vapor Lasers

The active medium in a self-terminating pulsed metal vapor laser consists of metal atoms or ions in the vapor phase usually as a minority species in an inert buffer gas such as neon or helium. Laser action occurs between a resonance upper laser level and a metastable lower laser level (Figure 1). During a fast pulsed electric discharge (typically with a pulse duration of order 100 ns) the upper laser level is preferentially excited by electron impact excitation because it is strongly optically connected to the ground state (resonance transition) and hence has a large excitation cross-section. For a sufficiently large metal atom (or ion) density, the resonance radiation becomes optically trapped, thus greatly extending the lifetime of the upper laser level such that decay from the upper laser level is channelled through the emission of laser radiation to the metastable lower laser level. Lasing terminates when the electron temperature falls to a point such that preferential pumping to the upper laser level is no longer sustained, and the build-up of population in the metastable lower laser level destroys the population inversion. Therefore after each excitation pulse, the resulting excited species in the plasma (in particular the metastable lower laser levels which are quenched by collisions with cold electrons) must be allowed sufficient time to relax and the plasma must be allowed to partially recombine before applying the next excitation pulse. The relaxation times for self-terminating metal vapor lasers correspond to operating pulse repetition frequencies from 2 kHz to 200 kHz.

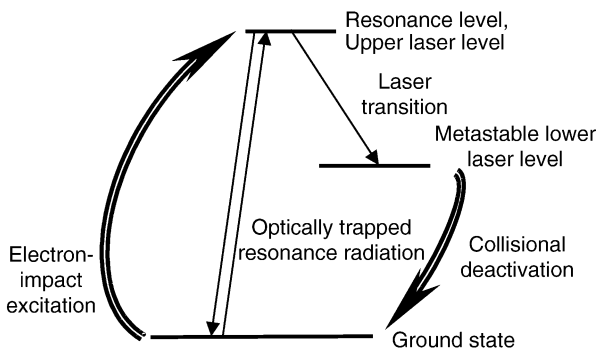

Figure 1 Resonance-metastable energy levels for self-terminating metal vapor lasers.

Many metal vapors can be made to lase in the resonance-metastable scheme and are listed together with their principal wavelengths and output powers in Table 1. The most important self-terminating pulsed metal vapor laser is the copper vapor laser and its variants which will be discussed in detail in the following sections. Of the other pulsed metal vapor lasers listed in Table 1, only the gold vapor laser (principal wavelengths 627.8 nm and 312.3 nm), and the barium vapor laser which operates in the infrared (principal wavelengths 1.5 μm and 2.55 μm) have had any commercial success. All the self-terminating pulsed metal vapor lasers have essentially the same basic design and operating characteristics as exemplified by the copper vapor laser.

Copper Vapor Lasers

Copper vapor lasers (CVLs) are by far the most widespread of all the pulsed metal vapor lasers. Figure 2 shows the energy level scheme for copper. Lasing occurs simultaneously from the $^2P_{3/2}$ level to the $^2D_{5/2}$ level (510.55 nm) and from the $^2P_{1/2}$ level to the $^2D_{3/2}$ level (578.2 nm). Commercial devices are available with combined outputs of over 100 W at 510.55 nm and 578.2 nm (typically with a green-to-yellow power ratio of 2:1).

A typical copper vapor laser tube is shown in Figure 3. High-purity copper pieces are placed at intervals along an alumina ceramic tube which typically has dimensions of 1–4 cm diameter and 1–2 m long. The alumina tube is surrounded by a solid fibrous alumina thermal insulator, and a glass or quartz vacuum envelope. Cylindrical electrodes made of copper or tantalum are located at each end of the plasma tube to provide a longitudinal discharge

Table 1 Principal self-terminating resonance-metastable metal vapor lasers

Metal	*Principal wavelengths (nm)*	*Powers*		*Total efficiencies*	*Pulse repetition frequency (kHz)*	*Technological development*
		Typical (W)	*Maximum (W)*			
Cu	510.55	2–70	2500 total	1%	4–40	Highly developed and commercially available

arrangement. The cylindrical electrodes and silica laser end windows are supported by water-cooled end pieces. The laser windows are usually tilted by a few degrees to prevent back reflections into the active medium. The laser head is contained within a water cooled metal tube to provide a coaxial current return for minimum laser head inductance. Typically a slow flow ($\sim$5 mbar l min^{-1}) of neon at a pressure of 20–80 mbar is used as the buffer gas with an approximately 1% H_2 additive to improve the afterglow plasma relaxation. The buffer gas provides a medium to operate the discharge when the laser is cold and slows diffusion of copper vapor out of the ends of the hot plasma tube. Typical copper fill times are of order 200–2000 hours (for 20–200 g copper load). Sealed-off units with lifetimes of order 1000 hours have been in production in Russia for many years.

During operation waste heat from the repetitively pulsed discharge heats the alumina tube up to approximately 1500 °C at which point the vapor pressure of copper is of approximately 0.5 mbar which corresponds to the approximate density required for maximum laser output power. Typical warm-up times are therefore relatively long at around one hour to full power.

One way to circumvent the requirement for high temperatures required to produce sufficient copper density by evaporation of elemental copper (and hence also reduce warm-up times) is to use a copper salt with a low boiling point located in one or more side-arms of the laser tube (Figure 4). Usually copper halides are used as the salt, with the copper bromide laser being the most successful. For the CuBr laser, a temperature of just 600 °C is sufficient to produce the required Cu density by dissociation of CuBr vapor in the discharge. With the inclusion of 1–2% H_2 in the neon buffer gas, HBr is also formed in the CuBr laser, which has the additional benefit of improving recombination in the afterglow via dissociative attachment of free electrons: $HBr + e^- \rightarrow H + Br^-$, followed by ion neutralization: $Br^- + Cu^+ \rightarrow Br + Cu^*$. As a result of the lower operating temperature and kinetic advantages of HBr, CuBr lasers are typically twice as efficient (2–3%) as their elemental counterparts. Sealed-off CuBr systems with powers of order 10–20 W are commercially produced.

An alternative technique for reducing the operating temperature of elemental CVLs is to flow a buffer gas mixture consisting of $\sim$5% HBr in neon at approximately 50 mbar l min^{-1} and allow this to react with solid copper metal placed within the plasma tube at about 600 °C to produce CuBr vapor *in situ*. The so-called Cu HyBrID (hydrogen bromide in discharge) laser has the same advantages as the CuBr laser (e.g., up to 3% efficiency) but at the cost of requiring flowing highly toxic HBr in the buffer gas, a requirement which has so far prevented commercialization of Cu HyBrID technology.

The kinetic advantages of the hydrogen halide in the CuBr laser discharge can also be applied to a conventional elemental CVL through the addition of small partial pressure of HCl to the buffer gas in addition to the 1–2% H_2 additive. HCl is preferred to HBr as it is less likely to dissociate (the dissociation energy of HCl at 0.043 eV is less than HBr at 0.722 eV). Such kinetic enhancement leads to a doubling in average output power, a dramatic increase in beam quality through improved gain characteristics, and shifts the optimum pulse repetition frequency for kinetically enhanced CVLs (KE-CVLs) from 4–10 kHz up to 30–40 kHz.

Preferential pumping of the upper laser levels requires an electron temperature in excess of the 2 eV range, hence high voltage (10–30 kV), high current (hundreds of A), short (75–150 ns) excitation pulses are required for efficient operation of copper vapor lasers. To generate such excitation pulses CVLs are typically operated with a power supply incorporating a high-voltage thyratron switch. In the most basic configuration, the charge-transfer circuit shown

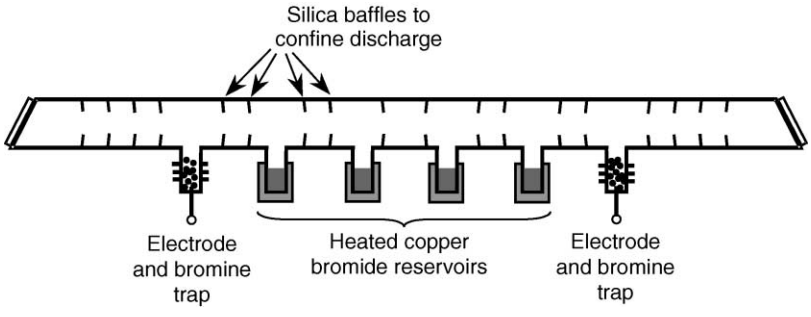

Figure 4 Copper bromide laser tube construction.

in Figure 5a, a dc high-voltage power supply resonantly charges a storage capacitor (C_S, typically a few nF) through a charging inductor L_C, a high-voltage diode and bypass inductor L_B, up to twice the supply voltage V_S in a time of order 100 μs. When the thyratron is triggered, the storage capacitor discharges through the thyratron and the laser head on a time-scale of 100 ns. Note that during the fast discharge phase, the bypass inductor in parallel with the laser head can be considered to be an open circuit. A peaking capacitor C_P ($\sim 0.5\ C_S$) is provided to increase the rate of rise of the voltage pulse across the laser head. Given the relatively high cost of thyratrons, more advanced circuits are now often used to extend the service lifetime of the thyratron to several thousand hours. In the more advanced circuit (Figure 5b) an LC inversion scheme is used in combination with magnetic pulse compression techniques and operates as follows. Storage capacitors C_S are resonantly charged in parallel to twice the dc supply voltage V_S as before. When the thyratron is switched, the charge on C_{S1} inverts through the thyratron and transfer inductor L_T. This LC inversion drags the voltage on the top of C_{S2} down to $-4V_S$. When the voltage across the first saturable inductor L_{S1} reaches a maximum ($-4V_S$) L_{S1} saturates, and allows current to flow from the storage capacitors (now charged in series) to the transfer capacitor ($C_T = 0.5C_{S2}$) thereby transferring the charge from C_{S1} and C_{S2} to C_T in a time much less than the initial LC inversion time. At the moment when the charge on transfer capacitor C_T reaches a maximum (also $-4V_S$), L_{S2} saturates, and the transfer capacitor is discharged through the laser tube, again with a peaking capacitor to increase the voltage rise time. By using magnetic pulse compression the thyratron switched voltage can be reduced by 4 and the peak current similarly reduced (at the expense of increased current pulse duration) thereby greatly extending the thyratron lifetime. Note that in both circuits a 'magnetic assist' L_A saturable inductor is provided in series with the thyratron to delay the current pulse through the thyratron until after the thyratron has reached high conductivity thereby reducing power deposition in the thyratron.

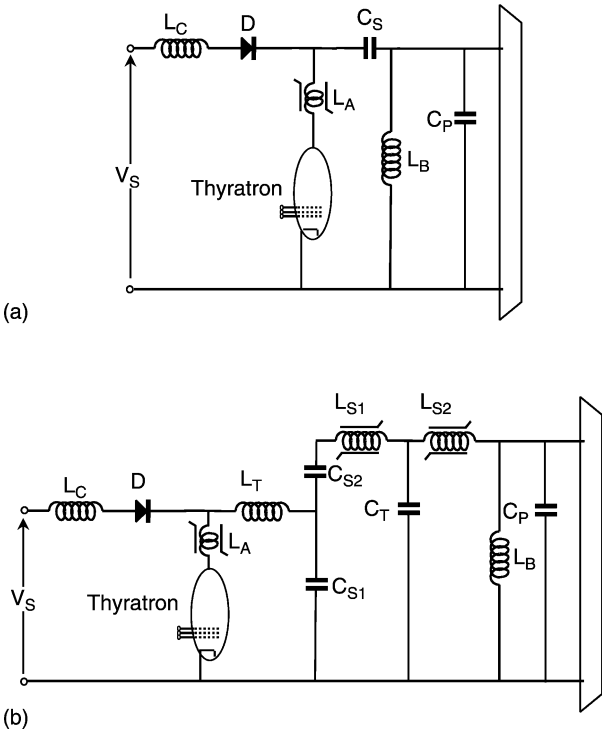

Figure 5 Copper vapor laser excitation circuits. (a) Charge transfer circuit; (b) LC inversion circuit with magnetic pulse compression.

Copper vapor lasers produce high average powers (2–100 W available commercially, with laboratory devices producing average powers of over 750 W) and have wall-plug efficiencies of approximately 1%. Copper vapor lasers also make excellent amplifiers due to their high gains, and the amplifiers can be chained together to produce average powers of several kW. Typical pulse repetition frequencies range from 4 to 20 kHz, with a maximum reported pulse repetition frequency of 250 kHz. An approximate scaling law states that for an elemental device with tube diameter D (mm) and length L (m) the average output power in watts will be of order $D \times L$. For example, a typical 25 W copper vapor laser will have a 25 mm diameter by 1 m long laser tube, and operate at 10 kHz corresponding to 2.5 mJ pulse energy and 50 kW peak power (50 ns pulse duration). Copper vapor lasers have very high single-pass gains (greater than 1000 for a 1 m long tube), large gain volumes and short gain durations (20–80 ns, sufficient for the intracavity laser light to make only a few round trips within the optical resonator). Maximum output power is therefore usually obtained in a highly 'multimode' (spatially incoherent) beam by using either a fully stable or a plane–plane resonator with a low reflectivity output coupler (usually Fresnel reflection from an uncoated optic is sufficient). To obtain higher beam quality a high magnification unstable resonator is required (Figure 6). Fortunately, copper vapor lasers have sufficient gain to operate efficiently with unstable resonators with magnifications ($M = R_1/R_2$) up to 100 and beyond. Resonators with such high magnifications impose very tight geometric constraints on propagation of radiation on repeated round-trips within the resonator, such that after two round-trips the divergence is typically diffraction-limited. Approximately half the stable-resonator

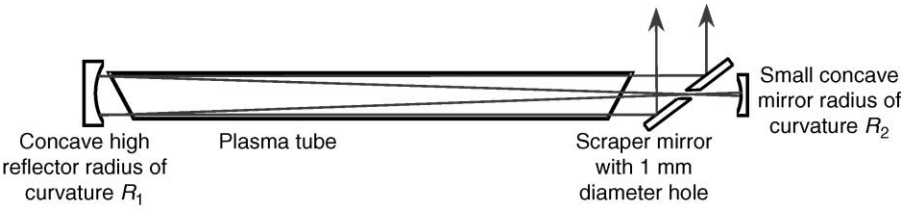

Figure 6 Unstable resonator configuration often used to obtain high beam quality from copper vapor lasers.

output power can therefore be obtained with near diffraction-limited beam quality by using an unstable resonator. Often, a small-scale oscillator is used in conjunction with a single power amplifier to produce high output power with diffraction-limited beam quality. Hyperfine splitting combined with Doppler broadening lead to an inhomogeneous linewidth for the laser transitions of order 8–10 GHz corresponding to a coherence length of order 3 cm.

The high beam quality and moderate peak power of CVLs allows efficient nonlinear frequency conversion to the UV by second harmonic generation (510.55 nm → 255.3 nm, 578.2 nm → 289.1 nm) and sum frequency generation (510.55 nm + 578.2 nm → 271.3 nm) using β-barium borate β-BaB_2O_4 (BBO) as the nonlinear medium. Typically average powers in excess of 1 W can be obtained at any of the three wavelengths from a nominally 20 W CVL. Powers up to 15 W have been obtained at 255 nm from high-power CVL master-oscillator power-amplifier systems using cesium lithium borate; CsLi B_6O_{10} (CLBO) as the nonlinear crystal.

Key applications of CVLs include pumping of dye lasers (principally for laser isotope separation) and pumping Ti:sapphire lasers. Medically, the CVL yellow output is particularly useful for treatment of skin lesions such as port wine stain birth marks. CVLs are also excellent sources of short-pulse stroboscopic illumination for high-speed imaging of fast objects and fluid flows. The high beam quality, visible wavelength and high pulse repetition rate make CVLs very suited to precision laser micromachining of metals, ceramics and other hard materials. More recently, the second harmonic at 255 nm has proved to be an excellent source for writing Bragg gratings in optical fibers.

Afterglow Recombination Metal Vapor Lasers

Recombination of an ionized plasma in the afterglow of a discharge pulse provides a mechanism for achieving a population inversion and hence laser output. The two main afterglow recombination metal vapor lasers are the strontium ion vapor laser (430.5 nm and 416.2 nm) and calcium ion vapor laser (373.7 nm and 370.6 nm) whose output in the violet and UV spectral regions extends the spectral coverage of pulsed metal vapor lasers to shorter wavelengths.

A population inversion is produced by recombination pumping where doubly ionized Sr (or Ca) recombines to form singly ionized Sr (or Ca) in an excited state: $Sr^{++} + e^- + e^- \rightarrow Sr^{+*} + e^-$. Note that recombination rates for a doubly ionized species are much faster than for singly ionized species hence recombination lasers are usually metal ion lasers. Recombination (pumping) rates are also greatest in a cool dense plasma, hence helium is usually used as the buffer gas as it is a light atom hence promotes rapid collisional cooling of the electrons. Helium also has a much higher ionization potential than the alkaline-earth metals (including Sr and Ca) which ensures preferential ionization of the metal species (up to 90% may be doubly ionized).

Recombination lasers can operate where the energy level structure of an ion species can be considered to consist of two (or more) groups of closely spaced levels. In the afterglow of a pulsed discharge electron collisional mixing within each group of levels will maintain each group in thermodynamic equilibrium yielding a Boltzmann distribution of population within each group. If the difference in energy between the two groups of levels (5 eV >> kT) is sufficiently large then thermal equilibrium between the groups cannot be maintained via collisional processes. Given that recombination yields excited singly ionized species (usually with a flux from higher to lower ion levels), it is possible to achieve a population inversion between the lowest level of the upper group and the higher levels within the lower group. This is the mechanism for inversion in the Sr^+ (and analogous Ca^+) ion laser as indicated in the partial energy level scheme for Sr^+ shown in Figure 7.

Strontium and calcium ion recombination lasers have similar construction to copper vapor lasers described above. The lower operating temperatures (500–800 °C) mean that minimal or no thermal insulation is required for self-heated devices.

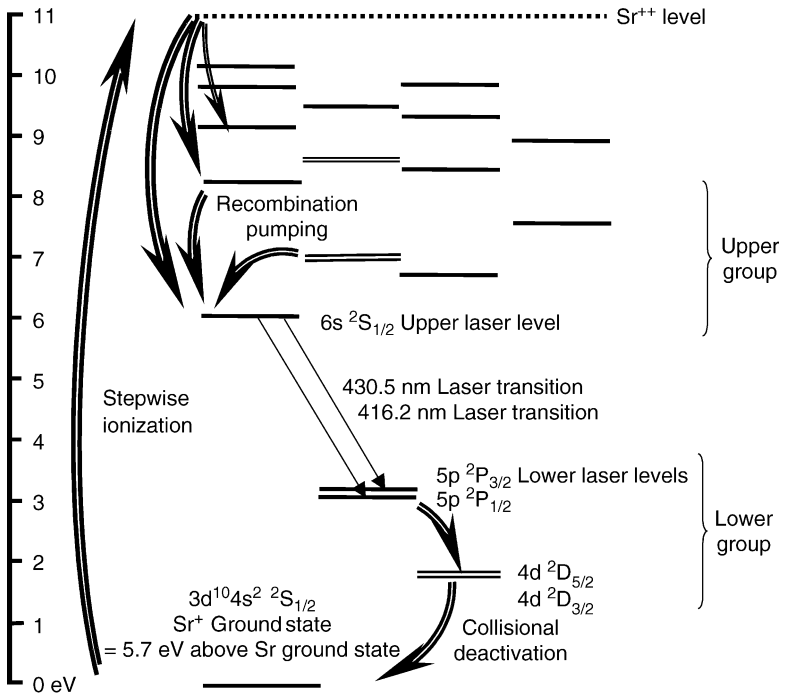

Figure 7 Partial energy level scheme for the strontium ion laser.

For good tube lifetime BeO plasma tubes are required due to the reactivity of the metal vapors. Usually helium at a pressure of up to one atmosphere is used as the buffer gas. Typical output powers at 5 kHz pulse repetition frequency are of order 1 W (~0.1% wall plug efficiency) at 430.5 nm from the He Sr^+ laser and 0.7 W at 373.7 nm from the He Ca^+ laser. For the high specific input power densities (10–15 W cm^{-3}) required for efficient lasing, overheating of the laser gas limits aperture scaling beyond 10–15 mm diameter. Slab laser geometries have been used successfully to aperture-scale strontium ion lasers. Scaling of the laser tube length beyond 0.5 m is not practical as achieving high enough excitation voltages for efficient lasing becomes problematic. Gain in strontium and calcium ion lasers is lower than in resonance-metastable metal vapor lasers such as the CVL, hence optimum output coupler reflectivity is approximately 70%. The pulse duration is also longer at around 200–500 ns resulting in moderate beam quality with plane–plane resonators.

For both strontium and calcium ion lasers the two principal transitions share upper laser levels and hence exhibit gain competition such that without wavelength-selective cavities usually only the longer wavelength of the pair is produced. With wavelength-selective cavities up to 60% (Sr^+) and 30% (Ca^+) of the normal power can be obtained at the shorter wavelength.

Many potential applications exist for strontium and calcium ion lasers, given their ultraviolet (UV)/violet wavelengths. Of particular importance is fluorescence spectroscopy in biology and forensics, treatment of neonatal jaundice, stereolithography, micromachining and exposing photoresists for integrated circuit manufacture. Despite these many potential applications, technical difficulties in power scaling mean that both strontium ion and calcium ion lasers have only limited commercial availability.

Continuous-Wave Metal Ion Lasers

In a discharge excited noble gas, there can be a large concentration of noble gas atoms in excited metastable states and noble gas ions in their ground states. These species can transfer their energy to a minority metal species (M) via two key processes: either charge transfer (Duffendack reactions) with the noble gas ions (N^+):

$$M + N^+ \rightarrow M^{+*} + N + \Delta E$$

(where M^{+*} is an excited metal ion state)

or Penning ionization with a noble gas atom in an excited metastable state (N^*):

$$M + N^* \rightarrow M^{+*} + N + e^-$$

In a continuous discharge in a mixture of a noble gas and a metal vapor, steady generation of excited metal ions via energy transfer processes can lead to a steady state population inversion on one or more pairs of levels in the metal ion and hence produce cw lasing.

Several hundred metal ion laser transitions have been observed to lase in a host of different metals. The most important such laser is the helium cadmium laser, which has by far the largest market volume by number of unit sales of all the metal vapor lasers. In a helium cadmium laser, Cd vapor is present at a concentration of about 1–2% in a helium buffer gas which is excited by a dc discharge. Excitation to the upper laser levels of Cd (Figure 8) is primarily via Penning ionization collisions with He^+ 2^3S_1 metastable ions produced in the discharge. Excitation via electron-impact excitation from the ion ground state may also play an important role in establishing a population inversion in Cd^+ lasers. Population inversion can be sustained continuously because the $^2P_{3/2}$ and $^2P_{1/2}$ lower laser levels decay via strong resonance transitions to the $^2S_{1/2}$ Cd^+ ground state, unlike in the self-terminating metal vapor lasers. Two principal wavelengths can be produced, namely 441.6 nm (blue) and 325.0 nm (UV) with cw powers up to 200 mW and 50 mW available respectively from commercial devices.

Typical laser tube construction (Figure 9) consists of a 1–3 mm diameter discharge channel typically 0.5 m long. A pin anode is used at one end of the laser tube together with a large-area cold cylindrical cathode located in a side-arm at the other end of the tube. Cadmium is transported to the main discharge tube from a heated Cd reservoir in a side-arm at 250–300 °C. With this source of atoms at the anode end of the laser a cataphoresis process (in which the positively charged Cd ions are propelled towards the cathode end of the tube by the longitudinal electric field) transports Cd into the discharge channel. Thermal insulation of the discharge tube ensures that it is kept hotter than the Cd reservoir to prevent condensation of Cd from blocking the tube bore. A large-diameter Cd condensation region is provided at the cathode end of the discharge channel. A large-volume side arm is also provided to act as a gas ballast for maintaining correct He pressure. As He is lost through sputtering and diffusion through the Pyrex glass tube walls, it is replenished from a high-pressure He reservoir by heating a permeable glass wall separating the reservoir from the ballast chamber which allows He to diffuse into the ballast chamber. Typical commercial sealed-off Cd lasers have operating lifetimes of several thousand hours. Overall laser construction is not that much more

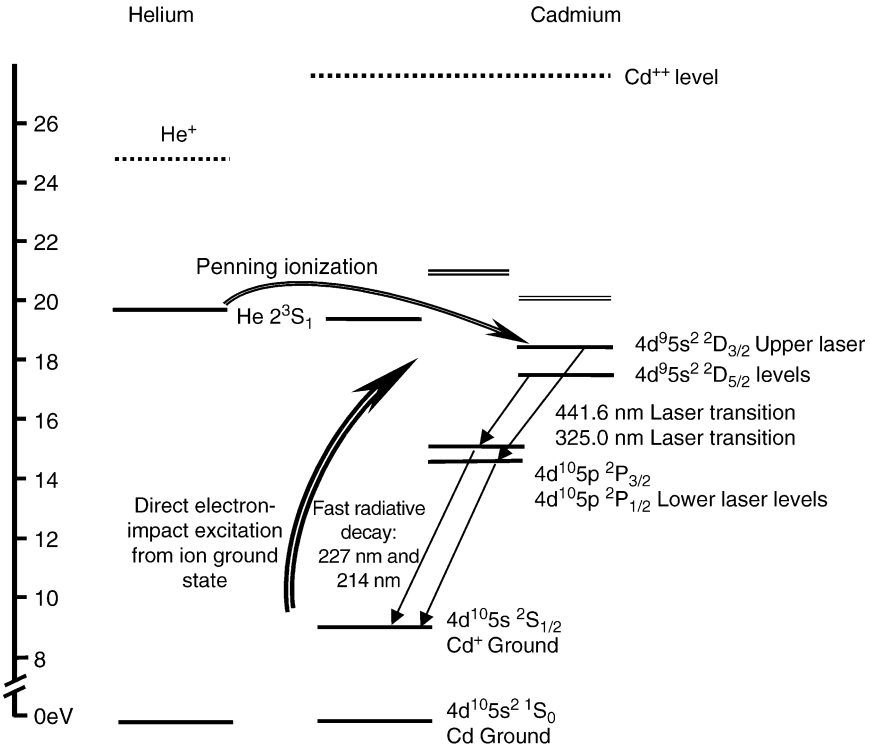

Figure 8 Partial energy level diagram for helium and cadmium giving HeCd laser transitions.

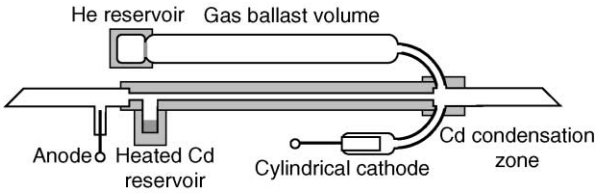

Figure 9 Helium cadmium laser tube construction.

complex than a HeNe laser, hence unit costs are considerably lower than low-power argon ion lasers which also provide output in the blue. Usually Brewster angle windows are provided together with a high Q stable resonator (97–99% reflectivity output coupler) to provide polarized output.

With their blue and UV wavelengths and relatively low cost (compared to low-power argon ion lasers), HeCd lasers have found wide application in science, medicine and industry. Of particular relevance is their application for exposing photoresists where the blue wavelength provides a good match to the peak photosensitivity of photoresist materials. A further key application is in stereolithography where the UV wavelength is used to cure an epoxy resin. By scanning the UV beam in a raster pattern across the surface of a liquid epoxy, a solid three-dimensional object may be built up in successive layers.

List of Units and Nomenclature

Boltzmann constant	[eV K^{-1}]	k

History

The argon ion laser was discovered in early 1964, and is still commercially available in 2004, with about $70 million in annual sales 40 years after this discovery. The discovery was made independently and nearly simultaneously by four different groups; for three of the four, it was an accidental result of studying the excitation mechanisms in the mercury ion laser (historically, the first ion laser), which had been announced only months before. For more on the early years of ion laser research and development, see the articles listed in the Further Reading section at the end of this article.

The discovery was made with pulsed gas discharges, producing several wavelengths in the blue and green portions of the spectrum. Within months, continuous operation was demonstrated, as well as oscillation on many visible wavelengths in ionized krypton and xenon. Within a year, over 100 wavelengths were observed to oscillate in the ions

of neon, argon, krypton, and xenon, spanning the spectrum from ultraviolet to infrared; oscillation was also obtained in the ions of other gases, for example, oxygen, nitrogen, and chlorine. A most complete listing of all wavelengths observed as gaseous ion lasers is given in the Laser Handbook cited in the Further Reading section. Despite the variety of materials and wavelengths demonstrated, however, it is the argon and krypton ion lasers that have received the most development and utilization.

Continuous ion lasers utilize high current density gas discharges, typically 50 A or more, and 2–5 mm in diameter. Gas pressures of 0.2 to 0.5 torr result in longitudinal electric fields of a few V/cm of discharge, so that the power dissipated in the discharge is typically 100 to 200 W/cm. Such high-power dissipation required major technology advances before long-lived practical lasers became available. Efficiencies have never been high, ranging from 0.01% to 0.2%. A typical modern ion laser may produce 10 W output at 20 kW input power from 440 V three-phase power lines and require 6–8 gallons/minute of cooling water. Smaller, air-cooled ion lasers, requiring 1 kW of input power from 110 V single-phase mains can produce 10–50 mW output power, albeit at even lower efficiency.

Theory of Operation

The strong blue and green lines of the argon ion laser originate from transitions between the 4p upper levels and 4s lower levels in singly ionized argon, as shown in Figure 1. The 4s levels decay radiatively to the ion ground state. The strongest of these laser lines are listed in Table 1. The notation used for the energy levels is that of the L–S coupling model. The ion ground state electron configuration is $3s^2 3p^5 (^2P^o_{3/2})$. The inner ten electrons have the configuration $1s^2 2s^2 2p^6$, but this is usually omitted for brevity. The excited states shown in Figure 1 result from coupling a 4p or 4s electron to a $3s^2 3p^4 (^3P)$ core, with the resulting quantum numbers S (the net spin of the electrons), L (the net angular momentum of the electrons), and J (the angular momentum resulting from coupling S to L) are represented by $^{2S+1}L_J$, where $L = 0, 1, 2, \ldots$ is denoted S, P, D, F, … The superscript 'o' denotes an odd level, while even levels omit a superscript. Note that some weaker transitions involving levels originating from the $3s^2 3p^4 (^1D)$ core configuration also oscillate. Note also that the quantum mechanical selection rules for the L–S coupling model are not rigorously obeyed, although the stronger laser lines satisfy most or all of these rules. The selection rule $|\Delta J| = 1$ or 0, but not $J = 0 \rightarrow J = 0$ is always obeyed. All transitions shown in Figure 1 and Table 1 belong to the second spectrum of argon, denoted Ar II. Lines originating from transitions in the neutral atom make up the first spectrum, Ar I; lines originating from transitions in doubly ionized argon are denoted Ar III, and so forth for even more highly ionized states.

Much work has been done to determine the mechanisms by which the inverted population is formed in the argon ion laser. Reviews of this extensive research

[a]All levels are denoted in $L-S$ coupling with the (^{3}P) core unless otherwise indicated. Odd parity is denoted by the superscript 'o'.
[b]Relative strengths are given as power output from a commercial Spectra-Physics model 2080-25S argon ion laser.
[c]These lines may oscillate simultaneously with the nearby strong line, but are not resolved easily in the output beam.

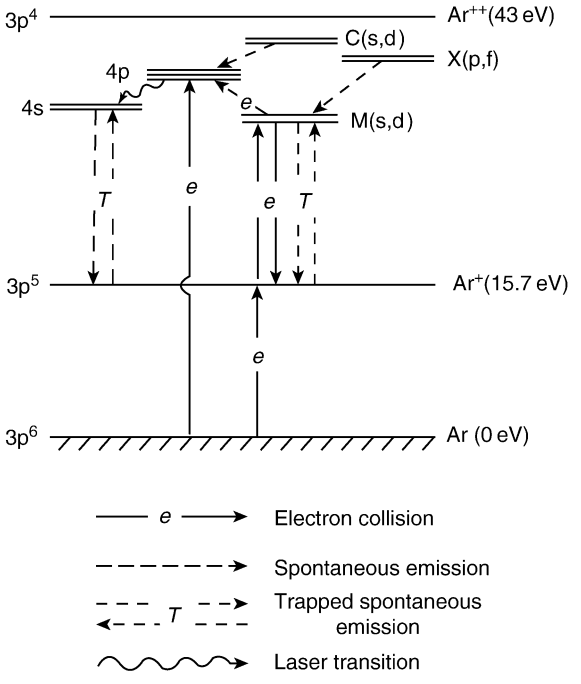

Figure 2 Schematic representation of energy levels in neutral and singly ionized argon, indicating alternative pathways for excitation and de-excitation of the argon ion laser levels.

are found in the Further Reading section. While a completely quantitative picture of argon ion laser operation is lacking to this day, the essential processes are known. Briefly, the 4p upper levels are populated by three pathways, as illustrated in Figure 2:

(i) by electron collision with the $3p^6$ neutral ground state atoms. This 'sudden perturbation process' requires at least 37 eV electrons, and also singles out the $4p\ ^2P^o_{3/2}$ upper level, which implies that only the 476 and 455 nm lines would oscillate. This is the behavior seen in pulsed discharges at very low pressure and very high axial electric field. This pathway probably contributes little to the 4p population under ordinary continuous wave (cw) operating conditions, however.

(ii) by electron collision from the lowest-lying s and d states in the ion, denoted M(s,d) in Figure 1. This only requires 3–4 eV electrons. These states have parity-allowed transitions to the ion ground state, but are made effectively metastable by radiation trapping (that is, there is a high probability that an emitted photon is re-absorbed by another ground state ion before it escapes the discharge region), or by requiring $|\Delta J|$ to be 2 to make the transition (forbidden by quantum selection rules). Thus, these levels are both created and destroyed primarily by electron collision, causing the population of the M(s,d) states to follow the population of the singly ionized ground state, which, in turn, is approximately proportional to the discharge current. Since a second electron collision is required to get from the M(s,d) states to the 4p states, a quadratic variation with current for the laser output power would be expected, and that is what is observed over some reasonable range of currents between threshold and saturation. Note that radiative decay from higher-lying opposite-parity p and f states, denoted X(p,f), can also contribute to the population of M(s,d), but the linear variation in population of the M(s,d) with discharge current is assured by electron collision creation and destruction.

(iii) by radiative decay from higher-lying opposite-parity s and d states, denoted C(s,d). These states are populated by electron collision with the $3p^5$ ion ground states, and thus have populations that also vary quadratically with discharge current. The contribution of this cascade process has been measured to be 20% to 50% of the 4p upper laser level population.

Note that it is not possible to distinguish between processes (ii) and (iii) by the variation of output power with discharge current; both give the observed quadratic dependence.

The radiative lifetimes of the 4s ^{2}P levels are sufficiently short to depopulate the lower laser levels by radiative decay. However, radiation trapping greatly lengthens this decay time, and a bottleneck

can occur. In pulsed ion lasers, this is exhibited by the laser pulse terminating before the excitation current pulse ends, which would seem to preclude continuous operation. However, the intense discharge used in continuous operation heats the ions to the order of 2300 K, thus greatly Doppler broadening the absorption linewidth and reducing the magnitude of the absorption. Additionally, the ions are attracted to the discharge tube walls, so that the absorption spectrum is further broadened by the Doppler shift due to their wall-directed velocities. The plasma wall sheath gives about 20 V drop in potential from the discharge axis to the tube wall, so most ions hit the wall with 20 eV of energy, or about ten times their thermal velocity. A typical cw argon ion laser operates at ten times the gas pressure that is optimum for a pulsed laser, and thus the radiation trapping of the $4s \rightarrow 3p^5$ transitions is so severe that it may take several milliseconds after discharge initiation for the laser oscillation to begin.

As the discharge current is increased, the intensities of the blue and green lines of Ar II eventually saturate, and then decrease with further current. At these high currents, there is a buildup in the population of doubly ionized atoms, and some lines of Ar III can be made to oscillate with the appropriate ultraviolet mirrors. Table 2 lists the strongest of these lines, those that are available in the largest commercial lasers. Again, there is no quantitative model for the performance in terms of the discharge parameters, but the upper levels are assumed to be populated by processes analogous to those of the Ar II laser. At still higher currents, lines in Ar IV can be made to oscillate as well.

Much less research has been done on neon, krypton, and xenon ion lasers, but it is a good assumption that the population and depopulation processes are the same in these lasers. Table 3 lists both the Kr II and Kr III lines that are available from the largest commercial ion lasers. Oscillation on lines in still-higher ionization states in both krypton and xenon have been observed.

Operating Characteristics

A typical variation of output power with discharge current for an argon ion laser is shown in Figure 3. This particular laser had a 4 mm diameter discharge in a water-cooled silica tube, 71 cm in length, with a 1 kG axial magnetic field. The parameter is the argon pressure in the tube before the discharge was struck. Note that no one curve is exactly quadratic, but that the envelope of the curves at different filling pressures is approximately quadratic. At such high discharge current densities (50 A in the 4 mm tube is approximately 400 A/cm^2) there is substantial pumping of gas out of the small-bore discharge region. Indeed, a return path for this pumped gas must be provided from anode to cathode ends of the discharge to keep the discharge from self-extinguishing. The axial electric field in this discharge was 3–5 V/cm, so the input power was of the order of 10 to 20 kW, yielding an efficiency of less than 0.1%, an unfortunate characteristic of all ion lasers.

Technology

With such high input powers required in a small volume to produce several watts output, ion laser performance has improved from 1964 to the present only as new discharge technologies were introduced. The earliest laboratory argon ion lasers used thin-walled (≈1 mm wall thickness) fused silica discharge tubes, cooled by flowing water over the outside wall of the tube. The maximum input power per unit length of discharge was limited by thermal stresses in the silica walls caused by the temperature differential from inside to outside. Typically, ring-shaped cracks would cause the tube to fail catastrophically. Attempts to make metal–ceramic structures with alumina (Al_2O_3) discharge tubes to contain the plasma were made early on (1965) but were not successful. Such tubes invariably failed from fracture by thermal shock as the discharge was turned on. Later, successful metal–ceramic tubes were made with beryllia (BeO), which has a much higher thermal conductivity than silica or alumina and is much more resistant to thermal shock. Today, all of the lower power (less than 100 mW output) are made with BeO discharge tubes. Some ion lasers in the 0.5 to 1 W range are also made with water-cooled BeO discharge tubes.

A typical low-power air cooled argon ion laser is shown in Figure 4. The large metal can (2) on the right end of the tube contains an impregnated-oxide hot cathode, heated directly by current through ceramic feed-through insulators (3). The small (≈1 mm diameter) discharge bore runs down the center of the BeO ceramic rod (1), and several smaller diameter gas return path holes run off-axis parallel to the discharge bore to provide the needed gas equalization between cathode can and anode region. A copper honeycomb cooler is brazed to the cathode can, two more to the outer wall of the BeO cylinder, and one to the anode (4) at the left end of the tube. The laser mirrors (5) are glass-fritted to the ends of the tube, forming a good vacuum seal. Note that in this small laser, the active discharge bore length is less than half of the overall length.

The very early argon ion lasers were made with simple smooth dielectric tubes, allowing the continuous variation in voltage along the length of the tube required by the discharge longitudinal electric field. However, this variation can be step-wise at the discharge walls, and still be more or less smooth along the axis. Thus, the idea arose of using metal tube segments, insulated one from another, to form the discharge tube walls. The first version of this idea (1965) used short (≈1 cm) metal cylinders supported by metal disks and stacked inside a large diameter silica envelope, with each metal cylinder electrically isolated from the others. The tubes and disks were made of molybdenum, and were allowed to heat to incandescence, thus radiating several kilowatts of heat through the silica vacuum envelope to a water-cooled collector outside. While this eliminated the problems of thermal shock and poor thermal conductivity inherent in dielectric wall discharges, it made another

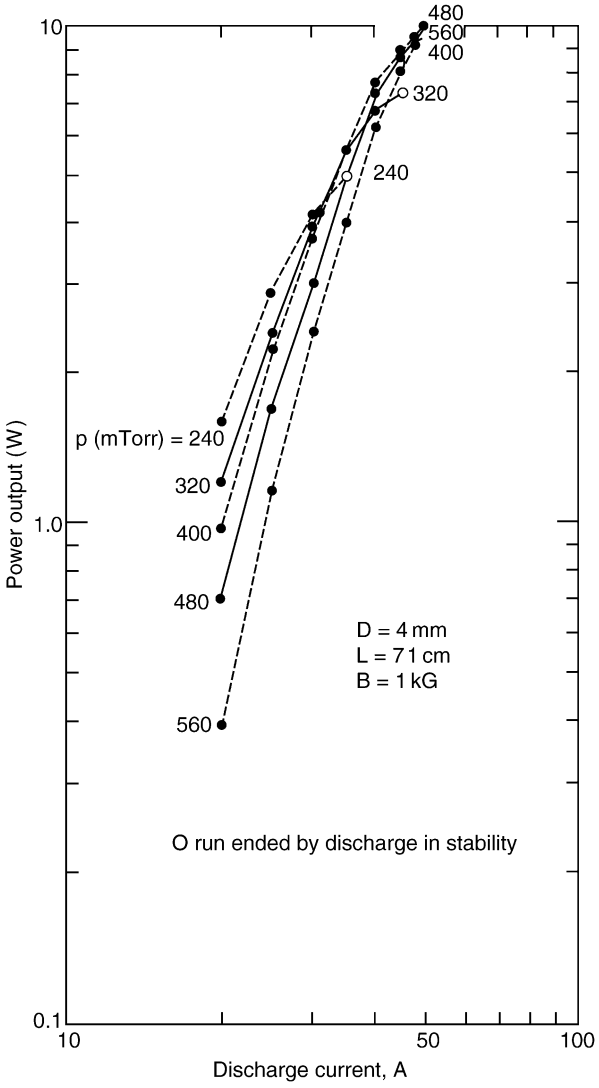

Figure 3 Laser output power (summed over all the blue and green laser lines) versus discharge current for a laser discharge 4 mm in diameter and 71 cm long, with a 1 kilogauss longitudinal magnetic field. The parameter shown is the argon fill pressure in mTorr prior to striking the discharge. The envelope of the curves exhibits the quadratic variation of output power with discharge current.

problem painfully evident. The intense ion bombardment of the metal tube walls sputtered the wall material, eventually eroding the shape of the metal cylinders and depositing metal films on the insulating wall material, thus shorting one segment to another.

Many different combinations of materials and configurations were investigated in the 1960s and 1970s to find a structure that would offer good laser performance and long life. It was found that simple thin metal disks with a central hole would effectively confine the discharge to a small diameter (on the order of the hole size) if a longitudinal d-c magnetic field of the order of 1 kiloGauss were used. The spacing between disks can be as large as 2–4 discharge diameters. Of the metals, tungsten has the lowest sputtering yield for argon ions in the 20 eV range (which is approximately the energy they gain in falling to the wall across the discharge sheath potential difference). An even lower sputtering yield is exhibited by carbon, and graphite cylinders contained within a larger diameter silica or alumina tube were popular for a while for ion laser discharges. Unfortunately, graphite has a tendency to flake or powder, so such laser discharge tubes became contaminated with 'dust' which could eventually find its way to the optical windows of the tube. Beryllia and silica also sputter under argon ion bombardment, but with still lower yields than metals or carbon; however, their smaller thermal conductivities limit them to lower-power applications.

The material/configuration combination that has evolved for higher-power argon ion lasers today is to use a stack of thin tungsten disks with 2–3 mm diameter holes for the discharge. These disks, typically 1 cm in diameter, are brazed coaxially to a larger copper annulus (actually, a drawn cup with a 1 cm hole on its axis). A stack of these copper/tungsten structures is, in turn, brazed to the inside wall of a large diameter alumina vacuum envelope. The tungsten disks are exposed to and confine the discharge, while the copper cups conduct heat radially outward to the alumina tube wall, which, in turn, is cooled by fluid flow over its exterior. Thus, the discharge is in contact only with a low-sputtering material (tungsten) while the heat is removed by a high thermal conductivity material (copper). Details differ among manufacturers, but this 'cool disk' technology seems to have won out in the end. A photo of a half-sectioned disk/cup stacked assembly from a Coherent Innova™ ion laser is shown in Figure 5. The coiled impregnated-tungsten cathode is also shown.

Sputtering of the discharge tube walls is not uniform along the length of the gas discharge. The small diameter region where the laser gain occurs is always joined to larger diameter regions containing cathode and anode electrodes (as shown in Figure 5, for example). A plasma double sheath (that is, a localized increase in potential) forms across the discharge in the transition region between large and small diameter regions (the discharge 'throats,' which may be abrupt or tapered). This sheath is required to satisfy the boundary conditions between the plasmas of different temperatures in the different regions. Such a double sheath imparts additional energy to the ions as they cross the sheath, perhaps

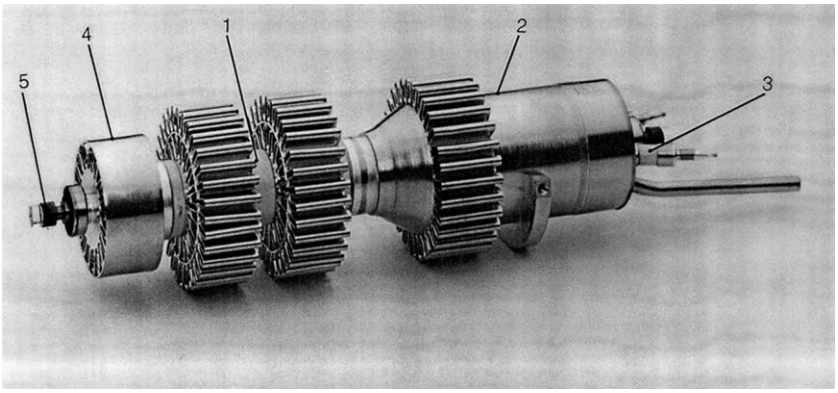

Figure 4 A typical commercial low-power, air-cooled argon ion laser. The cathode can (2) is at the right and the beryllia bore (1) and anode (4) is at the left. The cathode current is supplied through ceramic vacuum feed-throughs (3). Mirrors (5) are glass fritted onto the ends of vacuum envelope. (Photo courtesy of JDS Uniphase Corp.)

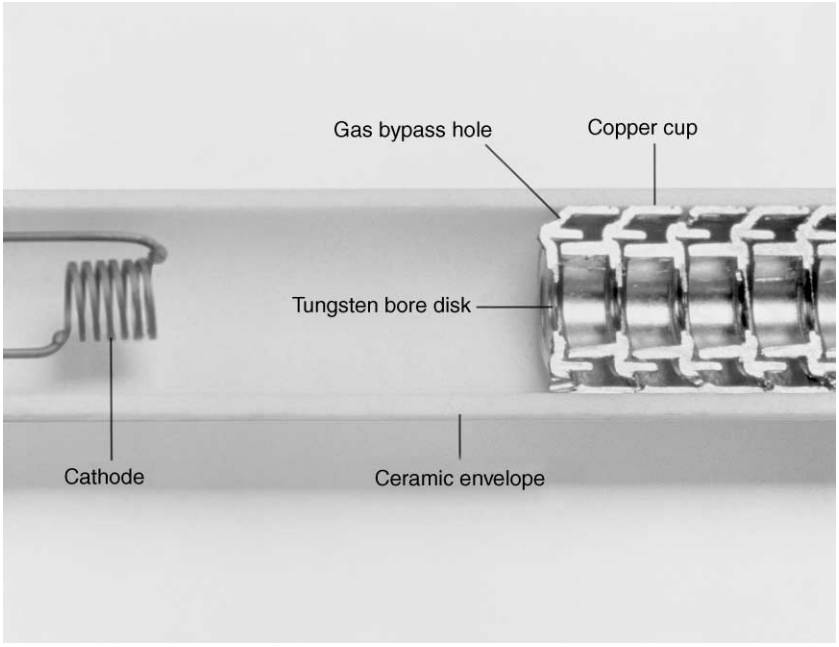

Figure 5 Discharge bore structure of a typical commercial high-power argon ion laser, the Coherent Innova™. Copper cups are brazed to the inner wall of a ceramic envelope, which is cooled by liquid flow over its outer surface. A thin tungsten disk with a small hole defining the discharge path is brazed over a larger hole in the bottom of the copper cup. Additional small holes in the copper cup near the ceramic envelope provide a gas return path from cathode to anode. Also shown is the hot oxide-impregnated tungsten cathode. an additional 20 eV. When these ions eventually hit the discharge walls near the location of the sheath, they have 40 eV of energy rather than the 20 eV from the normal wall sheath elsewhere in the small diameter discharge. Sputtering yield (number of sputtered wall atoms per incident ion) is exponentially dependent on ion energy in this low ion energy region, so the damage done to the wall in the vicinity of the 'throat' where the double sheath forms may be more than ten times that elsewhere in the small diameter bore region. This was the downfall of high-power operation of dielectric discharge bores, even BeO; while sputtering was acceptable elsewhere in the discharge, the amount of material removed in a small region near the discharge throat would cause catastrophic bore failure at that point. This localized increase in sputtering in the discharge throat is common to all

ion lasers, including modern cooled tungsten disk tubes. Eventually, disks near the throat are eroded to larger diameters, and more material is deposited on the walls nearby. Attempts to minimize localized sputtering by tapering the throat walls or the confining magnetic field have proven unsuccessful; a localized double sheath always forms somewhere in the throat. Because of the asymmetry caused by ion flow, the double sheath is larger in amplitude in the cathode throat than the anode throat, so that the localized wall damage is larger at the cathode end of the discharge than at the anode end.

Another undesirable feature of sputtering is that the sputtered material 'buries' some argon atoms when it is deposited on a wall. This is the basis of the well-known Vac-Ion® vacuum pump. Thus, the operating pressure in a sealed laser discharge tube will drop during the course of operation. In low-power ion lasers, this problem is usually solved by making the gas reservoir volume large enough to satisfy the desired operating life (for example, the large cathode can in Figure 4). In high-power ion lasers, the gas loss would result in unacceptable operating life even with a large reservoir at the fill pressure. Thus, most high-power ion lasers have a gas pressure measurement system and dual-valve arrangement connected to a small high-pressure reservoir to 'burp' gas into the active discharge periodically to keep the pressure within the operating range. Unfortunately, if a well-used ion laser is left inoperative for months, some of the 'buried' argon tends to leak back into the tube, with the gas pressure becoming higher than optimum. The pressure will gradually decrease to its optimum value with further operation of the discharge (in perhaps tens of hours). In the extreme case, the gas pressure can rise far enough so that the gas discharge will not strike, even at the maximum power supply voltage. Such a situation requires an external vacuum pump to remove the excess gas, usually a factory repair.

In addition to simple dc discharges, various other techniques have been used to excite ion lasers, primarily in a search for higher power, improved efficiency and longer operating life. Articles in the Further Reading section give references to these attempts. Radio-frequency excitation at 41 MHz was used in an inductively coupled discharge, with the laser bore and its gas return path forming a rectangular single turn of an air-core transformer. A commercial product using this technique was sold for a few years in the late 1960s. Since this was an 'electrode-less' discharge, ion laser lines in reactive gases such as chlorine could be made to oscillate, as well as the noble gases, without 'poisoning' the hot cathode used in conventional dc discharge lasers. A similar electrode-less discharge was demonstrated as a quasi-cw laser by using iron transformer cores and exciting the discharge with a 2.5 kHz square wave. Various microwave excitation configurations at 2.45 GHz and 9 GHz also resulted in ion laser oscillation. Techniques common to plasma fusion research were also studied. Argon ion laser oscillation was produced in Z-pinch and Θ-pinch discharges and also by high-energy (10–45 keV) electron beams. However, none of these latter techniques resulted in a commercial product, and all had efficiencies worse than the simple dc discharge lasers.

It is interesting that the highest-power output demonstrations were made in less than ten years after the discovery. Before 1970, 100 W output on the argon blue-green lines was demonstrated with dc discharges two meters in length. In 1970, a group in the Soviet Union reported 500 W blue-green output from a two-meter discharge with 250 kW of dc power input, an efficiency of 0.2%. Today, the highest output power argon ion laser offered for sale is 50 W output.

Manufacturers

More than 40 companies have manufactured ion lasers for sale over the past four decades. This field has now (2004), narrowed to the following:

Coherent, Inc.	http://www.coherentinc.com
INVERSion Ltd.	http://inversion.iae.nsk.su
JDS Uniphase	http://www.jdsu.com
Laser Physics, Inc.	http://www.laserphysics.com
Laser Technologies GmbH	http://www.lg-lasertechnologies.com

Optical fiber lasers were first demonstrated in the 1960s, and since then have developed to become versatile optical sources with many desirable properties. Aided by developments in associated technologies, such as fiber design and fabrication methods, semiconductor pump diode technology, and fiber-coupled and in-fiber components such as Bragg grating filters, optical fiber lasers now compete with other laser technologies in many applications, from telecommunications to materials processing.

An optical fiber laser is fundamentally an optical oscillator, which converts input pump power to coherent optical output power at one or more well-defined wavelengths. Optical oscillators require two basic elements: optical gain, and optical feedback. For sustained oscillation to occur the round-trip gain in the laser cavity must be unity, and the round-trip phase a multiple of 2π. In optical fiber lasers the optical gain is provided by an optical fiber amplifier using one or a combination of fundamental physical processes, e.g., stimulated emission, stimulated scattering, or nonlinear parametric processes. Early fiber amplifiers used stimulated Raman scattering to produce optical gain; however, rare-earth-doped fiber amplifiers, in which gain is provided by stimulated emission, are now more common. The reader is referred to **Optical Amplifiers:** Erbrium Doped Fiber Amplifiers for Lightwave Systems, for more details on doped fiber amplifiers, and to **Scattering:** Stimulated Scattering, **Nonlinear Optics, Applications:** Raman Lasers, **Optical Parametric Devices:** Optical Parametric Oscillators (Pulsed), and **Scattering:** Raman Scattering, for more details on stimulated scattering and parametric gain processes. Optical feedback may be provided in two fundamental ways, e.g., by using a closed ring of fiber, or from reflections from nonuniformities and discontinuities in the waveguide such as in Bragg grating filters or at fiber ends. The reader is referred to **Fiber Gratings** for more details on fiber Bragg gratings.

The main advantages of optical fiber lasers are derived from the confinement of the pump and signal in a small optical waveguide. In contrast with bulk lasers, the pump intensity in the fiber waveguide is largely independent of the laser length, resulting in large amplifier gain and low laser threshold, even for gain media with small absorption and emission cross-sections. The large gain enables lossy elements such as optical fiber-coupled devices and bulk optical elements to be incorporated into the laser cavity, providing additional control over the optical signal being generated. To obtain a large gain optical fiber amplifiers must usually be relatively long (i.e., from several centimeters to many meters), and so the linear and nonlinear properties of the fiber waveguide can have a significant influence on the optical signal being generated, resulting in some interesting and useful phenomena, e.g., as in soliton fiber lasers. The reader is referred to **Fiber and Guided Wave Optics:** Optical Fiber Cables, for fiber-based components, to **Fiber and Guided Wave Optics**: Dispersion, Light Propagation, and Nonlinear Effects (Basics), for a review of the linear and nonlinear properties of optical fibers, and to **Solitons:** Soliton Communication Systems, and Temporal Solitons, for the theory and applications of temporal solitons.

Whilst optical fibers may be fabricated in a range of materials, including polymer and crystalline materials, most fibers and fiber lasers are currently made of silica containing rare-earth ion dopants – see **Fiber and Guided Wave Optics:** Fabrication of Optical Fiber, for details. Lasers in silica optical fiber have much in common with other glass-host lasers, including a wide range of potential pump and lasing wavelengths, and broadband absorption and gain due to homogeneous and inhomogeneous broadening of the lasing energy levels in the amorphous glass host. For example, erbium-doped amplifiers in alumino-silicate glass fibers at room temperature have lasing transitions with homogeneous and

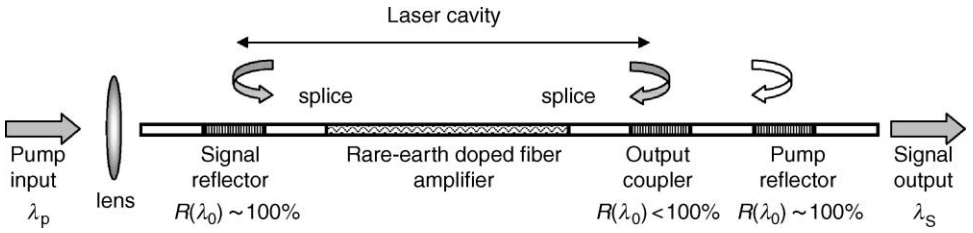

Figure 1 Example of a simple all-fiber optical oscillator. The rare-earth doped fiber provides optical gain, and the Bragg gratings provide narrowband optical feedback.

inhomogeneous linewidths of several nanometers, and can be optimized to provide around 30 dB gain over an 80 nm bandwidth centered around 1570 nm. The large gain-bandwidth is useful for achieving either wide tunability of the lasing wavelength and/or ultrashort pulse generation. Table 1 summarizes the most commonly used pump and signal transitions for a range of rare-earth dopants in silicate optical fibers.

Other desirable properties of silica fiber lasers include high efficiency, excellent thermal dissipation, substantial energy storage, high power capability, and compatibility with a wide range of optical fiber devices and systems. The characteristics of optical fiber lasers can be optimized for some very different applications, ranging from narrow linewidth and low-noise lasers to broadband pulsed lasers with high energy and/or high peak power. In the following sections the fundamentals of laser theory as applied to fiber lasers will be reviewed, highlighting the reasons underlying such versatility.

Fiber Laser Fundamentals

An example of a simple all-fiber laser is shown schematically in Figure 1. The laser contains the basic elements of optical gain (e.g., a rare-earth doped fiber amplifier) and optical feedback (e.g., a pair of Bragg grating filters). In the laser shown, the two Bragg gratings provide optical feedback only over a narrow range of wavelengths, which further restricts the range of possible lasing wavelengths. One grating must have a reflectivity less than unity to allow a proportion of the lasing signal to be coupled out of the laser cavity. At threshold, the gain in the amplifier exactly compensates for the loss in the output coupler.

The optical pump, typically from a semiconductor laser diode, is absorbed as is propagates along the fiber amplifier, e.g., by rare-earth ion dopants, which are raised to an excited state. The absorbed energy is stored and eventually emitted at a longer wavelength by either spontaneous or stimulated emission. Spontaneous emission produces unwanted noise and is associated with a finite excited state lifetime, whilst stimulated emission produces optical gain provided the gain medium is 'inverted', i.e., with more active ions in the upper lasing energy level than the lower lasing energy level. In practice some energy is also lost to nonradiative (thermal) emissions, e.g., in the transfer of energy between the pump and upper lasing energy levels. In an ideal gain medium the nonradiative transfer rate between the pump and upper lasing energy levels is much larger than the spontaneous or stimulated emission rates, so the inversion may usually be assumed to be independent of nonradiative transfer rates. Energy level diagrams for three- and four-level atoms are shown in Figure 2.

The local optical gain coefficient (i.e. power gain per unit length, in nepers[2]) in a fiber amplifier is proportional to the local inversion, i.e., $g(z) \sim \sigma_S \Delta N(z)$, where σ_S is the emission cross-section at the

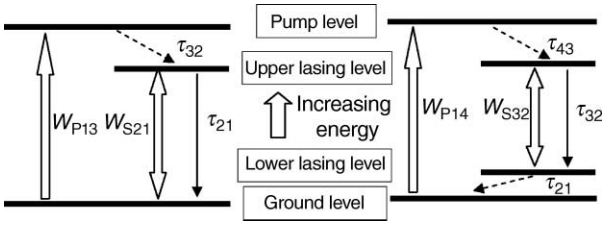

Figure 2 Energy level diagrams for three- and four-level laser transitions. *W* represents the probability of an optical transition per unit time associated with stimulated absorption or emission, and $1/\tau$ is the rate of spontaneous emission. Dotted lines represent nonradiative transitions (e.g., between the pump and upper lasing level).

signal wavelength, and $\Delta N(z)$ the difference in population density between the upper and lower lasing energy levels ($\Delta N > 0$ if the gain medium is inverted). The local inversion can be calculated by solving the rate equations including all stimulated and spontaneous transitions between the laser energy levels. The end-to-end amplifier power gain, $G = P_S(L_A)/P_S(0)$, in length L_A of amplifying fiber is then

$$G = \exp\left[\int_0^{L_A} g(z)\,\mathrm{d}z\right] \qquad [1]$$

which in decibels is

$$G = 4.34\int_0^{L_A} g(z)\,dz$$

A large gain coefficient is desirable for amplification with minimal added noise (i.e., low noise figure), and a large gain per unit pump power is desirable for low threshold lasing. For a given gain medium the only factor usually accessible to control the inversion and hence gain is the pump rate, i.e., the rate at which pump energy is absorbed by the gain medium, which for an unbleached amplifier is proportional to pump intensity. For example, in an ideal four-level unsaturated laser medium with uniform pump intensity, the small signal gain is approximately

$$\int_0^{L_A} g(z)\,\mathrm{d}z \approx \sigma_S \frac{P_{Pabs}\tau}{h\nu_P A} \qquad [2]$$

in which τ is the lifetime of the upper lasing level, P_{Pabs} is the pump power absorbed in the fiber amplifier with cross-sectional area A, h is Planck's constant, and ν_P is the pump frequency.

For a three-level laser under the same conditions, the small signal gain is

$$\int_0^{L_A} g(z)\,\mathrm{d}z \approx -\sigma_S N L_A + \sigma_S \frac{2P_{Pabs}\tau}{h\nu_P A} \qquad [3]$$

in which the first term corresponds to ground state absorption of the signal, in which N is the dopant ion density, and the factor of 2 in the second term is due to the fact that in an ideal three-level system every absorbed pump photon increases the inversion, ΔN, by two. Equation [3] can be approximated by multiplying [2] by the factor $(P_{Pabs} - P_{Psat})/(P_{Pabs} + P_{Psat})$, where $P_{Psat} = h\nu_P A/(\sigma_P\tau)$ is the pump power which must be absorbed to reduce the pump absorption coefficient to half its unpumped value (or the signal absorption coefficient to zero), and σ_P is the pump absorption cross-section. Unlike four-level lasers in which gain is available as soon as pump power is applied, three-level lasers require half the active ions to be excited before the inversion becomes positive and gain is produced.

The main advantages of optical fiber amplifiers are now clear; in an optical fiber waveguide the light is confined in a very small cross-sectional area, typically less than ten microns diameter. Consequently even a small coupled pump power can have a large intensity and produce a large gain coefficient, or low laser threshold. Even if the pump absorbed per unit length in the fiber amplifier is small (e.g., due to low dopant concentration or low absorption coefficient), this can often be compensated by using a long length of fiber with small intrinsic loss. Furthermore, rare-earth dopants have relatively long metastable state lifetimes, τ, which further assists in producing a large inversion throughout the fiber, and hence large overall gain or low lasing threshold, even at low pump powers. For example, a typical four-level neodymium doped fiber amplifier providing gain at $\lambda_S = 1.06\ \mu m$, pumped at $\lambda_P = 0.8\ \mu m$, with core diameter $7\ \mu m$, $\tau = 0.5$ ms, $\sigma_S = 1.4 \times 10^{-20}\ cm^2$, and $\sigma_P = 23 \times 10^{-21}\ cm^2$, could theoretically provide a small signal gain of 0.3 dB for every milliwatt of absorbed pump power.

Whilst the above analysis highlights the main advantages of fiber amplifiers, it is approximate in a number of respects. For example, eqns [2] and [3] assume both pump and signal have a uniform intensity distribution across the gain medium, and completely overlap. In single mode optical fibers the intensity distribution across the fiber core is not uniform but approximately Gaussian, with a width and effective area that depends on the numerical aperture of the waveguide and the wavelength. Consequently the overlap of the pump and signal beams with the doped fiber core and with each other is less than 100%, and the pump and signal intensities are higher in the center of the fiber than at the core-cladding boundary. The nonuniform distribution of pump and signal beams slightly modifies both the gain efficiency and gain saturation behavior

(i.e., the dependence of gain on signal power) in fiber amplifiers. More accurate analysis would also take into account factors such as the rare-earth dopant distribution (which may not be uniform), the variation of pump and signal intensities along the fiber, spectral variation in the absorption and emission cross-sections, spatial and spectral hole-burning in the gain medium, degeneracies in the energy levels, excited state absorption and other loss mechanisms, temperature, and spontaneous emission noise.

Continuous Wave Fiber Lasers

The ideal continuous wave (cw) laser converts input pump power with low coherence to a highly coherent optical output signal which is constant in amplitude and wavelength, with the spectral purity of the output (i.e., linewidth) limited only by cavity losses. Practical continuous wave lasers may be characterized by four parameters: the pump power required for the onset of oscillation (i.e., threshold); the conversion efficiency of pump to signal power above threshold; the peak wavelength of the optical output; and the spectral width of the optical output. Continuous wave fiber lasers often have a low threshold, high efficiency, and narrow linewidth relative to other types of laser. Output powers approaching 100 watts have been achieved using specialized techniques.

The threshold power is determined by the total cavity loss and gain efficiency (i.e., gain per unit of absorbed pump power) of the fiber amplifier. For example, for the laser shown in Figure 1 the internal losses are minimal, and the pump power required to reach threshold may be calculated by setting the product of the round-trip small-signal gain, and the output mirror reflectivity, G^2R, equal to unity. For the laser configuration shown in Figure 1, and using eqns [1] and [2] for a four-level laser, the pump power which must be absorbed in the amplifier for the laser to reach threshold is

$$P_{\text{th}} = \alpha_{\text{cav}} L_{\text{C}} \frac{h\nu_{\text{P}} A}{\sigma_{\text{S}} \tau} \qquad [4]$$

in which L_{C} is the cavity length, and $\alpha_{\text{cav}} = \alpha_{\text{int}} + \frac{1}{2} L_{\text{C}} \ln(1/R)$ is the total cavity loss per unit length, comprising both internal losses, α_{int}, and outcoupling losses through a mirror with reflectivity R. For example, if the internal losses were negligible and the transmittance, $T = 1 - R$, of the output reflector in the laser shown in Figure 1 was 50% (i.e. 3 dB), and the other fiber parameters were the same as above (i.e. $G = 0.3$ dB/mW), then the laser threshold would be 5 mW. In three-level fiber lasers ground state absorption of the signal is usually the dominant loss mechanism which must be overcome before a net gain is produced, and hence the threshold of three-level lasers is given approximately by eqn [4] with $\alpha_{\text{int}} = \sigma_{\text{S}} N L_{\text{A}} 2 L_{\text{C}}$, and increases with amplifier length. In either case the pump power required at the input of the laser to reach threshold, $P_{\text{P}}(0)$, may be approximated using the relation $P_{\text{Pabs}} = P_{\text{P}}(0) - P_{\text{P}}(L_{\text{A}}) \approx P_{\text{P}}(0)[1 - \exp(-\sigma_{\text{P}} N L_{\text{A}})]$.

For either three- or four-level lasers pumped above threshold, the inversion of the gain medium remains at its threshold level as the internal round-trip gain must remain unity; however a coherent optical output signal at the peak emission wavelength grows from noise until its amplitude is limited by saturation of the amplifier gain. Provided the output coupling loss is not too large (e.g., $T < 60\%$) such that the total signal intensity is constant along the whole length of the fiber amplifier, it can be shown that changes in pump power above threshold cause a proportional change in the signal power coupled out of the Fabry–Perot cavity in one direction, P^{+}_{Sout}, i.e.

$$P^{+}_{\text{Sout}} = \frac{(1-R)}{\delta_0} \frac{\nu_{\text{S}}}{\nu_{\text{P}}} (P_{\text{Pabs}} - P_{\text{th}}) \qquad [5]$$

in which $\delta_0 = 2\alpha_{\text{int}} L + \ln 1/R$ represents the total round-trip loss at threshold. The relationship between absorbed pump power and output signal power is shown schematically in Figure 3. The constant of proportionality is known as the slope or conversion efficiency, defined as $\eta_{\text{S}} = P_{\text{Sout}}/(P_{\text{Pabs}} - P_{\text{th}})$. In both three- and four-level fiber lasers with small intrinsic losses $\alpha_{\text{int}} \approx 0$, and small output coupling (i.e., $R \approx 1$), the slope efficiency can approach the intrinsic quantum efficiency, $\nu_{\text{S}}/\nu_{\text{P}}$.

Sustained oscillation can only occur if the optical path length around the cavity is an integral number of wavelengths. Wavelengths satisfying this condition are called 'modes' of the cavity, determined by

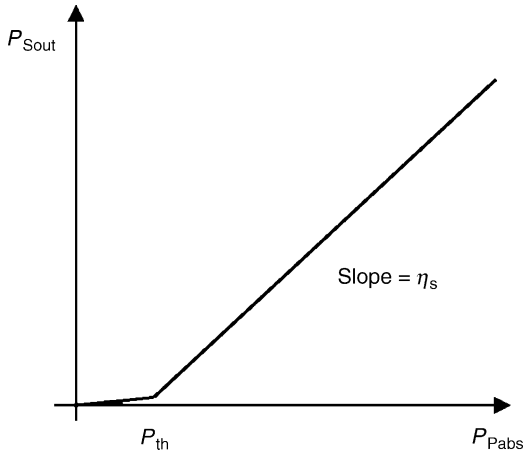

Figure 3 Representative plot of laser output power versus absorbed pump power.

$2nL_C = m\lambda_0$, where n is the effective refractive index seen by light propagating in the cavity, L_C is the cavity length, m is an integer, and λ_0 is the free-space wavelength. In Figure 1, the cavity length comprises the amplifying fiber, and two Bragg grating filters which may be regarded as having an effective length (i.e., less than the actual grating length) which depends on the grating characteristics. In fiber lasers the cavity is typically between several centimeters and many meters in length, hence there are usually very many potential lasing modes within the gain-bandwidth of the amplifying medium. For example, in the Fabry–Perot cavity of Figure 1, if the cavity length was 5 meters, the mode spacing would be $\nu_{m+1} - \nu_m = c/(2nL_C) = 20$ MHz, i.e. orders of magnitude less than the bandwidth of the optical amplifier.

Ideally the first mode to reach threshold would determine the laser output wavelength and the spectral width, or linewidth, of the laser output would be $\Delta\nu_L = h\nu/(2\pi\tau_C^2 P_{Sout})$, in which τ_C is the lifetime of photons in the cavity and determined by cavity losses, including outcoupling, and given by $\tau_C = t_R/\varepsilon$, where t_R is the cavity round trip time and ε the fractional energy loss in the cavity per round trip. In practice, the linewidth is usually significantly larger than the latter theoretical limit due to transient lasing of different modes within the bandwidth of the optical amplifier and environmental perturbations to the fiber cavity. Fiber amplifiers typically have a large homogeneously broadened gain-bandwidth, and being long and flexible are susceptible to acoustic and thermal perturbations, hence care must be taken to physically stabilize the laser cavity to minimize both mode-hopping and the output linewidth.

Whilst the CW laser shown in Figure 1 has the advantage of simple construction, it would not be ideal for narrow linewidth CW generation. The reason is that counterpropagating waves in the Fabry–Perot cavity form a standing wave, i.e., in which the local signal intensity varies due to interference between forward and backward propagating waves. The standing wave can cause spatial hole-burning in the gain medium (i.e., a spatial variation in gain, linked to the spatial variation in intensity) which in turn reduces the average gain for the lasing mode and promotes mode-hopping and hence spectral broadening of the output.

A preferable arrangement for many fiber lasers is a traveling wave laser, which can be realized using a ring configuration, as shown in Figure 4. In this configuration the optical isolator ensures unidirectional lasing and avoidance of spatial hole-burning. Additional components in the cavity can include a wavelength selective coupler (WSC), i.e., to couple the pump wavelength into the laser cavity whilst not coupling the signal wavelength out, and a narrowband filter (e.g. a small Fabry–Perot resonator) to further stabilize and/or narrow the lasing linewidth. Rare-earth doped fiber lasers with similar cavity configurations have been realized with linewidths of approximately 10 kHz, limited by environmental (e.g., acoustic) perturbations.

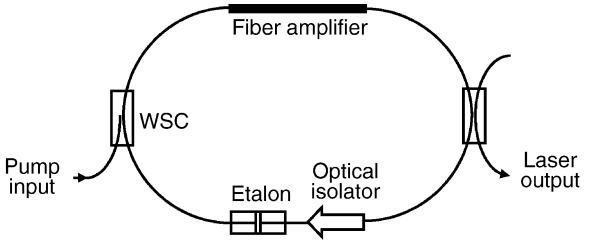

Figure 4 Schematic of a traveling wave laser, useful for low noise continuous wave oscillation. The wavelength selective coupler (WSC) is required to couple pump power into the laser cavity without coupling signal out.

Pulsed Fiber Lasers

There are two main types of fiber laser useful for generating short high-power pulses: Q-switched lasers, and mode-locked lasers. Q-switched fiber lasers are useful for generating large energy pulses (e.g., microjoules) with very high peak power (e.g., kilowatts) with relatively long pulse duration (e.g., tens of nanoseconds), whilst mode-locked fiber lasers are typically capable of generating ultrashort pulses (e.g., sub-picosecond) with moderate energy (e.g., nanojoules) and moderate-to-high peak power (e.g., tens of watts). Pulsed lasers typically produce less average output power than CW lasers (e.g., up to about 10 W). Both types of pulsed laser typically contain an element for loss modulation within the cavity, however the pulse generation mechanisms are very different.

Q-switched lasers operate by rapid switching of the cavity loss. Whilst the intracavity loss is high and the laser below threshold, energy is transferred from the pump to the lasing medium. The long excited state lifetime and small emission cross-sections of rare-earth dopants assists greatly in the latter process, so that a significant amount of energy can be stored in long fiber amplifiers before amplification of spontaneous emission noise begins to deplete the inversion. After the gain medium is fully inverted the cavity loss is suddenly reduced, and the laser is taken well above threshold, resulting in a rapid build-up of noise and the formation of a pulse which ideally extracts all the stored energy within a few round-trips in the laser cavity. The situation is shown schematically in Figure 5.

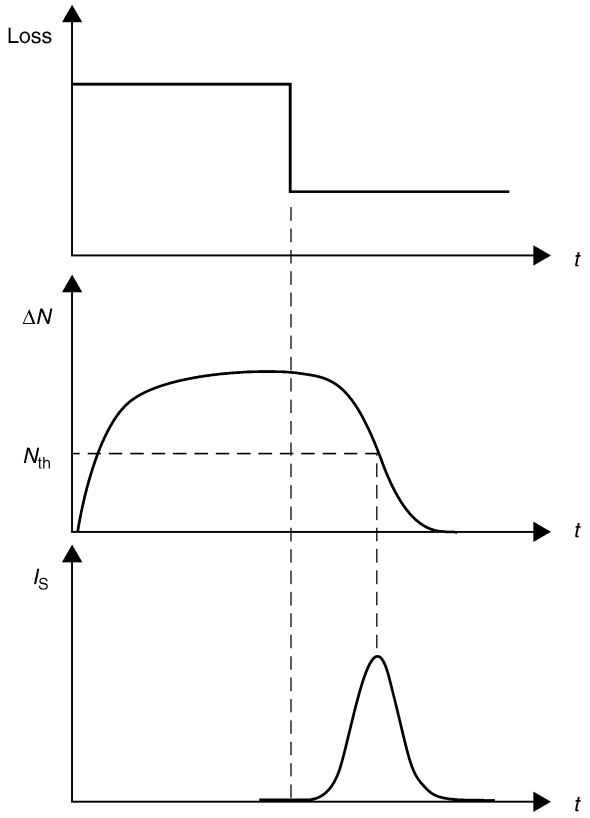

Figure 5 Pulse generation in a *Q*-switched laser. Initially the intracavity loss is high, the laser remains below threshold, and the inversion of the gain medium increases. When the intracavity loss is suddenly reduced, the laser goes well above threshold and spontaneous emission noise is rapidly amplified into a large pulse which extracts much of the energy previously stored in the gain medium.

An upper limit on the pulse energy obtainable from a *Q*-switched laser may be determined by assuming all active ions in the laser cavity are excited before the pulse is generated (i.e., at the time the cavity Q is switched high), that no ions remain excited immediately after the pulse is generated, and that the pulse generated is much shorter than the time required to pump all the ions into their excited state. The energy stored in the gain medium, and hence the maximum conceivable pulse energy, would then be $E = h\nu_S NV$, where N is the density of active ions and V is the cavity volume. For example, a typical erbium-doped fiber laser of length 10 m and dopant density $N = 10^{19}$ ions/cm in a single-mode fiber with core diameter 7 μm could ideally store up to 500 μJ of energy.

Two things limit the maximum inversion and energy storage achievable in practice: spontaneous emission noise (due to the finite excited-state lifetime) which is amplified and depletes the inversion, and unwanted feedback (e.g., due to the finite extinction ratio of the Q-switching element) which results in cw lasing which limits the inversion. Following from eqns [1] and [2], the unidirectional gain per unit of stored energy in a fiber laser may be expressed as $G = 4.34/(A_{core}F_{sat}) = 4.34/E_{sat}$ decibels per joule, where $F_{sat} = h\nu_S/\sigma_S$ is the saturation fluence, and $E_{sat} = A_{sat}F_{sat}$ is the saturation energy. For example, if the maximum gain achievable before the onset of cw lasing was 30 dB (i.e., even when the Q-switch introduces a large loss), then the maximum energy storable in the gain medium would be $E = 6.9E_{sat}$. For the same erbium-doped fiber parameters as used in the previous paragraph, the maximum storable energy would be $E \approx 70$ μJ.

Only a proportion of the energy stored in the gain medium may usually be converted into a Q-switched output pulse. The actual Q-switched pulse energy, duration, and peak power can be calculated by solving the rate equations for the photon flux and the population difference between the lasing energy levels in the gain medium. The equations must usually be solved numerically, however assuming the Q changes much more rapidly than the pulse build-up time, which is in turn much shorter than the time taken for a significant change in inversion to either pumping or spontaneous emission, the pulse parameters may be approximated analytically and are found to be determined by only two parameters, i.e., the population inversion (or stored energy) just before Q-switching, and the lifetime of photons within the cavity, τ_C, defined previously.

Under the conditions described above, standard analysis gives the Q-switched pulse duration as

$$T_P \approx \frac{\tau_C(r-1)}{(r-1-\ln r)} \qquad [6]$$

where r is the ratio of the inversion just before Q-switching (low Q) to the threshold inversion for cw lasing after Q-switching (Q high). In fiber lasers the gain can be very high, hence it is common for $r \gg 1$ and almost all available energy stored in the gain medium is extracted as a Q-switched laser pulse. The Q-switched pulse duration is then determined primarily by the cavity lifetime; shorter pulses can be obtained only by shortening the laser cavity and/or increasing the cavity loss. For example, for a 10 m long ring cavity in which the sum of cavity and outcoupling losses is 10 dB and $r \gg 1$, the pulse duration would be $T_P\tau_C = 22$ ns.

The exact proportion of energy stored in the gain medium that is converted to a Q-switched pulse depends on the number of energy levels in the lasing medium, the degeneracy of those levels, and the rate

of nonradiative energy transfer between those levels. For example, for an ideal three-level gain medium (e.g., erbium dopant) with no internal cavity losses the maximum available Q-switched pulse energy is half the stored energy, or $E_{\text{pulse}} = E/2$. It can be shown that the peak of the output pulse power occurs as the inversion decreases through threshold, and may be approximated by dividing the pulse energy by the pulse duration. Even for moderate pulse energies the peak power is potentially very high. For the erbium-doped fiber laser parameters used previously, the peak pulse power would be approximately 1600 W, i.e., sufficient to cause significant spectral broadening of the output wavelength due to stimulated Raman scattering and other nonlinear effects within the optical fiber.

Mode-locked lasers generate optical pulses by forcing many cavity modes to be locked in phase. As per Fourier theory, the pulse repetition rate is related to the spacing of the lasing modes, and the more modes that add coherently, the greater the pulse bandwidth and the shorter the transform-limited pulse duration. For example, the relationship between mode spacing and pulse repetition rate, and between the spectral and temporal envelopes of a train of Gaussian pulses is shown in Figure 6.

In mode-locked lasers a nonlinear or time-varying element must be present which synchronously modulates the optical signal circulating in the cavity in amplitude or phase at a frequency which is a harmonic of the cavity mode spacing. There are two main methods of mode locking:

(i) active mode locking (e.g., by an electro-optic modulator), in which amplitude or phase modulation is driven by an external source; and
(ii) passive mode locking (e.g., by a fast or slow saturable absorber), in which an element with nonlinear gain or loss responds to the optical signal in the laser cavity itself.

In both cases the modulation provided by the mode-locking element distributes energy between neighboring modes, effectively injection-locking them in phase. A variation of mode locking techniques often present in fiber lasers is soliton mode-locking, in which the active or passive modulation is weak, and a balance between nonlinearity and dispersion is the dominant process underlying pulse formation. Hybrid mode-locking techniques can also be used to combine the best aspects of different pulse-generation methods.

Whilst the latter frequency-domain view of mode locking is helpful, nonlinear effects are almost always significant in mode-locked fiber lasers, and hence the linear concept of a mode is not appropriate for detailed analysis. Hence it is usually preferable to describe pulse generation in mode-locked fiber lasers in the time domain; for stable operation the pulse at any point in the cavity must self-replicate after each round-trip, with the net effects of temporal and spectral loss, gain, dispersion and nonlinearity all canceling.

An optical pulse propagating in a fiber laser is usually described by a slowly varying complex envelope, $\Psi(z,t)$, where $|\Psi(z,t)|^2$ is the instantaneous power in a frame of reference moving at the pulse group velocity, and $\arg[\Psi(z,t)]$ is the instantaneous phase relative to the optical carrier. The various elements in the laser cavity, such as the passive fiber, optical fiber amplifier, filters, and mode-locking devices, each modify the complex pulse envelope as it propagates around the laser cavity.

For example, in the absence of other effects, group velocity dispersion (GVD) causes different wavelengths to travel at different velocities along the fiber, resulting in 'chirping' and temporal broadening of optical pulses by an amount proportional to the distance propagated. The effect can be described mathematically as the accumulation of a phase shift which is quadratic in frequency, i.e., $\Psi(z,\omega) = \Psi(0,\omega)\exp[i\beta_2\omega^2 z/2]$. Taking the derivative with respect to propagation distance, and using $\partial/\partial t = -i\omega$, the incremental change in the complex envelope

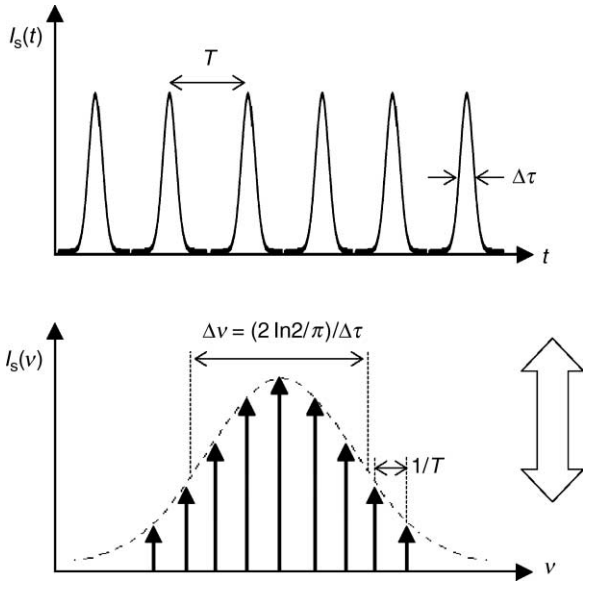

Figure 6 Schematic showing the Fourier-transform relationship between an infinite train of Gaussian pulses and the lasing modes in a mode-locked laser. The temporal and spectral widths are measured full width at half the maximum intensity.

with propagation distance is

$$\frac{\partial \Psi}{\partial z} = -\mathrm{i}\frac{\beta_2}{2}\frac{\partial^2 \Psi}{\partial t^2} \qquad [7]$$

If the GVD parameter, β_2, is positive then long wavelengths propagate faster than shorter wavelengths, and the dispersion is called 'normal'. If the reverse is true, the dispersion is 'anomalous'. In standard single-mode step index optical fibers the dispersion passes through zero at wavelengths around 1300 nm, and is anomalous for longer wavelengths. It is often necessary to control the net dispersion in a fiber laser, and this can be done by incorporating specially designed fibers with wavelength-shifted or otherwise modified dispersion characteristics, or by using chirped Bragg grating reflectors.

Whilst silica is not commonly regarded as a nonlinear medium (i.e., in which the optical properties are a function of the intensity of light), in ultrashort pulsed fiber lasers the peak powers are usually such that nonlinear effects cannot be ignored. In silica the main nonlinearity is associated with the Kerr effect, and is readily observed as an intensity-dependent refractive index, i.e. $n = n_0 + n_2 I$, where the nonlinear index, n_2, is typically about 3×10^{-20} m^2/W in silica fibers. Other nonlinear effects related to the Kerr nonlinearity which can sometimes be important are cross-phase-modulation and four-wave mixing. In the absence of other effects, the nonlinear index results in self-phase modulation (SPM), or a phase shift in the optical carrier which is proportional to the instantaneous intensity of the signal. Mathematically, $\Psi(z,t) = \Psi(0,t)\exp[\mathrm{i}\gamma|\Psi(0,t)|^2 z]$, in which $\gamma = n_2\omega_0/(cA)$ is the nonlinear coefficient of the fiber, ω_0 is the radian frequency of the optical carrier, and A is the effective core area for the guided mode. The incremental change per unit length in the complex pulse envelope induced by self-phase modulation is then

$$\frac{\partial \Psi}{\partial z} = \mathrm{i}\gamma|\Psi|^2\Psi \qquad [8]$$

For example, self-phase-modulation is used to realize a nonlinear switching element in the passively mode-locked laser cavity shown schematically in Figure 7. For obvious reasons the laser is called a 'figure-8' laser, though it is actually a ring laser into which a device known as a nonlinear amplifying loop-mirror (NALM) has been incorporated. The NALM acts as a fast saturable absorber, with transmittance dependent on the instantaneous optical intensity. The NALM operates as follows: light propagating through the optical isolator is divided equally into co- and counter-propagating waves in the loop-mirror on the right-hand side. The light propagating in a clockwise direction is amplified immediately, and propagates around the loop with high intensity, whilst the counter-clockwise propagating signal has a low intensity for most of its time in the loop. The difference in intensity means that the co- and counter-propagating waves experience different nonlinear phase shifts. When they are recombined at the coupler, high-intensity light is transmitted back into the ring, whilst low-intensity light is reflected back to the isolator, and lost. In this way the NALM provides both gain and a nonlinear transmittance which depends on the instantaneous power of the input, described by

$$T \approx G\left\{1 - \frac{1}{2}\left[1 + \cos\left(\frac{1}{2}\gamma L P_{\mathrm{in}} G\right)\right]\right\} \qquad [9]$$

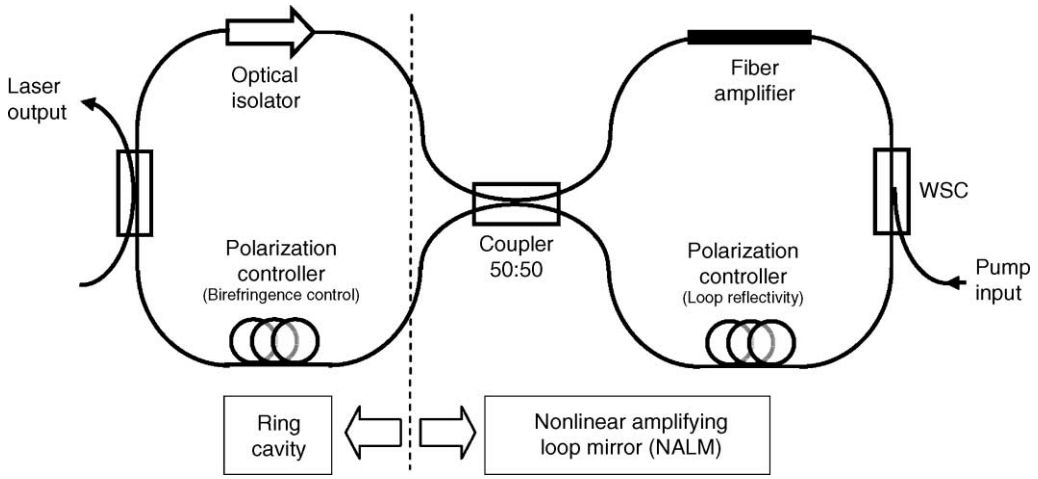

Figure 7 Schematic of a 'figure-8' fiber laser. The laser is passively mode-locked by the nonlinear amplifying loop mirror on the right, which acts as a fast saturable absorber, transmitting and amplifying high-power optical signals whilst reflecting low optical power signals.

in which G is the linear gain of the amplifier, and L the loop length, P_{in} is the input power, and T the ratio of transmitted power to input power. The nonlinear transmittance of the NALM promotes pulse formation and shortening in the laser cavity, and hence passively mode-locks the laser. The polarization controllers are to compensate for unwanted birefringence in the optical fiber, and to control the transmittance of the loop-mirror at low input powers. The fiber dispersion and nonlinearity, together with other factors, further influence the pulses generated in the laser, as described in the following paragraphs.

The combined effects of dispersion and self-phase-modulation can give rise to some interesting and useful physical phenomena. In lossless optical fibers, or fiber lasers in which loss is balanced by gain, pulse propagation is described by the nonlinear Schrödinger equation (NLSE), i.e., a nonlinear wave equation including the effects of both group velocity dispersion and intensity-dependent refractive index. The NLSE may be derived by combining eqns [8] and [9], i.e.

$$\mathrm{i}\frac{\partial \Psi}{\partial z} - \frac{\beta_2}{2}\frac{\partial^2 \Psi}{\partial t^2} + \gamma|\Psi|^2\Psi = 0 \qquad [10]$$

It can be shown that if the dispersion is anomalous ($\beta_2 < 0$) then for a particular shape of pulse envelope the distributed effects of dispersion and nonlinearity can exactly cancel, so $\partial\Psi/\partial z = 0$, and the pulse propagates without changing shape. Such pulses are called fundamental solitons, the solution for which is $\Psi(z,t) = \Psi_0\,\mathrm{sech}(t/T_0)\exp[\mathrm{i}z/(2L_D)]$, in which the peak amplitude is $\Psi_0 = 1/\sqrt{\gamma L_D}$, T_0 is the pulse width parameter, and $L_D = T_0^2/\beta_2$ is known as the dispersion length. For example, in a standard silica fiber at $\lambda = 1.55\ \mu\mathrm{m}$, $\beta_2 \approx -20\ \mathrm{ps}^2/\mathrm{km}$ and $\gamma \approx 10\ \mathrm{W}^{-1}\mathrm{km}^{-1}$, hence a soliton with $T_0 = 1$ ps would have peak power 2 W and energy $E_0 = 2|\beta_2|/(\gamma T_0) = 4$ pJ. The energy of a soliton is quantized, in that pulses with initial energy between 0.5 and 1.5 times E_0 can evolve into a fundamental soliton during propagation. Consequently solitons behave somewhat like particles, and are robust even in the presence of significant perturbations. The pulses which form spontaneously in the figure-8 fiber laser have many of the properties of solitons.

Mode-locked fiber lasers, such as that shown in Figure 7, can often be described by a generalized nonlinear Schrödinger equation, in which extra terms are included in eqn [10] to account for the average effects of an excess linear gain or loss, nonlinear gain and loss (e.g., due to a saturable absorber), spectral filtering, and temporal modulation, etc. Assuming the effects of the added elements can be regarded as distributed over the length of the cavity rather than lumped, such that the envelope of any pulse generated in the laser does not change shape significantly as it propagates around the cavity, then the master differential equation describing propagation of an optical signal within a fiber laser which is passively mode-locked by a fast saturable absorber can be written

$$\mathrm{i}\frac{\partial U}{\partial \zeta} + \left(\frac{D}{2} - \mathrm{i}\beta\right)\frac{\partial^2 U}{\partial \tau^2} + (1 - \mathrm{i}\varepsilon)|U|^2 U = \mathrm{i}\delta U - (\nu - \mathrm{i}\mu)|U|^4 U \qquad [11]$$

Equation [11] is known as the Ginzburg–Landau equation, which describes propagation of the normalized pulse envelope, $U(\zeta, \tau)$, as a function of delayed time, τ, and normalized distance, ζ, and under the combined influence of group velocity dispersion ($D = \pm 1$ for anomalous or normal group velocity dispersion, respectively), dispersion due to band-limiting by amplification in a homogeneously broadened gain medium ($\beta > 0$), nonlinear refractive index, nonlinear gain or loss (ε), linear gain (δ), and quintic terms, μ and ν, which if less than zero relate to saturation of the nonlinear gain and refractive index, respectively. Note that if the right-hand side of the equation is set to zero, and $\varepsilon = \beta = 0$, then the equation reduces to the normalized form of the nonlinear Schrödinger equation. Stable pulses generated within the laser are solutions of the above equation with $\partial U/\partial\zeta = 0$, and hence the effect of all terms must balance. Consequently it is possible for stable pulses to be generated even with normal dispersion in the cavity, though the pulses are then generally strongly chirped, and have an envelope which is approximately Gaussian shaped rather than the hyperbolic secant shape expected with anomalous dispersion. Stable soliton-like pulses can be found by solving the Ginzburg–Landau equation for specific ranges of parameters. There are many numerical solutions, and some analytical solutions, but in general the dynamics of pulse formation and propagation in passively mode-locked fiber lasers can be quite complex, and for some sets of parameters remarkable and unexpected numerical solutions can be found. One such example which has been observed experimentally is the 'exploding' soliton, which unlike the usual soliton is periodically unstable, as shown in the plot of pulse evolution in Figure 8.

Other Fiber Lasers

The lasers discussed in the previous sections are indicative of the main types of fiber laser in terms of their output characteristics; however it should be

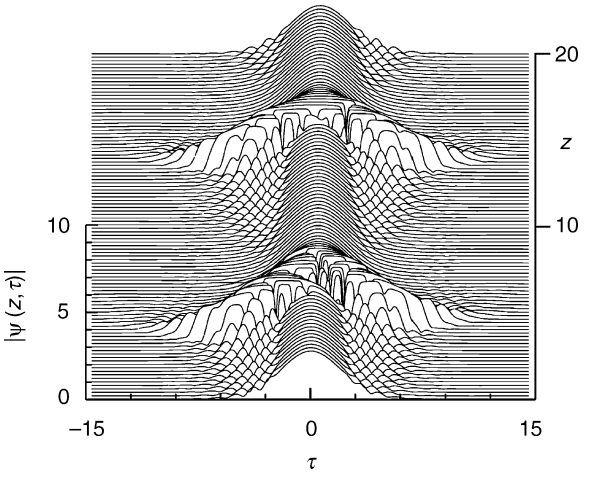

Figure 8 Two periods of the evolution of an exploding soliton found by numerical solution of the quintic Ginzburg–Landau equation with normalized parameters $\varepsilon = 1.0$, $\delta = 0.1$, $\beta = 0.125$, $\mu = 0.1$, and $\nu = 0.6$. The process never repeats itself exactly in successive 'periods'; however the pulse always returns to the same shape. Such solutions cannot be found in analytic form; nevertheless they are as common as stationary pulse solutions and exist for a wide range of parameters.

noted that there is a wide range of other fiber laser configurations with similar behaviors incorporating a variety of other fiber and/or bulk elements. For example, specially designed fibers in which the pump and/or signal has a large cross-sectional area can be used to realize fiber lasers with a high output power, comparable to that in many bulk laser systems. Linear and/or nonlinear processing of the output of fiber lasers can be used to increase their peak output power and/or pulse energy, or to change their output wavelength (i.e., by harmonic generation) from that achievable in the laser cavity itself. In mode-locked fiber lasers it is now common to include passive semiconductor devices which provide a slow saturable absorber action to initiate and stabilize soliton mode-locking.

It should also be noted that there are a number of fiber lasers which generate optical outputs using different or modified physical processes compared to those described in previous sections. For example, it is possible to realize up-conversion fiber lasers in which the output wavelength is shorter than the pump wavelength, multiwavelength fiber lasers (pulsed and cw) which produce outputs at several wavelengths simultaneously, and lasers with limited output coherence such as chaotic fiber lasers and broadband superfluorescent sources, etc. Lastly, whilst the rare-earth doped fiber lasers dealt with in previous sections have some very desirable properties, it should be recognized that optical fiber lasers based on other optical gain mechanisms, such as stimulated scattering and parametric effects, can also be realized (e.g., as in fiber Raman lasers, and fiber Brillouin lasers). In the latter cases the lasing wavelength is limited only by available pump wavelengths. The reader is referred to the references in the Further Reading for information on the wide range of fiber lasers that are possible in practice.

List of Units and Nomenclature

Absorption cross-section	σ_a	$[m^{-2}]$
Amplifier length	L_A	[m]
Area	A	$[m^2]$
Cavity length	L_C	[m]
Complex amplitude	Ψ	$[W^{0.5}]$
Dispersion length	L_D	[m]
Distance	z	[m]
Emission cross-section	σ_e	$[m^{-2}]$
Frequency	ν	[Hz]
Gain coefficient	g	$[m^{-1}]$
Group velocity dispersion	β_2	$[s^2m^{-1}]$
Inversion ratio	r	
Lifetime	τ	[s]
Loss coefficient	α	$[m^{-1}]$
Nonlinear coefficient	γ	$[m^{-1}W^{-1}]$
Nonlinear refractive index	n_2	$[m^2W^{-1}]$
Number density	N	$[m^{-3}]$
Power gain	G	
Pump power	P_P	[W]
Pump wavelength	λ_P	[m]
Reflectivity	R	
Saturation energy	E_{sat}	[J]
Saturation fluence	F_{sat}	$[J.m^{-2}]$
Signal power	P_S	[W]
Signal wavelength	λ_S	[m]
Threshold power	P_{th}	[W]

Organic Semiconductors and Polymers

Introduction

Organic semiconductors, and conjugated polymers in particular, are emerging as an interesting new class of visible laser media. The polymers are electroluminescent, broadband visible emitters and exhibit large optical gain coefficients. As plastics, they are amenable to simple processing, and can be shaped into complex structures. This combination of photonic, electronic, and processing properties make these materials extremely well suited to forming novel microlasers, with future prospects as inexpensive, plastic diode lasers operating throughout the visible spectrum.

Conjugated Polymers

Plastics are widely used in low-cost optical components such as lenses, diffraction gratings, optical fibers, and adhesives. Their common use derives from a combination of qualities: good optical transmission, a wide range of mechanical properties and simple fabrication via molding: extrusion or solution processing. Functional optical polymers, including liquid crystals and photorefractives, have also been widely applied to polarization control and for nonlinear- and electro-optics. Conjugated polymers are a remarkable class of functional plastics that exhibit some unusual properties. Firstly, they are plastics that can conduct electricity; and in fact are electrically semiconducting. Secondly, they are plastics that can be stimulated either optically or electrically to emit visible light.

These two unusual properties derive from a particular chemical structure specific to this family of plastics. In all conjugated polymers, the backbone of the molecule is a chain of carbon atoms joined by alternating single and double covalent bonds. The simplest example is illustrated in **Figure 1a**, which shows the chemical structure of the polymer poly(acetylene). Structural integrity of the polymer is provided by a string of single σ-bonds between adjacent carbon atoms. The additional bonding electrons in the double bonds are located in π-orbitals oriented perpendicular to the polymer chain. Adjacent π-orbitals overlap, and their electrons can be widely delocalized along the polymer backbone. The delocalized electrons can move relatively freely along the chain, giving the electronic properties of the material. The π-orbitals can be transformed between bonding and anti-bonding states by the absorption or emission of light, leading to strong optical transitions. While poly(acetylene) is a very inefficient light emitter, other conjugated polymers, notably those that include phenyl rings in the backbone (**Figure 1b–d**), can be highly emissive. Photoluminescence quantum

efficiencies, approaching unity in solution and as high as 60% in the semiconducting solid state, have been realized.

Organic Semiconductor Lasers

While organic dye lasers have been widely used since the mid-1960s, the history of organic semiconductor lasers is much more recent. Other than a few early observations of lasing in molecular crystals in the 1970s by Karl and others, the field of organic semiconductor lasers began in earnest following the related discovery in 1990 by Burroughes *et al*. of electroluminescence in a conjugated polymer. In 1992, Moses demonstrated lasing for the first time in a solution of the conjugated polymer MEH-PPV (Figure 1b). However, it was another four years – once material synthesis had been sufficiently refined – before stimulated emission and then true laser action were observed in polymers in the semiconducting solid state. In the following year the first demonstrations were made of dye-doped small molecular semiconductor lasers. Since that time, there has been a great growth in interest in the field with an average of ~30 research papers per year. Further details of the development of the field of organic semiconductor lasers can be found in the Further Reading.

So what are the particular properties of conjugated polymers that have stimulated interest in developing organic semiconductor lasers? Firstly these materials are broadband visible emitters. Through appropriate chemical design, their emission can be tuned throughout the visible spectrum, from 400 nm to 700 nm (Figure 2). The polymers exhibit large optical gain coefficients, because the optical transitions are dipole-allowed. Compared with small molecular dyes, polymers exhibit a relatively low degree of self-absorption of the emitted light, and much reduced quenching of the luminescence with increased concentration. This means that it is possible to work with much higher chromophore densities than conventional laser dyes, which is advantageous for achieving very low threshold lasing in extremely compact resonators. Furthermore, because these materials are semiconducting, they have the potential for direct electrical excitation. This could lead to semiconductor diode lasers operating throughout the visible spectrum and, in particular, in the blue and green spectral bands where currently there are few commercially viable inorganic semiconductor sources. Finally, these materials are plastics and so are amenable to simple processing, and can be shaped and structured into complex feedback resonators.

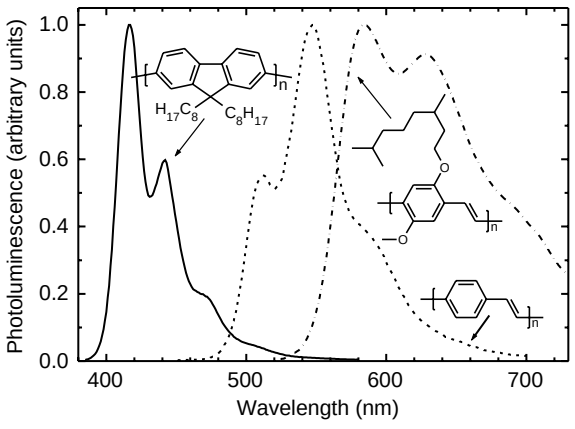

Figure 2 Photoluminescence spectra of three commonly used conjugated polymers; chemical structures inset.

Organic Semiconductor Gain Materials

A great advantage of organic laser media is that a very wide range of materials can be readily synthesized, and through minor changes in the molecular structure one can relatively simply tune the emission properties of the material. Many different organic semiconductors have been applied as lasers, though they fall into three major categories. These are conjugated polymers, dye-doped small molecular semiconductors, and molecular single crystals. Conjugated polymers make up the most diverse materials set, most notably including derivatives of poly(paraphenylene-vinylene), poly(paraphenylene), and poly(fluorene) (Figure 1b–d). The second category comprises small molecular semiconductors that are co-evaporated under vacuum with a dopant laser dye. In this blend of materials, the organic semiconductor functions simply as an energy transfer host for the emitting dye molecules. In the third category are organic single crystals, including materials such as polyacenes and thiophene oligomers. These materials have the advantage of having the highest electrical mobilities of any organic semiconductors, which is important for electrical excitation. However, they can be demanding to grow into high-quality single crystals, and so lack the key processing advantages of the other families of organic semiconductors.

Figure 3a shows a typical exciton energy level structure of a semiconducting polymer. Similar to a conventional laser dye, the energy levels comprise a manifold of singlet states and a manifold of triplet states, each with vibrational sublevels. The laser transition occurs from the bottom of the first excited singlet state S_1 to the vibronic overtones of the ground

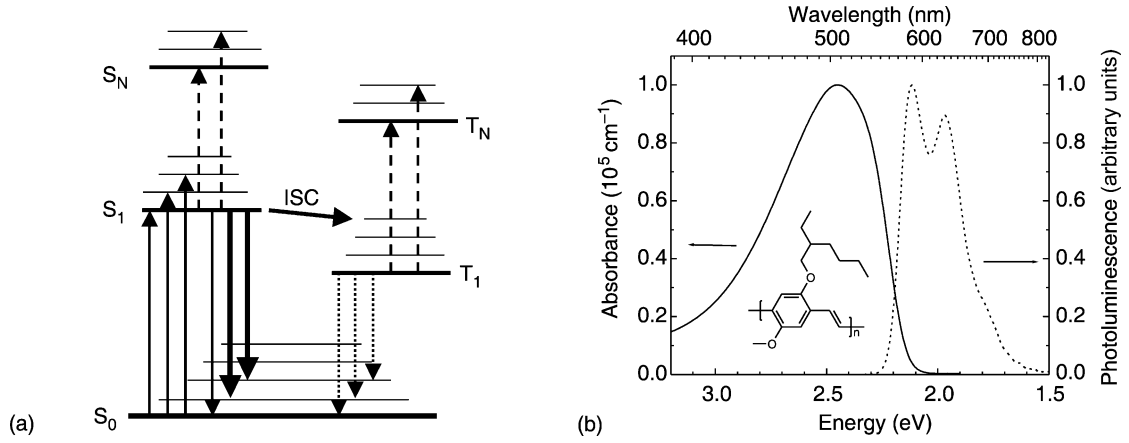

Figure 3 (a) Generic energy level structure and optical transitions of a conjugated polymer. S_N refers to the Nth singlet state; T_N refers to the Nth triplet state; ISC: intersystem crossing. (b) Absorption and photoluminescence spectra of the polymer MEH-PPV.

state S_0, so forming a classic 4-level laser system. The optical transition is dipole-allowed and so has a high oscillator strength. As a result, conjugated polymers typically exhibit simulated emission cross-sections in the range 10^{-16} cm^2 to 10^{-15} cm^2, while the population inversion lifetime is as short as a few hundred picoseconds.

There are, however, several other transitions that can compete with the stimulated emission process. There can be excited-state absorption from the S_1 singlet state into higher-lying singlet states. Additionally intersystem crossing from the S_1 state to the lowest excited triplet state T_1 can subsequently lead to excited triplet absorption. Other processes in the polymer can also impede the stimulated emission. Firstly, charged excitations can exhibit absorption bands that overlap with the emission. Secondly, at high excitation densities, exciton–exciton annihilation can significantly deplete the excited states available for stimulated emission. Ultimately, singlet–singlet annihilation is the limiting factor for the maximum excitation density possible, and while polymer films can have a repeat-unit density of $\sim 10^{21}$ cm^{-3}, the excited state density is typically limited to around 10^{18} cm^{-3}. In many materials this is not restrictive on achieving optical gain because stimulated emission can occur at densities of 10^{17} cm^{-3} and below.

An important factor that distinguishes the photophysics of semiconducting polymers from conventional laser dyes is an internal process of exciton migration between the absorption and emission of a photon. Excitations are confined to short straight sections of the polymer between kinks or twists in the chain. These straight sections, or 'sites', are typically a few repeat units in length, though there is a statistical spread of site lengths in any given material. When formed, excitons tend to hop to the longest, lowest-energy, sites before emitting a photon. The exciton migration process has two effects. First, it means the emission takes place from a subset of the chain segments, resulting in a lower degree of inhomogeneous broadening of the emission spectrum (vibronic peaks are better resolved than in absorption (see Figure 3b)). Second, the peaks of the absorption and emission spectra tend to be widely separated in wavelength, reducing the level of self-absorption at the lasing wavelength.

As mentioned above, blending materials is a particularly attractive approach towards further reducing self-absorption in organic semiconductor lasers. In such systems, a narrow bandgap dopant chromophore is blended with a concentration of 1–2% in a wider bandgap semiconducting host. Emission from the host is strongly quenched via nonradiative Förster energy transfer to the guest molecule. The blended material exhibits an absorption profile that is dominated by the host absorption, while the emission profile is almost completely that of the guest dopant. By strongly separating the emission peak from the absorption edge of the host, it is possible to achieve a substantially reduced (by perhaps an order of magnitude or more) residual absorption coefficient at the lasing wavelength. In doing so, the combined material acts much more like an ideal 4-level laser medium and can thereby have substantially lower pump thresholds for stimulated emission.

Measuring Gain

The dynamics of the excited state population in semiconducting polymers have been widely studied using femtosecond transient absorption experiments.

This is a pump–probe technique in which the transmission of the broadband probe pulse is compared in the presence and absence of a pump pulse that excites molecules into the first excited state. Such measurements have the time resolution of the pump pulses used and so can typically be ~100 fs. By systematically delaying the arrival of the broadband probe pulse, it is possible to map out the evolution of the gain dynamics across the emission spectrum of the material with very high time resolution.

Figure 4 shows a series of snapshots of the absorption induced by a pumping pulse in a poly(thiophene) derivative. This figure shows the changing absorption of the sample between 200 fs and 400 ps after excitation. Within the absorption band of the material, one finds that the level of absorption is slightly reduced because the pump pulse has partly depleted the ground state. In the emission band there is also a reduction in the absorption that mimics in shape the photoluminescence spectrum of the polymer. This negative absorption – or optical gain – shows direct evidence for stimulated emission through much of the emission band. In the low energy tail of the emission, however, there is an increase in absorption that arises due to the excited-state absorption process mentioned earlier. Clearly, for a good laser material, the spectra of excited-state and charge-induced absorptions should overlap as little as possible with the photoluminescence.

Many other investigations of gain in semiconducting polymer films have used a phenomenon known as spectral line narrowing to explore indirectly the amplifying properties of the medium. The experimental procedure for such studies is as follows. A thin film of the semiconducting material, of typically 100 nm thickness, is excited by a pulsed pump laser focused to a stripe of dimensions ~100 μm wide by a few millimeters in length. A significant fraction of the light emitted by the material is trapped in the film by total internal reflection at the polymer–air and polymer–substrate interfaces, and is thereby waveguided along the length of the excitation stripe. This waveguided spontaneous emission can be amplified by stimulated emission before being emitted out the edge of the film.

One finds that, above a particular threshold of pump energy, there is a superlinear increase in the output energy with pump intensity. Associated with this is a dramatic narrowing of the broad emission spectrum to a linewidth of typically less than 10 nm, as illustrated in Figure 5. These two features are signatures of gain narrowing via the process of amplified spontaneous emission. The line-narrowed feature usually appears at the first vibronic overtone of the optical transition, where the gain exceeds the losses in the material by the greatest amount. This particular wavelength experiences the greatest amplification and, above a particular pumping density, undergoes a runaway effect in which most of the light is stimulated to emit at that wavelength at the expense of the rest of the spectrum.

In the case of amplified spontaneous emission or mirrorless lasing as it is also known, the spontaneous emission guided along the length of the stripe acts as

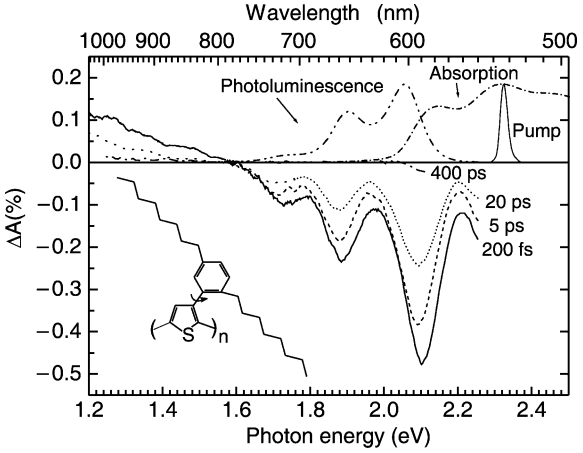

Figure 4 Transient absorption spectra of poly[3-(2,5-dioctylphenyl)-thiophene]; chemical structure inset. Copyright (1998), with permission from Elsevier.)

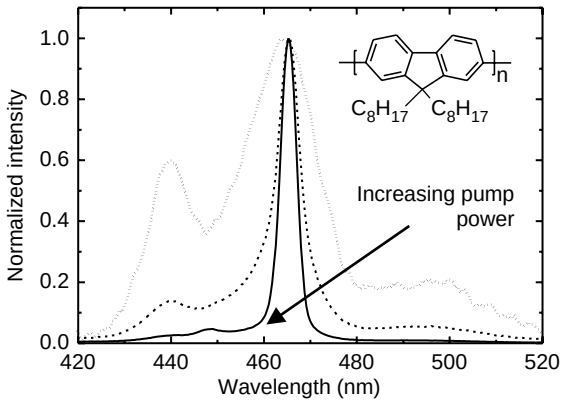

Figure 5 The change in spectral shape with increasing excitation density (from 10 to 133 μJ cm^{-2}) of the edge emission from a PFO film – the normalized spectra show a significant spectral line narrowing at high excitation densities. (Adapted from Heliotis G, Bradley DDC, Turnbull GA and Samuel IDW (2002) Light amplification and gain in polyfluorene waveguides. *Applied Physics Letters* 81: 415–417. Copyright (2002), with permission from American Institute of Physics.)

the 'probe pulse'. In these experiments it is therefore necessary to extract information indirectly about the net gain in the material. By integrating the spontaneous and stimulated emission along the length of the stripe, one finds that the wavelength-dependent output intensity $I(\lambda)$ of the spectral line narrowed light is given by the relationship

$$I(\lambda) \propto \frac{1}{g(\lambda)}[\exp[g(\lambda)l] - 1] \qquad [1]$$

where I_p is pumping intensity, l is the length of the stripe, and $g(\lambda)$ is the net gain coefficient. Therefore, by monitoring the intensity of the line-narrowed emission as a function of the length of the pump stripe, one can extract the value of the net gain for the material. Similarly, by progressively moving the stripe further and further away from the edge of the film, it is possible to evaluate the waveguide losses of light propagating through an unpumped region of the waveguide. Waveguide losses in conjugated polymers typically lie in the range of 3–50 cm^{-1}. Net gains can be as high as 60 cm^{-1} or 260 dB cm^{-1} at modest pumping densities of 4 kW cm^{-2}. These substantial gains, in very small propagation lengths, therefore highlight the attraction of waveguide-based resonators for polymer lasers. In the next section we will discuss the most commonly used feedback structures that have been used for polymer lasers.

Polymer Laser Resonators

The first demonstration of cavity lasing in a conjugated polymer was made by Moses in 1992. The resonator consisted simply of two flat dielectric mirrors on either side of a cuvette containing the polymer in solution. Lasing occurred at the peak wavelength of the gain profile. Subsequent developments in solid-state polymer lasers have involved more sophisticated resonators that exploit the capacity of these materials for very simple processing. For example, solution-processing methods such as spin-casting or dip-coating, make it possible to fabricate very high-quality optical waveguides. Wavelength-scale microstructures can also be readily formed, allowing the straightforward fabrication of laser microresonators.

Many different resonators have been explored for solid-state polymer lasers. Some of the key types are shown in Figure 6, including different geometries of both microcavities and distributed feedback structures. The first resonator used, by Tessler *et al.*, was a planar microcavity (Figure 6a), in which the polymer film was sandwiched between two mirrors. The structure supported standing-wave resonances perpendicular to the plane of the film, at three

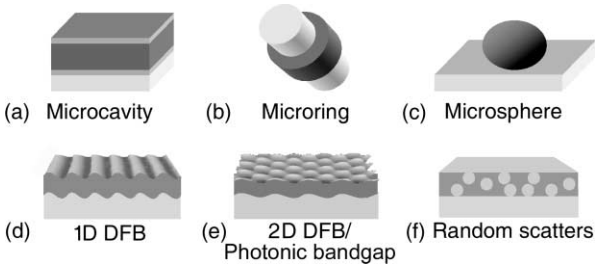

Figure 6 Resonators used for conjugated polymer lasers. (a) Planar microcavity; (b) annular microcavity; (c) spherical microcavity; (d) distributed feedback resonator; (e) 2D DFB/ photonic crystal resonator; (f) random laser.

wavelengths in the emission band of the polymer. Above laser threshold, light was preferentially stimulated into only one of these modes. Microcavities of other geometries have also been studied, including annular and spherical microresonators (Figure 6b,c), in which the optical field is confined in waveguide modes, whispering gallery modes, or a superposition of the two. Such structures provide a longer interaction length in the gain medium for stimulated emission; though tend to lase on many longitudinal modes and have no directional output beam.

The final key group of resonators are distributed feedback (DFB) structures, which researchers have progressively favored to attain the low pump threshold densities that will be required to realize electrically pumped lasing. Figure 6d shows a typical DFB laser structure. The device is based on a thin polymer film that is typically 100 nm in thickness deposited on top of a silica substrate. The silica–polymer–air structure forms an asymmetric slab waveguide that supports only the lowest order transverse electric mode TE_0. To provide the feedback, the substrate is modulated with a wavelength-scale periodic grating structure. These corrugations give rise to Bragg scattering of the waveguide mode. Through careful selection of the grating period, one may arrange that optical wavelengths close to the peak of the polymer gain will be Bragg scattered from the propagating TE_0 mode to the counter-propagating TE_0 mode. This is achieved when the Bragg equation

$$2n_{\text{eff}}\Lambda = m\lambda_B \qquad [2]$$

is satisfied, where Λ is the grating period, n_{eff} is the effective refractive index of the waveguide, m is an integer, and λ_B is the Bragg wavelength. In so doing, one may arrange that two counter-propagating waveguide modes can be coupled together, thereby providing the distributed resonant feedback for the laser process. Commonly in semiconducting polymer

lasers, a second-order (i.e., $m = 2$) Bragg grating has been favored to provide the feedback for the laser, so that the first-order scattering provides a surface-emitted output coupling, perpendicular to the plane of the guide. This surface-emitting geometry is particularly attractive in polymer lasers because it is relatively difficult to achieve a high optical quality edge to the waveguide. DFB lasers have the advantage over simple microcavity resonators in that they can combine long interaction lengths, limited by the scattering length of the Bragg grating, with excellent wavelength selection, which is controlled by the grating period.

In addition to conventional 1D DFB gratings, a number of more exotic 2D and 3D DFB, and photonic crystal resonators have been explored in semiconducting polymers. Even randomly located scattering sites in a polymer film have been used to provide a weak closed-loop cavity feedback. Examples of 2D gratings are given in Figure 7, which shows atomic force micrographs of an eggbox structure, formed from two orthogonal gratings, and a circular DFB grating. Such 2D DFB structures can significantly improve the operation of surface-emitting polymer lasers compared with 1D gratings. Improved feedback yields lower oscillation thresholds, combined with higher slope efficiencies and significantly improved beam quality. Indeed, such surface emitting DFB lasers can produce nearly diffraction limited laser beams.

Typical operating characteristics of an egg-box DFB polymer laser are shown in Figure 8. This laser, which is based on the material MEH-PPV, is transversely pumped with a pulsed pump laser focused onto a small region of the waveguide; up to 90% of the incident pump light is absorbed in the 100 nm thick film. The laser has a threshold pump energy of 4 nJ and an external slope efficiency of $>7\%$, and operates on a single frequency close to the Bragg wavelength of the periodic waveguide. Lasing does not occur exactly at the Bragg wavelength, because at this wavelength the propagation of light is suppressed by the periodic structure. This leads to a photonic stopband within which the emission is reduced. At the edges of this stopband the microstructure can support standing wave electric field patterns of the same spatial period. At these wavelengths there can be a strong interaction between the electric field and excited states in the gain medium, which leads to low-threshold band edge lasing as observed in the figure.

Although DFB resonators have advantages over microcavity devices, the complicated lithographic and etching steps involved in their fabrication can detract from the key material advantage of simple processing. To address this issue, several different techniques for simply replicating the complicated microstructures have been explored. These include UV embossing of flexible plastic substrates, and hot embossing and micromolding of the active

polymer itself. Such techniques can very readily reproduce structures with feature sizes as small as 100 nm and could allow future mass production of photonic microstructures in these materials.

Towards Plastic Diode Lasers

A typical experimental configuration for characterising optically pumped polymer lasers is shown in Figure 9. The laser is mounted in a vacuum chamber in order to isolate the polymer from oxygen and water. A pulsed visible or ultraviolet pump laser is attenuated and then focused onto the waveguide to transversely pump the polymer laser. The emission is collected using a CCD spectrograph for spectral measurements and energy meter and beam profilers for other characteristics. Typical pulsed pump lasers, which have been used, include nitrogen laser pumped dye lasers, and spectral harmonics of regeneratively amplified Ti^{3+}-sapphire lasers or flashlamp pumped Nd^{3+}:YAG lasers. Recent advances have shown the thresholds to be low enough to be successfully pumped with a modest Nd^{3+} pulsed microchip laser.

So while optically pumped polymer lasers are now proving to be compact, functional light sources, a major motivation for research in this field remains the prospect of electrically driven plastic diode lasers. Such lasers could be very low-cost, flexible light sources that would access any wavelength throughout the visible spectrum. In particular, there are exciting prospects of producing blue and green diode lasers in spectral regions currently difficult to access with inorganic semiconductors. The lowest threshold densities reported for optically pumped organic semiconductor lasers are of the order of 100 W cm^{-2}. To achieve similar excitation densities electrically, one requires pump current densities of $\sim$200 A cm^{-2}. This is substantially more than the few mA cm^{-2} commonly used in polymer LEDs for display applications. Presently, such high current densities are infeasible with continuous excitation, but can be exceeded with short current pulses of a few tens of nanoseconds duration.

Electroluminescence in conjugated polymers was first achieved in 1990 by Burroughes and co-workers. Since that time there has been remarkable progress made in the science and technology of organic LEDs. Commercial products are now on the market, and the feasibility of both flexible and full-color light-emitting displays, in which the individual pixels have been ink-jet printed, have been demonstrated in the laboratory. Despite such rapid progress in the field of organic LEDs, there have been no successful demonstrations to date of electrically pumped lasing in any organic semiconductor. In this section we highlight some of the challenges that must be faced if electrically pumped lasing is to be achieved. To understand the problems associated with electrical driving of organic semiconductor lasers, it is useful first to review the generic structure of organic light-emitting diodes.

A generic organic LED structure is shown in Figure 10. The device consists of one or more organic layers sandwiched between two electrical contacts. Usually a transparent anode is used, commonly made from ITO, which allows light to be emitted from the front face of the LED. A low work-function metal, such as calcium or aluminum, is used as the cathode. The organic part of the device may consist of several layers. These include one or more charge transport layers, plus a light-emitting layer in which the electrons and holes combine to form excitons before emitting light. Typically, the combined thickness of these organic layers is as little as 100 nm. Such thin devices are necessary to keep operating voltages low, to overcome potential barriers for injection, and because charge mobilities in organic semiconductors are very low (10^{-5} to 10^{-2} cm^2 V^{-1} s^{-1}).

The inclusion of electrical contacts into organic semiconductor laser structures can be problematic since they need to be situated very close to the emitting region. Metallic contacts can quench the luminescence and introduce losses to the waveguide mode, thereby increasing the oscillation thresholds. Furthermore, the ITO anode has a high refractive index and so can reduce the spatial overlap of the

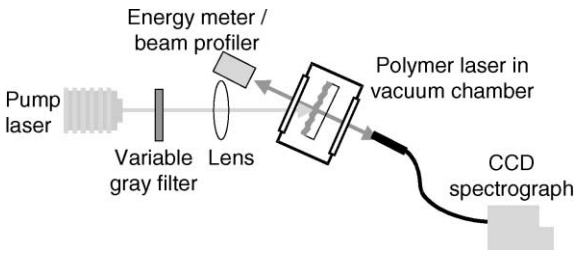

Figure 9 Schematic of a typical experimental configuration for characterizing polymer lasers.

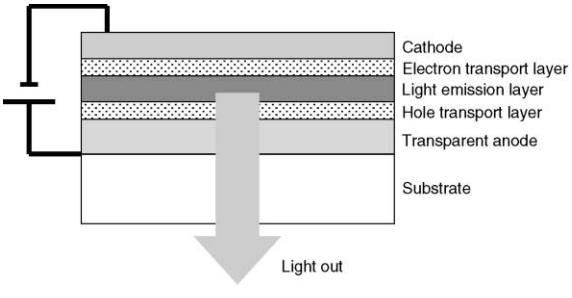

Figure 10 Schematic structure of a generic organic light-emitting diode.

guided mode with the active medium. Such issues indicate that the design of organic LEDs needs to be somewhat modified for achieving electrically pumped lasing. In particular, there needs to be a trade-off between the optimum electronic and photonic designs. To address these issues, various device structures have been proposed that distance the optical mode from metallic contacts, while reducing the thickness of the ITO layer to optimize the mode confinement in the active material.

A more demanding obstacle to electrically pumped lasing is the additional excited state absorption associated with the electrical pumping scheme. As many as three-quarters of the generated excitons in an organic LED are formed in the triplet state which is nonemissive and can lead to excited-state absorption, albeit principally at lower energies than the lasing wavelength. Additionally, injected charges that have not yet formed excitons, exhibit strong absorption, which overlaps significantly with the peak of the material gain. Indeed, this charge-induced absorption has so far prevented the demonstration of injection lasing in conjugated polymers, even in optimized device structures mentioned above. A possible alternative route for efficient pumping of polymer lasers could be through indirect electrical pumping. For example, an inorganic diode laser or LED, or even an organic LED, could be used as an electrically efficient optical pump for the semiconducting polymer laser. Recent advances in GaN-based LEDs and lasers provide interesting prospects for such alternative systems.

Research on semiconducting polymer lasers continues, both to reduce the excitation densities needed for threshold and to investigate new material systems that could overcome the obstacle of charge-induced absorption. By building on recent developments in resonator geometries, material blends, and compact pumping schemes, semiconducting polymer laser systems, whether optically or electrically pumped, should soon become practical, visible light sources for a range of applications.

List of Units and Nomenclature

Charge mobility	$[\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}]$
Current density	$[\mathrm{A\,cm}^{-2}]$
Energy density	$[\mu\mathrm{J\,cm}^{-2}]$
Excited state densities	$[\mathrm{cm}^{-3}]$
Gain coefficient α ($\exp(\alpha z)$)	$[\mathrm{cm}^{-1}]$
Intensity/power density	$[\mathrm{kW\,cm}^{-2}]$
Optical gain	$[\mathrm{dB\,cm}^{-1}]$
Stimulated emission cross-section	$[\mathrm{cm}^2]$
Waveguide propagation loss coefficient γ ($\exp(-\gamma z)$)	$[\mathrm{cm}^{-1}]$
Wavelength	[nm]

Planar Waveguide Lasers

Introduction

Lasers have evolved to become true marvels of technology. From their invention in the early 1960s, laser light has changed the way society operates, its application stretching to virtually every aspect of human activity. The versatility of lasers is derived from the fact that there are several different types, each with a unique set of advantages. Solid-state lasers, made from specific semiconducting materials, are commonly used in the optical networks that underlie the greatest machine on Earth – the Internet. High power gas lasers, such as CO_2 lasers, are used in industrial machining, whereas rare-earth doped and dye lasers have found applications ranging from eye surgery to tattoo removal.

Planar waveguide lasers are a relatively new class of lasers made possible by advances in the field of optical waveguides. Over the past decade, with the aim to miniaturize optical components, planar waveguide technology has been developed to a high degree of sophistication. Likewise, Er and other rare-earth doping was studied extensively owing to its importance in all-optical amplification. These elements turned out to be the building blocks for the development of fiber lasers and subsequently planar waveguide lasers.

This chapter will discuss the basic concepts underlying this category of lasers, the variations therein, and the main characteristics. It is important to understand the basic features of waveguides and lasers, which is included as a prelude. We will then discuss planar waveguide lasers with emphasis on the essential elements: the laser materials, the various designs, their performance, and the resultant advantages as well as the applications.

Waveguides

A waveguide is a general conduit for efficient propagation of an electromagnetic field. It is usually defined by making a region of higher refractive index within a dielectric medium. This behaves as an attractive potential well that confines light in the form of bound modes, much like a potential well that confines electrons to a bound state. The propagating field is referred to as the lightwave and is governed by Maxwell's equation. For a weakly guiding approximation, as is the case when the refractive index contrast (Δn) is small, Maxwell's equation can be reduced to a scalar wave equation for the transverse electric field. For a given wavelength (λ) and polarization, the scalar wave equation in a nonmagnetic medium is

$$\nabla^2 E(x) + \frac{4\pi^2}{\lambda^2} n(x)^2 E(x) = 0 \qquad [1]$$

where E is the electric field. For a waveguide aligned in the z direction, the field is the sum of the two propagating transverse modes, each with the form $E(x) = \Phi(x, y)e^{ik_z z}$ where $\Phi(x, y)$ is the field distribution and k_z is the propagation constant. The wave equation for the transverse mode reduces to

$$\frac{\lambda^2}{4\pi^2}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)\Phi(x, y) + n(x, y)^2\Phi(x, y) = (\bar{n})^2\Phi(x, y) \qquad [2]$$

Here, $\bar{n}$ is referred to as the effective refractive index and is given by $\bar{n} = k_z\lambda/2\pi$. The effective index dictates the occurrence of bound modes – these states occur when $\bar{n}$ is between n_{core} and n_{cladding}. For smaller values of $\bar{n}$, there is a continuum of unbound and radiation modes. These are leaky modes that are dispersed quickly over a short distance. Only bound modes are guided in the core of the waveguide structure.

Planar Waveguides

Waveguides formed on a flat substrate are called planar waveguides. These are typically made by stepwise deposition of films of dielectric materials (typically glass). The waveguide core is defined by one of several methods, the most common of which uses lithography and etching. In this case, a film of an appropriately higher index material is deposited on an 'under-cladding' film and then selectively etched to define a core. This is generally covered with a suitable 'upper-cladding' layer so that the index contrast is controlled in all directions. Other methods of forming the core include patterned ion exchange or ion implantation or increasing the index of the medium using a femtosecond laser, etc. In all these cases, the end result is the formation of an embedded higher-index region whose locus defines the optical path for the lightwave. A circuit made from these waveguides is known as planar lightwave circuits (PLC).

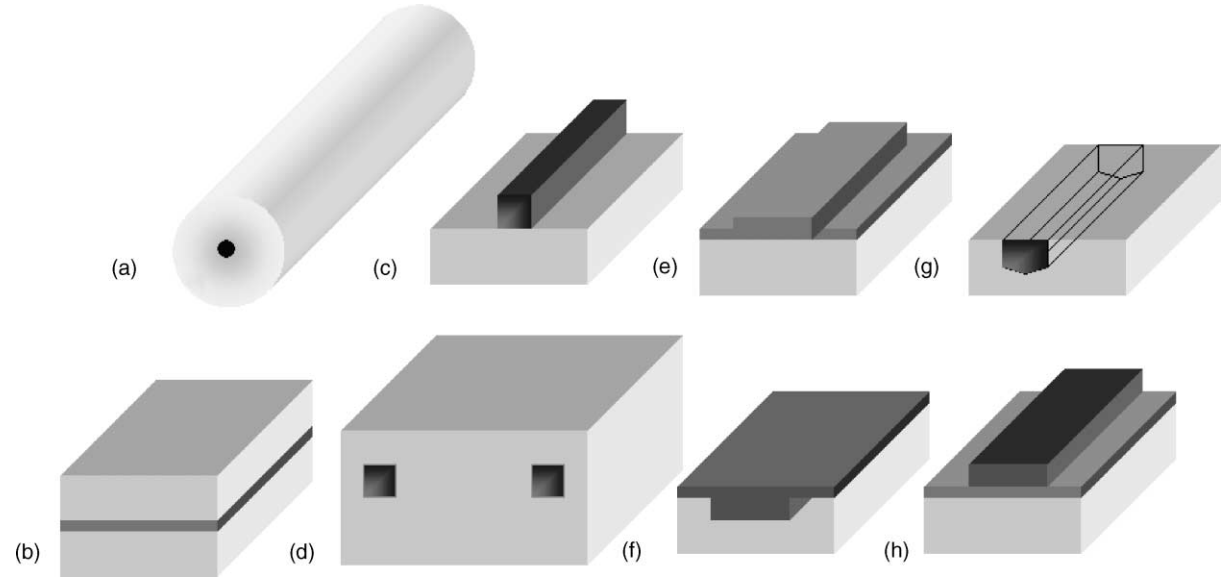

Figure 1 Range of different waveguide designs, with the core represented by the darker regions: (a) Optical fiber; (b) slab waveguide; (c) channel waveguide; (d) embedded channel waveguides with a layer of the overcladding; (e) rib waveguide; (f) inverted rib; (g) ion diffused; and (h)strip loaded, comprising of a strip of a different higher index material (that serves to confine light) on a core layer.

Waveguide cores may be designed in several different configurations, as shown in Figure 1. These designs allow for different fabrication processes as well as the control over the modal properties of the lightwave. For a given index contrast, the number of modes traveling in the waveguide is primarily determined by the dimensions of the waveguide. The aspect ratio of the waveguide affects the propagation of the transverse electric (TE) and the transverse magnetic (TM) modes, due to different propagation constant k_z for each mode.

Lasers

The generation of laser light requires four basic conditions to be satisfied:

- a source capable of light emission;
- an energy supply source – typically electrical, optical, or chemical;
- population inversion to the excited state in the lasing medium; and
- absence of parasitic effects that would absorb the emitted light.

Laser light is often a result of either electronic or vibrational excitation. This is because these excitations involve transfer between energy states that coincide with the radiation of UV, visible, or infrared light. Population inversion is an important requirement in lasers since the emission is stimulated. This involves having a greater fraction of the atoms or molecules in the excited state so that a stimulating photon can cause a radiative decay to the lower energy level. The stimulated light from most lasing media is weak, which requires unacceptably long lengths to generate sufficient power. Instead, as shown in Figure 2, lasers are made with two parallel mirrors with an axial light-generating source in between. This configuration is known as a resonant cavity, a resonator, or an oscillator. The back mirror is usually fully reflective but a partial front mirror allows a portion of the light in the cavity to pass through. The two mirrors cause the light to bounce to and fro, forcing it into making multiple passes through the cavity. Light emanating from this structure is thus amplified and is also coherent (that is the lightwaves are in phase

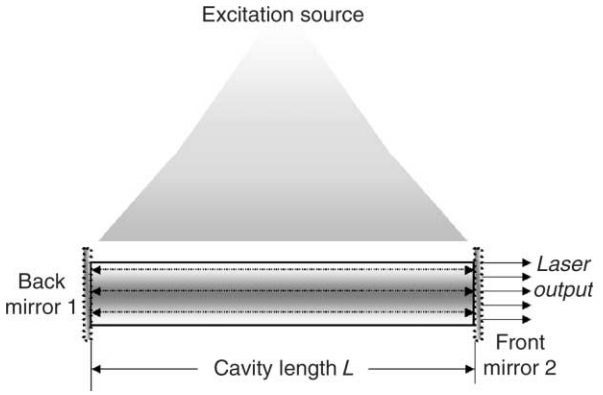

Figure 2 Conceptual representation of a simple Fabry–Perot laser.

with each other spatially and temporally). This has come to represent the signature output of a laser.

Planar Waveguide Lasers (PWL)

By way of an example, let us consider a solid state, rare-earth doped laser, such as an Nd-doped YAG laser. All rare-earth ions are able to fluoresce, some (e.g., Nd) more efficiently than others, and hence can be light emitters. These ions have to be dissolved (doped) into a solid host, say, a glass or a single crystal such as YAG (**Y**ttrium **A**luminum **G**arnet). The excitation of these ions is done optically with light of a suitably higher energy (or lower wavelength). When this 'pump' light is made incident on a rod of the rare earth doped material, it is absorbed by the rare earth ions and used to reach an excited electronic state. Amongst all the possible higher energy states, only certain ones are sustainable because the electron resides in that state for an acceptably long period of time (called the lifetime). Hence, population inversion can be more readily achieved in these longer lifetime states and stimulated processes such as amplification and lasing are readily possible. The laser light generated in the doped rod is emitted across its entire cross-section.

Planar waveguide lasers are designed to miniaturize the kinds of stand-alone solid state lasers describe above. In principle, a PWL is a laser where the light emitting resonant cavity is a planar waveguide. This topic of our interest is a relatively recent development that renders some unique advantages. These can be broadly classified into two categories: one relating to making efficient high-power lasers and the other, to the integration of lasers with other optical components.

An example of the first type is a Nd-YAG laser configured into a planar geometry so that the laser light is now contained within the waveguide. One design that has evolved to achieve this well is shown in Figure 3. The light is guided by the waveguiding structure setup by the sapphire planes. Since both the excitation (or pump) and the lasing modes are well confined, high modal overlap is achieved. These PWLs can be edge-pumped or face-pumped and high powers (measured in the order of Watts) can be achieved.

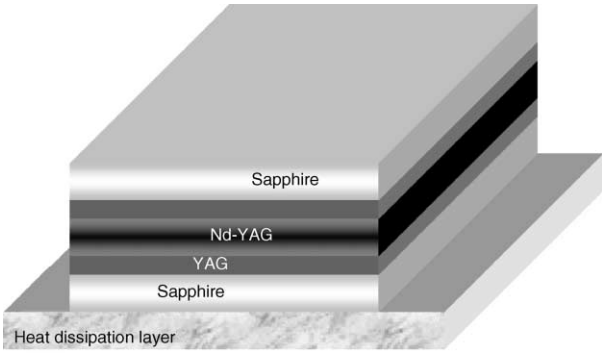

Figure 3 End view of a planar waveguide form of a Nd-YAG laser made using sapphire (single crystal Al_2O_3) for cladding.

In the above design, the cavity is defined by two parallel reflectors bracketing the light-generating medium and is known as a Fabry–Perot etalon. The distance between the two mirrors sets up a wavelength filtering mechanism whereby only resonant wavelengths are sustained. These are related to the intra-mirror distance by the simple equation shown below:

$$L_c = \frac{a\lambda}{2n} \qquad [3]$$

where L_c is the length of the cavity, a is an integer, n is the refractive index of the medium, and λ is the wavelength in vacuum. As the cavity length increases, the number of possible resonant wavelengths increases and the spacing between wavelengths is reduced. These are called the longitudinal modes (Figure 4a). Likewise, lateral modes (Figure 4b) can be generated in the cavity as well, tending to make the operation of the laser multimoded, as shown in Figure 5. This is characteristic of a Fabry–Perot laser, which can be overcome by embellishing the basic etalon design.

As stated above, another big advantage here is that the platform for fabricating PWLs can be chosen to be the same as to make PLCs. Waveguide comprizing the laser can be continued further and configured into other desirable components, such as splitters, couplers, etc. Thus the laser does not have to be separately coupled to the waveguide. This is a major advantage as this connecting process is time-consuming and incurs loss of light. In the field of photonics, the ability to integrate active components with passive ones onto the same chip is considered to be the first step toward photonic chips, analogous to the integrated circuit chip that has revolutionalized our world. This is the driver behind continued research and development of active elements such as PWLs that can be coupled with other actives, such as thin film electro-optic modulators or acousto-optic filters, etc.

Waveguide Laser Materials

The waveguiding structure is comprised of materials that are either dielectrics or semiconductors, both inorganic and organic. For their homogeneity and broad transmittance, high silica glasses are ideal

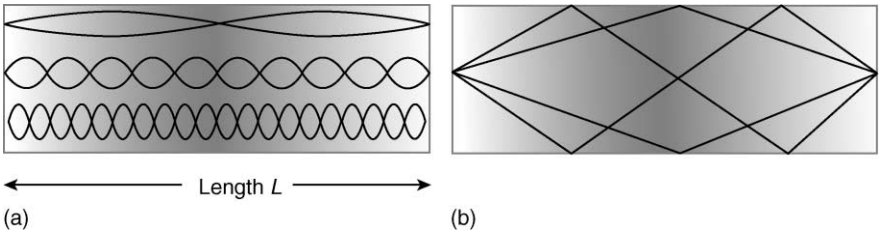

Figure 4 Generation of longitudinal (a) and lateral modes (b) in a Fabry–Perot laser.

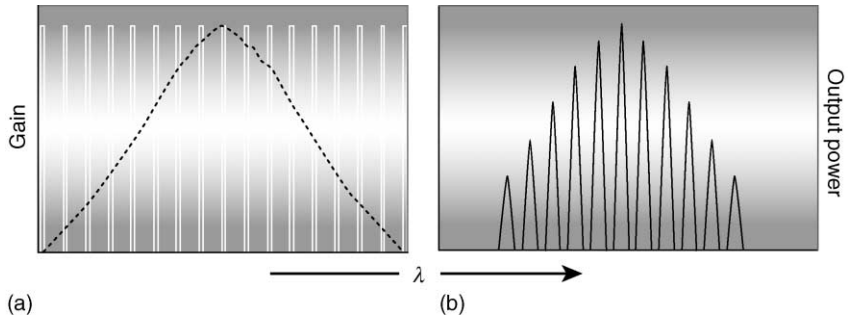

Figure 5 The output of a Fabry–Perot laser: (b) is governed by the number of modes within the gain spectrum of the lasing medium shown by the dotted lines (a). The spacing between the modes can be altered changing the length of the cavity. The smallest mode in output spectrum (b) needs to have enough gain to overcome the lasing threshold.

materials for waveguiding. The chief advantages of high silica waveguides are easy index and mode matching to standard optical fibers, low propagation loss, and good durability. When crystalline materials are used, they have to be single-crystalline to avoid grain boundary scattering (for instance, Ti-diffused waveguide in single-crystal $LiNbO_3$). If semiconductors are used, the bandgap of the material needs to be sufficiently high so as to avoid absorption of the photons. Silicon waveguide (bandgap = 1.1 eV) on a silica cladding (SOI) is commonly used system in PLCs used for telecommunication applications.

The PWLs described above are fabricated in rare-earth doped glass waveguides. Waveguides have to be much shorter than fiber, so the challenge of incorporating the rare-earth ions at high concentration in the host material has to be overcome. Planar waveguide lasers are a compressed version fiber lasers that have the unique advantage that they can be directly integrated with other components on the same chip using very large-scale integration (VLSI)-style processing. The concentration of Er (or the lasing ion in general) in a PWL needs to be many times that in fiber amplifiers (~100 ppm). The need for high gain in a short length requires high pump powers and high lasing ion concentration, both of which lead to nonideal behavior. Since rare earth ions tend to have multiple excited electronic states, there can be absorption at the excited state level as well. When a higher energy state is separated from the upper emission level by the energy in one laser photon, the ions can undergo excited state absorption or ESA (Figure 6). Rare-earth ions in close proximity tend to undergo cooperative upconversion processes, where two excited ions transfer energy between each other so that neither ion may fluoresce at the desired wavelength. These processes can negatively affect the

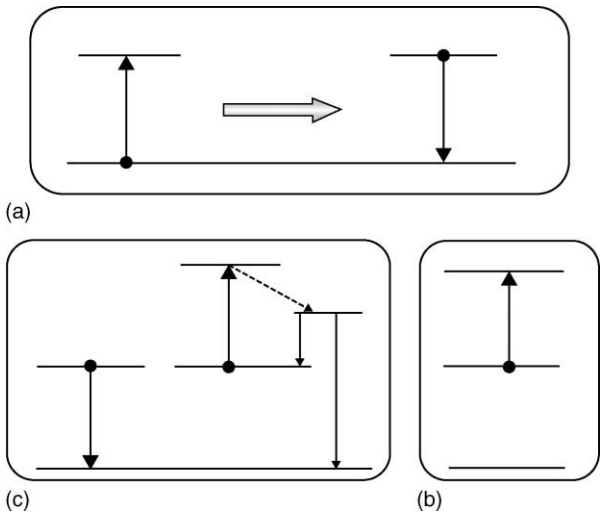

Figure 6 The energy level diagram for a representative two level system. The inset (a) shows the excitation and emission process. Excited state absorption is shown in (b) and cooperative upconversion is shown in (c).

useful gain of the system. Ensuring high spatial dispersion of the Er atoms is critical to minimize this effect. Special glass compositions, such as phosphate glasses, are used here to ensure that the Er is not phase separated or clustered. These glasses also provide a high induced cross-section for gain. Glasses with low phonon energy are also desirable to minimize phonon-mediated nonradiative decays in the rare earths. Light emitting semiconductors and polymers containing fluorescent dyes have also been used to make PWLs.

Now that we have gained an overall perspective of PWLs, we can discuss different manifestations. The following discussion uses a Er doped system as a model since there is a substantial body of work on this system.

Distributed Bragg Reflector (DBR) PWL

In planar waveguide systems, it is difficult to construct efficient mirrors or reflective facets perpendicular to the waveguide. However, mirrors can be replaced by Bragg gratings, which be fabricated relatively easily. In-line Bragg gratings result in wavelength specific reflection as per eqn [4]:

$$\Lambda = \frac{m\lambda}{2\bar{n}} \qquad [4]$$

where Λ is the grating pitch, m is the order of the grating, and λ is the central Bragg wavelength. Gratings have another important benefit in that they ensure that unwanted frequencies outside the limited reflection spectrum are dispersed before they reach the lasing threshold.

A DBR laser is similar in principle to a Fabry–Perot design but uses a Bragg grating on either end of planar Er-doped waveguide. This is shown schematically in Figure 7. Gratings can be made in a number of different ways. One popular way is to exploit the photosensitivity of glasses using 193 nm or 244 nm UV light to periodically alter the refractive index of a glass waveguide. Photosensitivity occurs by a combination of molecular changes (such as the formation of oxygen deficiency sites or color centers) as well as changes in the material strain in the region exposed to the UV light (Figure 7c). Alternatively, gratings can also be formed using etching to make periodic grooves in the waveguide. These are called corrugated or surface relief gratings (Figure 7a and 6b).

The back Grating 1 has a high reflectance of almost 100%, whereas Grating 2 is a weaker grating. The reflectance strength of Grating 2 is determined by taking into account the gain coefficient of the material and the output power required from the laser. The reflection intensity can be altered according to the following equation:

$$R = \tanh^2\left[\frac{\pi L_G \Delta n_{\text{eff}} \eta(V)}{\lambda_B}\right] \qquad [5]$$

where L_G is the grating length, Δn_{eff} is the index modulation of the grating, λ_B is the Bragg wavelength, $\eta(V)$ is the confinement factor, a function of the waveguide parameter V that represents the fraction of the integrated mode intensity contained in the core. Increasing the reflectance strength also widens the linewidth of reflected light. The overlap of the spectral width between the back (Grating 1) and the front grating (Grating 2) becomes the effective output window within the gain spectrum of the lasing material (Figure 8).

Not unexpectedly, a DBR structure generates longitudinal and lateral modes. These modes are, however, limited to the overlapping section of the reflection spectrum of the two gratings, as opposed to the entire gain spectrum as in Fabry–Perot lasers (Figure 9). Yet, this can lead to problems such as spectral hole burning and mode hopping, whereby the dominant mode hops from one wavelength to another. The separation between the modes needs to

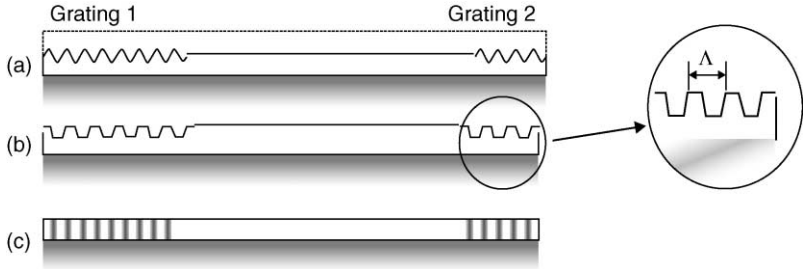

Figure 7 DBR planar waveguide laser. The PWLs shown in (a) and (b) have sinusoidal and trapezoidal surface-relief gratings respectively etched in their cores. An in-line grating of the kind seen in (c) could be fabricated using the photosensitivity of the glass. The top cladding is shown only in (a).

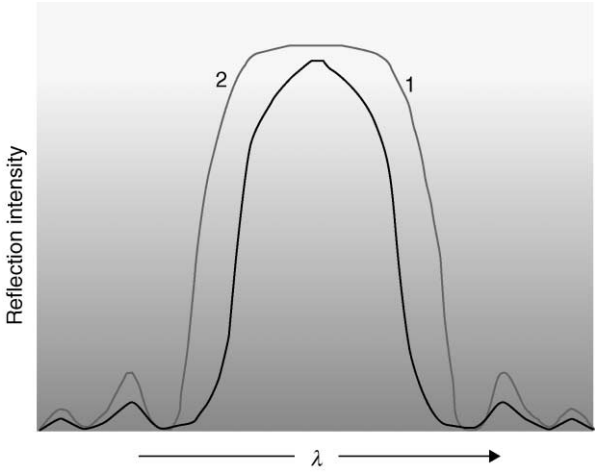

Figure 8 The reflection spectrum of the back (1) and the front (2) gratings. As the intensity of the reflected light is made to increase, so does the linewidth. Hence, the narrower spectrum of partially reflecting grating 2 tends to dictate the operating wavelength range of a DBR.

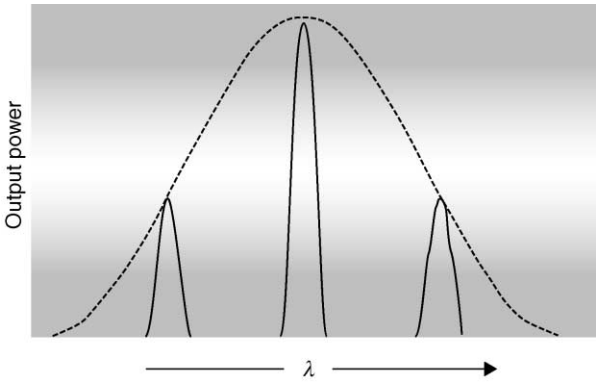

Figure 9 A sample output from a DBR laser, shown in this case with 3 modes. The dotted line shows the effective overlap between the two gratings. The existence of the modes depends on several factors, in particular the pump intensity.

be made sufficiently high compared to the spectral overlap so that single-mode operation can be achieved. But in practice the length of the cavity (L_c in eqn [3]) is determined by factors such as power and space and may not be independently altered to achieve this. However, the reflection spectrum of the back and the front gratings could be slightly shifted in opposite directions to realize a smaller overlap within which only one or a few modes may exist (Figure 10). The occurrence of a single mode also depends on the gain profile of the lasing material and the optical pump power. In Er-doped PWLs, modes other than the primary one can be suppressed by using a pump power below a threshold limit and stable operation can be thus achieved.

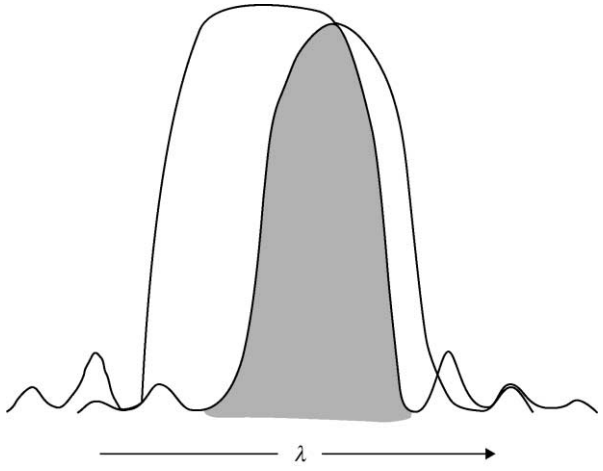

Figure 10 Shifting the front and back gratings is one means of controlling the width of the overlap region, shown in gray. This way a single mode operation can be achieved even for a longer cavity with many modes.

Distributed Feedback (DFB) PWL

The modal problems listed above can be addressed by having a single, distributed grating that is placed along the entire length of the lasing waveguide itself (Figure 11). Alternatively, the gratings may be also placed in the upper or the lower claddings to minimize loss of optical power due to scattering because of the longer grating. In this case, it is the evanescent portion of the light that interacts with the grating. In all cases, the periodicity of the grating leads to a condition for a single lasing wavelength based on constructive interference. The strongest mode occurs when the period Λ of the Bragg grating satisfies the primary Bragg condition (for first order grating or $m = 1$) in eqn [4]. The device will also function if the grating pitch is equal to small integer multiples of $(\lambda/2\bar{n})$.

The grating needs to be made strong enough to generate sufficient feedback (reflections), which also widens the linewidth of the spectrum. To ensure a single narrow linewidth output, a quarter wave phase shift is introduced in the grating, as seen in Figure 11. This phase shift creates a transmission fringe in the spectrum (Figure 12) that significantly narrows the linewidth of the output signal. This design is considered to be standard for the DFB lasers of today. Figure 13 shows a typical output of a DFB laser.

Any of the geometries seen in Figure 1 can be used to make the waveguide for the laser. Due to processing constraints, rib (c) and ion diffused (d) configurations are commonly used. Waveguide losses, characteristically due to scattering from sidewall roughness, have to be low. Otherwise, this adds a

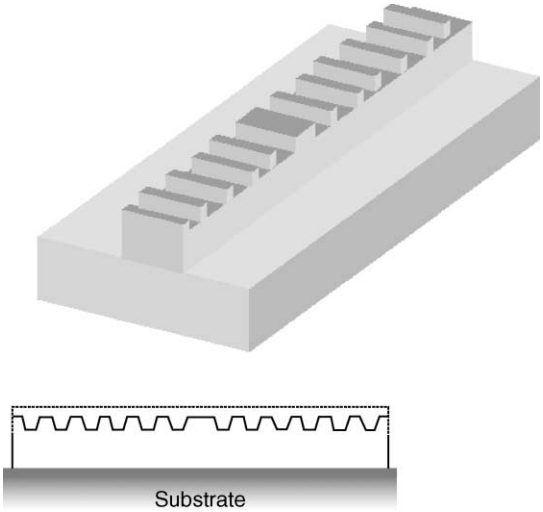

Figure 11 A DFB planar waveguide laser.

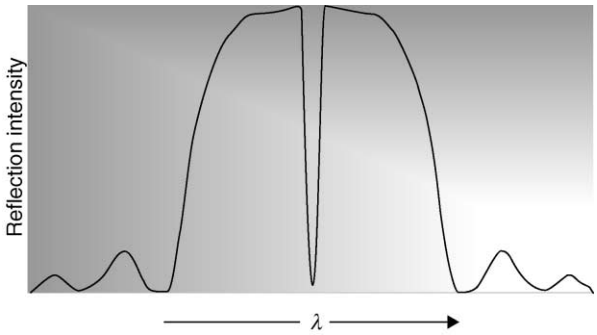

Figure 12 The reflection spectrum of a grating with a central $\lambda/4$ shift in the pitch, showing the transmission fringe.

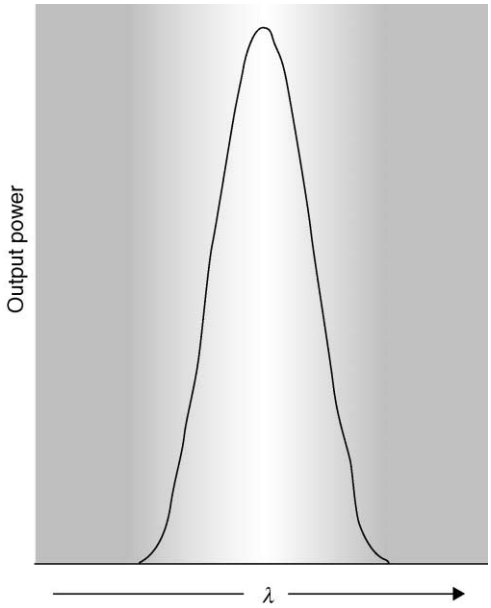

Figure 13 The typical output of a DFB PWL. The linewidth can be made to be as narrow as a few hundred kHz.

significant overhead onto the pump power and lowers the output of the PWL. Birefringence caused by thermal expansion coefficient differences and excessive sidewall roughness also need to be minimized as they can substantially alter the loss of the TE mode compared to TM.

Though their spectral properties are ideal as sources for long haul transmission, DFB lasers tend to be less powerful than the corresponding DBR designs. But the DBR PWLs are very sensitive to reflections that can cause a broadening of the laser linewidth or can act as a source of noise. In both cases, single mode lasers with very narrow linewidths in the kHz range with low radiance and noise, have been demonstrated. But neither is known to have been commercialized yet.

PWL Arrays

One of the unique advantages of the PWLs is that they are often processed using VLSI techniques. One important implication of this is the ability to make a PWL array where multiple lasers are formed simultaneously on the same chip, each with a unique output (Figure 14). Such arrays are likely to be very useful in future dense wave division multiplexing (DWDM) optical network systems where as many as 128 channels (and more) are planned. Since packaging of individual lasers can be up to 75% of the total cost, making chips with multiple lasers is very attractive. The lasers may be DBRs or DFBs whose output wavelength is controlled by changing the grating parameters. To vary the individual wavelengths either the effective index and/or the pitch of the grating can be changed. Thus, any output spectrum can be designed and executed merely by making the appropriate lithography mask.

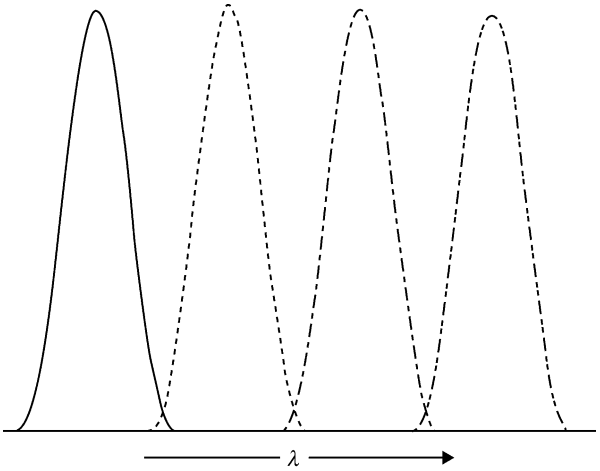

Figure 14 Idealized output from a 4-PWL array.

The gratings are often written holographically, where the wafer is exposed to an interference pattern caused by two coherent light beams. The wafer underneath can be sensitized with a photosensitive glass layer or a film a photoresist. It is not efficient to do multiple holographic exposures to individually change each of the gratings in the array. One way of doing this with a single holographic exposure is by constructing the waveguides at different relative angles. Then the component of the index modulation, resolved along the axis of the waveguide, would vary for each waveguide depending on the relative waveguide angle (Figure 15); this would lead to differences in $\bar{n}$. Alternatively, the waveguide array can be made of the same height but of different widths. This is easily done since waveguide height is usually deposited uniformly but the width is a function of the mask layout. Here the waveguide and the grating are orthogonal to each other and the variation in wavelengths is achieved by the fact that the effective propagation constant for each of the waveguides is different.

Arrays of PWLs have been made on a silicon substrate using deposition of an Er containing glass that is subsequently patterned into waveguide, and ultimately laser, arrays. Another approach has been to start with a phosphate glass as the host and the substrate. A phosphate glass is a superior host for rare-earth ions such as Er since the sensitization efficiency is nearly unity and much high doping levels are possible before concentration quenching effects set in. Waveguides are created by ion-exchange by immersion in a hot bath containing suitable ions (Na for Li, for instance). When starting with a uniformly doped glass, one issue in the assimilation of the laser array with other components is the fact that Er-doped region does not start and end with the waveguide laser section. Recently, the Er has been deposited selectively in the laser waveguide in phosphate glass using methods such as ion implantation, bringing the concept of integration closer to reality.

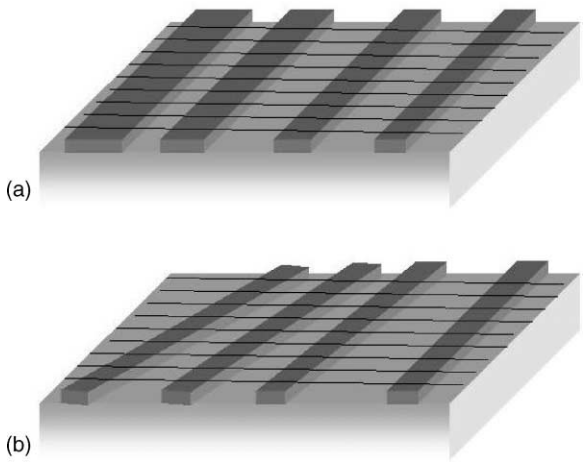

Figure 15 Two different means of making planar waveguide laser array with a single holographic exposure to write the gratings. The darker rectangular blocks represent the core channels or ribs. In (a) the width and hence the effective index of the waveguide is varied whereas the relative angle between the waveguides is altered in (b). The lines represent the direction of the gratings, which is orthogonal only to the left most waveguide in (b).

Pumping

One of the key issues here is the optical pumping of the rare-earth PWLs to generate acceptably high output power. Individual diode lasers or an array of diode lasers all on a single chip (called a diode bar) have been utilized as pumps. Both single and multimode diode lasers are available and have been used. There are pros and cons for either choice: whereas single mode lasers are less powerful (in the range of few 100 mW), it is difficult to convert the multimoded output of their counterparts to useful power. The choice is determined by the waveguide design, which needs to be optimized for high overlap of the lasing mode with the pump. Carefully tapered waveguides can be used distribute the pump power from a diode bar to the various lasers in an array without significant loss.

PWL Stability

Stable operation of a PWL is one of the big challenges. In DBR PWLs, it is seen that there is a threshold for pump power only below which single moded operation can be achieved. Additionally, any PWL die needs to be made immune to ambient temperature changes. These changes can affect many of the critical output parameters of the PWL: wavelength, linewidth, power and in the case of an array, the wavelength separation. This occurs primarily due to the thermal shift in the grating pitch as well as the thermo-optic effect. It is overcome by supplanting the laser die onto a heat spreader chip made from conducting material such as Cu or BeO, followed by a thermoelectric cooler. Ironically, the laser's output wavelength and linewidth are fine-tuned and 'fixed' using temperature to overcome any drifts due to processing errors or other reasons.
